The Small Fibrous Prostate.—A. L. Chute calls special attention to a class of obstructive prostates in which the rectal examination shows little, if any, increase in size of the gland. These prostates are dense and fibrous, showing little similarity to the large hypertrophic prostates. They are the result of an inflammatory process. Their recognition before there is an appreciable residual may be difficult. They are often associated with a contraction of the bladder neck or a bar at the bladder outlet. In order to give these patients relief it is important not to overlook either element of the obstruction.

Analysis of Wound Infection.—W. P. Graves states that the troublesome occurrence of wound infection is still sufficiently frequent in public hospital practice to deserve serious attention. The custom of frequently changing assistants is a considerable deterrent to well-organized and systematic surgical work, and probably has some influence in the matter of wound sepsis. Of 1,000 operative cases, 51 had some form of wound infection which in all but one case was of a mild form, the organism being a staphylococcus in all instances. Twenty-eight of these infected cases were laparatomy wounds in which the infection consisted mostly (19 cases) of slight sepsis of a buried catgut knot, the wound closing immediately after extraction of the knot. Some of these catgut knot infections did not appear until some time after the patient was discharged from the hospital. All the cases of general sepsis in the list occurred in hernia wounds. Wound infection is much more common in hospital work than in private practice, where it is almost nil. The difference is largely due to the personal equation of the patient, for the person whose skin is habitually clean is less likely to incur wound sepsis. Abdominal incisions are much more susceptible to superficial infection than are plastic wounds.

Comparative Histology of Femoral Bones.—J. S. Foote, as the result of a large series of examinations, finds that the pure Haversian system type is shown in the smallest number of animals, the laminar in the next, while the lamellar comprises the largest number. He believes that the Haversian system type is the one best adapted to support weight. He states that this study promises to widen the field of bone histology and possibly to account for some of the individual variations in human femurs which are responsible for bone diseases.

An Easy Method of Determining the Dose for Infants Below One Year. H. Fried.

The Discard Heap—Neurasthenia.—G. M. Parker states that in neurasthenia, the concept of thirty years ago, there are to be seen a considerable number of recent pictures, widely dissimilar. There have been various lines of divergence in the analysis of neurasthenia, namely, anatomical, physiological, psychological, and clinical. In the anatomical classification there had been evolved the splanchnic, spinal, and visceral types. From the physiological viewpoint the essential and isolated fatigue process of the nerve cell has been largely discredited. The toxemic theory has had a tremendous growth; while the rôle of metabolism, particularly the influence of the ductless glands has attracted considerable attention. Psychological inquiry was stimulated by the idea of an endogenous cell fatigue. Freud has perceived the morbid process in the insufficient inadequate sexual reaction in masturbation as distinguished from the adequate reaction of intercourse. The clinical lines present definite subdivisions. The constitutional and acquired neurasthenias were early distinguished. Psychasthenia was evolved from the neurasthenic mass. Traumatic and senile forms were recognized. From neurasthenia have been isolated certain psychoses, particularly the manic depressive group. Many of the so-called acquired neurasthenias are not acquired but have been developed upon a constitutional though latent basis. Many of the secretory and motility disturbances of the stomach fall in this category. In the gastric group the chief disturbance is the hyperchlorhydria, the hypochlorhydria, and achylia. The second main clinical group is that of the psychologically inferior neurasthenic. A third general clinical group has marks too scanty and incomplete to merit an entity. The symptoms are neurasthenic, but they are not neurasthenias. Freud's neurasthenia is placed within this general division, but with certain reservations. Psychasthenia, like neurasthenia, has suffered from its name; out of it, Janet has drawn the crises and derivative phenomena of tics, agitations, phobias, manias, ruminations, and obsessions. Præcox is a psychosis whose early stages bear certain superficial resemblances to neurasthenia. The author states that his paper is directed especially against the exclusive tendency toward psychological interpretation with scant consideration and curt disposition of the physiological factors.

Bacteriological Studies in General Paresis.—R. C. Rosenberger and S. Stern state that after a careful clinical study of this disease there would be detected a profound toxic state at times in certain cases, and the general appearances differed from those usually presented by any syphilitic stage or process usually observed. There was the rapid fulminating type in which syphilis could be surely excluded, as well as family and other indulgences. Certain cases would resemble in many ways an infection. Many cases of general paresis were very closely allied to, if not themselves pellagra. Bacteriological studies were performed as follows: Cerebrospinal fluid obtained by lumbar puncture was inoculated into culture media, and a bacillus was obtained in no way allied to Robertson's bacillus. The studies were carried out in twenty-nine cases, including other forms of insanity as controls. The organism obtained differed from any that had yet been described. It is the authors' opinion that general paresis is seen today is a symptom complex and not a disease entity as heretofore accepted; but a symptom group possible in at least three forms one is familiar with to-day. They refer to cerebrospinal syphilis, alcoholic pseudoparesis, and pellagra. They recognize the futility of endeavoring to secure an organism in the first and second, though the possibility of an organism in the third or the probability and possibility of even a fourth class or group of cases presenting the symptom complex of general paresis that may be due to bacterial invasion.

Atypical General Paralysis of the Insane.—B. Glueck in reporting a series of cases, quotes Wernicke, who insisted that a paretic is liable to show during the course of his disease any or all of the possible symptoms or groups of symptoms which may be caused by lesions in the cerebrum. The author perceives that the paretic process is able to produce severe circumscribed lesions of the posterior half of the cerebrum to such an extent that the predominant picture of the disease is that of manifestations of focal disturbances, before distinct signs of a general psychic disturbance can be manifested. Such cases tend to have prolonged remissions of the disease, interrupted by sudden manifestations of a focal nature. An easy transition from the ordinary to the atypical forms of the disease—because the pathological process is essentially the same—is readily possible. The importance of emphasizing upon the general practitioner the possibility of the disease manifesting itself in local paresis or hemiplegia solely, without the least signs of dementia until the disease has reached an advanced stage, cannot be overestimated. Of course, the use of the Wassermann reaction and the cytoanalysis of the cerebrospinal fluid should, under no circumstances, be neglected in these cases, because in the whole field of psychiatry there is nothing equal in importance to the earliest possible diagnosis of paresis.

Paratyphoid Fever.—G. P. Paul concludes that the diagnosis of paratyphoid fever is of most import. The clinical course of the disease bears a close resemblance to

that of typhoid fever, and it may be absolutely impossible to distinguish the two diseases clinically. There are, however, certain points of dissimilarity. The abrupt onset, the short prodromal period, the marked diurnal remission of temperature, the blotchy eruption, the moist tongue, and the bowel condition of parthyphoid fever will greatly aid in diagnosis. The surety of diagnosis must, notwithstanding, rest on bacteriological methods. The repeated absence of the Grueber-Widal reaction is of utmost importance. Gwyn has said that this reaction is found in 99.6 per cent. of all patients suffering from typhoid fever; hence its constant nonappearance or its occurrence only in low dilution (1 to 10 or 1 to 5) in a typhoidlike disease is very suggestive of paratyphoid fever. The finding of a paratyphoid agglutination is typical and may occur in dilution as high as 1 to 6,000. The most conclusive evidence, however, is the isolation of the bacillus from the patient's blood.

Digitalis.—J. Knott presents a study in the history, pharmacology, and therapeutics of this drug.

Hexamethylenamine in Meningitis.—W. Brem states that Crowe had shown that this drug is not only excreted in the bile and pancreatic juice, but also appears in the cerebrospinal fluid. The latter has recommended the prompt administration of hexamethylenamine in all cases in which meningitis is a threatened or possible complication. Following this suggestion the author treated a case of meningococcus meningitis with this drug, and was able to demonstrate its presence in the cerebrospinal fluid. The apparent effect of the drug upon the organisms of the spinal fluid, the comparatively long duration of an apparently very acute infection treated with hexamethylenamine, together with its demonstrated presence in the spinal fluid in strengths of from 1 in 50,000 to 1 in 200,000, indicate that the drug might be useful as an adjunct in the treatment of meningitis cases or as a substitute for Flexner's serum in meningococcus meningitis should the serum not be obtainable or delayed.

What Is a Rational Diet?—M. Lyon states that the study of the physiology of digestion will give the key to the general principle.

The Waters of Bad-Nauheim.—H. Engel gives the various indications and contraindications of these waters.

Determining the Dose for Infants Below One Year.—H. Fried has devised the following formula: Make the age in months the numerator and 150 the denominator of the fraction. Thus for a baby two months old 2/150 will be the dose. This does away with complex computation. The results are close to those obtained according to Young's rule, which is, however, more intricate; moreover, in the former the fractions are easily reduced.

Angina Pectoris.—J. B. Herrick points out certain fallacies in the popular conception of angina pectoris. The first is that in true cardiovascular angina pectoris, peripheral arterial sclerosis, cardiac hypertrophy, and high blood-pressure are essential. This is by no means always the fact. Arterial change may be widspread and the coronaries sclerotic without hypertrophy of the heart or rise in blood-pressure. The sclerotic or atheromatous process may be quite limited, localized to the beginning of the aorta and only encroaching a little on the coronaries, while the peripheral vessels may be normal. Especially in syphilitic cases are the conditions liable to be thus localized. In some of the most serious cases there may be no abnormal arterial pressure, indicating perhaps a weakened cardiac muscle. The finding of aneurysm or lesion of the aortic valves does not exclude angina, but is rather in its favor. The attacks are not always few in number, and following exertion, and life is not necessarily cut off within a few months after the appearance of the disease. Patients may live a number of years with comparatively frequent attacks. While comparatively rare in women, the disease is by no means unknown, and serious mistakes may be made in diagnosis, especially in nervous and hysterical cases. The cardiopath is often a neuropath also. Pain is not always excessive. Even in fatal cases there may be no constant pain. Unconsciousness, though unusual, is seen at times and, while the patient usually is afraid to move and will not lie down, there are exceptions to this rule. Eructations or vomiting during an attack do not prove it to be a false angina and not organic or cardiovascular. While the disease is very grave, there is no certainty that death is imminent. The kidneys, as well as the heart, must be investigated as regards prognosis. The nitrates are sometimes marvelously efficacious in checking an attack and their failure to give benefit does not exclude true angina. In some cases digitalis does more good than all the nitrates or iodides.

Visceral Anesthesias of Tabes.—L. A. Connor, remaking first the value of pain as a safeguard in the body and the disastrous effects of its absence in certain diseases, reports a case of fatal perforated appendicitis in a tabetic without symptoms of pain, tenderness, or muscular rigidity. Roux found atrophy of a large proportion of the small myeline fibers in the sympathetic trunk and concluded that destruction of these was a special pathological condition of tabes and responsible for the visceral loss of sensibility. The loss of painful response to visceral irritation is therefore emphasized as probably due to these lesions and constitutes a special danger in this disease.

The Teaching of Surgery.—M. B. Tinker finds that one great fault is ignoring the relative value of what is taught, and failure to realize that few graduates will actually practise major surgery. The things they will have to handle are comparatively neglected.

Paraplegia Caused by Spinal Compression.—A. Primrose states that hemorrhage in the neural canal may be the cause of the paraplegia, either extra- or intradural or into the substance of the cord. When the paralysis comes on after an interval of time between it and the injury, this possibility must be kept in mind. It is not possible always to say whether the hemorrhage is extradural or intradural, but hemorrhage into the cord is more likely to give local symptoms. Severe injury to the spinal cord may cause death by clot. Acute reflexion of the cervical spine, producing stretching of the cord with hemorrhage, causes paraplegia. If fragments of the neural arch have been driven forward, compressing the cord, early operation may give relief, and if there is any strong evidence of partial severance of the cord the same is true, even before we can absolutely determine the fact. The most common cause of compression paraplegia from disease is spinal caries, and this is frequently amenable to

milder measures, but occasionally operative interference is necessary and should not be delayed too long, as experience has demonstrated to the author. If treatment by extension for three months is not effective, he would advise laminectomy unless other conditions contraindicate it. In tumors of the cord valuable time is often lost by delay until after the cord is damaged beyond repair, and he seems to think that operation should be performed in dubious cases. Even when the growth is syphilitic gumma, operation is better than waiting to cure it by specific treatment. The operation of laminectomy, carefully performed, is not a dangerous procedure and does not seriously affect the stability of the spinal column.

Traumatic Facial Paralysis.—W. W. Grant reports a case of traumatic facial paralysis due to a pistol shot in which the ball lodged on the floor of the anterior fossa in front of the ear. It had cut the facial nerve between the chorda tympani and the stylomastoid foramen. The usual method of using the spinal accessory or hypoglossal anastomosis for the remedy of the paralysis was not employed in this case. After experimenting on several cadavers the author devised the method of connecting the facial nerve with the spinal accessory and the peripheral end of the accessory to the descendens hypoglossi. The results were satisfactory.

Intestinal Obstruction Due to Round Worms.—C. Whelan reports a case of fatal obstruction of the bowels by round worms in the jejunum.

Application of Artificial Heat.—S. E. Tracy recommends the use of the electric lamps, six or eight of which, of sixteen candle power, are attached to the inside of an asbestos-covered frame, covering the patient from shoulders to feet, for the purpose of stimulation by artificial heat after operation.

Foreign Body Calculus.—I. S. Hirsch describes a case of urinary calculus in a girl five years of age, that had formed about a pin as a nucleus.

Submucous Septum Resection.—C. E. Purcell states that the operation is peculiarly fitted for private patients, that the character of the incision is highly important, that the turbinates should be spared, that little cauterization should be done, and that the nose should seldom be meddled with after the operation.

Results of Submucuous Septum Resection.—F. P. Emerson reviews the indications for submucous resection of the nasal septum, and describes his own methods.

Cystic Kidney.—T. C. Witherspoon reports a case in which he treated a typical polycystic kidney by opening the various cysts with scissors and forceps, removing their thin covering and partitions, leaving only the bulkier solid tissue intact.

The Nutrition of the Feeble Infant.—H. D. Chapin believes that a muscular insufficiency of the stomach, comparable to myasthenia gastrica of later life, is responsible for difficulties in infantile nutrition. In the majority of cases the feeble infant with digestive disturbances is fed too frequently and the stomach does not have time to empty itself between the feedings, and thus each successive feeding becomes contaminated and butyric acid fermentation is set up. In a few cases dilatation was marked. He calls attention to the changes of view in regard to nutrition of late years; the recognition of the fact that there are different kinds of proteins, carbohydrates, and fats, and their digestive properties vary according to the combinations. There is no one rule for feeding infants; some thrive on one thing and some on another, and the question of what is theoretically correct must be subordinated to what will practically work. Some infants thrive on a high proportion of carbohydrates, others on a low, and the same variations are observed with proteins and fats. He has long advocated the use of dextrinized gruels, as some patients seem to thrive especially well with a mixture of carbohydrates in high proportion and a low proportion of fats. This is the reason of the success of Keller's malt soup in many cases, though it sometimes signally fails. The general method to be employed in feeding in difficult cases will have to be determined to a certain extent by experiment with the individual infant. The care taken in trying to find a universally applicable food would better be spent in testing individual capacities and idiosyncrasies. The author has tested Finkelstein's method of feeding, based on the theory that digestive disturbances are caused by the sugar of milk, but his results are not very promising. When results follow this method of feeding he thinks it is due more to the form of protein given than to the lessened amount of sugar.

Congenital Hip Dislocation.—E. H. Ochsner in discussing the prognosis of this condition states that no case should go undiagnosed beyond the age of three; that if properly treated at this age the great majority of dislocations can be successfully reduced and can be given good anatomic and functional results.

Radioactivity Induced by X-rays.—H. Schiller and P. S. O'Donnell believe from their experiments that they are able to store up *x*-rays or a part of them and make use of them after they have been long removed from the tube from which they have been derived.

Bites from Copperhead Snakes.—G. R. Davis reports three cases and states that the fact that patients generally recover indicates that the wounds are not serious.

Treatment of Acute Stage of Poliomyelitis.—H. M. McClanahan recommends, among other things, as a routine measure, the use of hexamethylenamine. Elimination by all channels is the keynote in this treatment.

The Treatment of Poliomyelitis from the Neurologist's Point of View.—B. Sachs believes that intelligent gymnastic exercise of the paralyzed or weakened limbs is the method to which one should pin one's faith, and from personal experience he states that the physician who directs these exercises intelligently, and who will direct them patiently, will have no reason to regret the time devoted to this good cause. In recent epidemics the disease has been of such varying intensity that one has no right to claim that any case is a hopeless one, and much can be done by properly directed therapeutic efforts.

The Orthopedic Treatment of Poliomyelitis.—J. Ridlon discusses this subject under the headings of movements, braces and splints, surgery and massage, contraction deformities, tendon surgery, and prognosis.

The Value of 606.—B. C. Corbus states that in order to fulfil the theory of Ehrlich's *therapia sterilisans magna*, there must be certainty of diagnosis and careful technique in preparing the substance for injection.

A Case of Uremia with Facial Paralysis and Intestinal Ulceration. G. Parker.
Radium and Radioactivity. Dr. Guyenot.

The Education of the Student of Medicine.—F. H. Marsh believes that as medicine has now become a department of biology its pursuit necessarily demands a sound acquaintance with the broad principles of those departments of biological science upon whose foundations it rests, namely, chemistry, anatomy, physiology, and pathology. The teaching of medicine has suffered from the incubus of an overloaded curriculum. Could there be some adjustment, the teaching of the preliminary subjects would become most valuable to the student.

Industrial Tuberculosis.—T. D. Lister states that the industrial classes suffer from consumption at least twice as heavily as the leisured classes, and in many occupations the penalty paid in phthisis mortality is from five to ten times that of the phthisis mortality falling upon those who toil. From the general review and rearrangement of the figures for male adults regarding the occupational mortality one can gather that there is a distinct relationship between certain kinds of employment and phthisis mortality. Apart from certain highly special conditions involving the respiration of sharp, metallic particles (*e.g.* the tin miners), the highest mortality from phthisis is associated either with the trade in alcohol, or with the occupations which are the refuge or the penalty in the struggle for existence of the least competent. The unskilled workers and laborers, the street sellers, and similar classes on the one hand, and systematic poisoning with alcohol on the other, cause a phthisis mortality of three to four times that of all males, and six to eight times that of the agriculturist. In these classes phthisis is part of a high general mortality. But there are many industries whose mortality as a whole is low and yet their phthisis mortality is about or above the average. Typical instances of these occupations are clerks, indoor shopkeepers, many of the textile industries, the printing trades, and those working in metals other than iron and steel. Confinement, foul air, metallic dust, bad housing, and other conditions inherent to the occupations are the causes of the phthisis excess. In writing on the eventual conquest of consumption medical writers and laymen interested deal with it too exclusively from the point of view of infection. This involves the idea that by treating the early cases and segregating the advanced cases this great scourge can be eradicated, but it seems that the greater part of the question would remain untouched. To secure a regular and systematic examination of every employee, as is now attempted in the case of school children, is at present a counsel of perfection, even if sufficient skilled observers were available to make the necessary early diagnosis. To attempt to segregate all the comparatively advanced cases would involve a great deal of concealment in the present state of popular ignorance. Compulsory notification is an essential first step in the discovery of the real number of the phthisical population. The widest possible health teaching among the poorest and most ignorant classes of the people, and the most careful regulation of all the conditions under which the more or less skilled but yet unhealthy industries are carried on, are also essential preliminaries to the real stamping out of consumption.

Mineral Waters as Artificial Sera.—C. Fleig contributes an account of investigations on the question of mineral waters as artificial sera and of injections of mineral waters into the tissues both from a physiological and a therapeutical point of view. The conception of mineral waters as vital plasma and as artificial sera rests on a triple series of facts, (1) the facility of their injection in enormous quantities and by every possible channel, within animals and in man; (2) the effects of their transfusion after copious blood-letting in animals and in man; and (3) the examples of the survival and reviving of organs or of cellular elements isolated from the body and placed in mineral waters. These effects are more beneficial than those observed from the use of normal salt solution. The mineral waters owe their physiological virtue to their electrical, calloidal, radioactive, and other properties still unknown. They can be used at their exit from the spring as injections in an aseptic condition without preliminary sterilization, thus avoiding the slightest change in their natural condition. In the event of sterilization being necessary it should be done at a low temperature by filtration. The advantages of injections of mineral waters into the tissues as a method of so-called cellular balneotherapy and of the application of the hydromineral cure in general are very numerous, but the greatest discrimination is imperative in utilizing these injections in certain cases, as they cannot in any way be looked upon as substitutes for the methods of administration habitually employed, although they are calculated to augment the activity of these last and to notably enlarge the field of application, already so extended, of hydromineral medication. The therapeutic employment of mineral water injections is logical. In a general way they can be used both in cases where injections of normal saline solution or of isotonic sea-water are indicated, as well as in those in which we consider it of importance to apply a hydromineral cure, the maximum conditions of activity of which one may wish to realize.

Ulcerating Granuloma of the Pudenda.—R. M. Carter states that this is not a venereal disease, but it is contagious and is autoinoculated by the host on other parts of the body. The disease is of extensive geographical distribution, being found more frequently in India than in other countries. It is caused by a parasite belonging to the same class as that found in Oriental sore.

Tumor of the Pituitary Body.—W. Boyd describes the case of a man thirty-eight years of age, who began eight years before to complain of severe neuralgic pains in the temples, then had failure of sight, epileptic attacks, ataxia, acute mania, lethargy, and stupor. He died suddenly. Post-mortem examination showed a large, soft, friable, vascular tumor growing from the infundibulum; microscopically it bore a close resemblance to a mixed-celled sarcoma. The chief points of interest in the case were: The long duration; the absence of wasting and of any symptoms of acromegaly; the sudden termination; the nasal discharge of cerebrospinal fluid; the enormous amount of albumin and extraordinary lymphocytosis in the fluid from a case of nonsyphilitic tumor (for the naked eye and microscopic characters, together with the resistance to large doses of potassium iodide, clearly pointed to the non-specific nature of the growth); and the remarkable destruction to the floor of the skull.

Treatment of Uterine Fibroid by X-Rays.—A. F. Savill describes her results in the treatment of a patient forty-three years old in whom a rapidly growing fibroid caused menstrual hemorrhages. The tumor was as high as the umbilicus, and upon the refusal of the patient to submit to surgical treatment, the author resorted to *x*-ray treatment, using Bordier's method. The result was a disappearance of the monthly flooding, although the size of the tumor was but little reduced.

Uremia with Facial Paralysis and Intestinal Ulceration.—G. Parker states that ulceration of the bowel and hemorrhage from it are important complications of Bright's disease and may lead to a fatal result. When a bowel hemorrhage takes the place of a cerebral one the patient may have a better chance of recovery if he survives the immediate risks, but if it is due to extensive ulceration the condition is a very serious one. He reports a case of intestinal hemorrhage and facial paralysis, which were the first symptoms of uremia that manifested themselves, and illustrated the difficulties sometimes encountered in the diagnosis of kidney disease.

The Education of the Student of Medicine.—See abstracts of articles from the *Lancet*.

Acute Arthritis of Doubtful Origin.—H. D. Rolleston states that cases are seen which are at first assumed to

be rheumatic fever, but which fail to react to salicylates, and yet as shown by the sequel are not pyemic, gonococcic, or due to any other obvious infection. Vigorous salicylate treatment may produce a reaction in cases of arthritis due to other causes than rheumatism. In some cases an attack of arthritis clears up under salicylates except in one or two joints which progress in spite of treatment, suggesting suppuration, which, however, does not occur, and eventually the joint or joints present some fibrous ankylosis. In other cases a complete recovery is followed by a relapse, but the arthritis does not subside under salicylates and fibrous ankylosis results. Patients with oral sepsis are especially prone to relapses of rheumatic fever. Acute non-rheumatic arthritis consists of two groups: 1, infective, in which microorganisms are present in the affected joints, and 2, toxic, in which the joints are sterile, and apparently the seat of poisons brought from other parts of the body. In addition to the recognized forms of infective arthritis, such as gonococcic, pneumococcic, etc., there are others due to the *Diplococcus intracellularis*, to the *Bacillus coli*, and to the influenza bacillus. In pyemia, apart from purulent arthritis, the joints may become swollen and painful, without anything further taking place. Acute epiphysitis in children is a form of pyemic arthritis. There are cases of multiple arthritis that respond to injections of polyvalent antistreptococcic serum. Acute synovitis in generalized miliary tuberculosis is rare. There is also a form of tuberculous pseudorheumatism. Still's disease, or the special form of chronic arthritis with enlargement of the spleen or lymphatic glands, has been thought to be a tuberculous manifestation. An obvious difference between the tuberculous pseudorheumatism of adults and Still's disease is the relatively acute nature of the former and the chronicity of the latter. Toxic arthritis has been noted after the use of diphtheria antitoxin. Both suppurative and toxic forms of arthritis may complicate scarlet fever. Intermittent hydrarthrosis is supposed to be an affection of the synovial membrane analogous to a cutaneous erythema.

Experiment and Observation in Medicine.—J. A. Codd states that the advances in medicine have not kept pace with those of the pure sciences. Science depends on exact measurement, and most of the observations in medicine do not take the form of measurement but of signs that have only a relative value. Moreover in medicine the element of control is largely lacking, that is, it is impossible to check up the results by comparison with identical cases. Empiricism still plays a large rôle, although pharmacology has made important progress. The want of correlation between chemical affinities and pharmacological affinities is still very marked. With the advances in medical practice there has been a decline in the use of alcohol for therapeutic purposes. The scope of the physician has been narrowing. The advance in surgery has been enormous, and much of it at the expense of the physician. The field of physical therapeutics is widening. The enlarging sphere of antitoxin and vaccine therapy represents work of an eminently scientific nature. Vaccine therapy is the most promising line of the future that will redeem the physician from the secondary rank into which his brilliant surgical colleague has placed him.

Fever Caused by the Sandfly.—T. G. Wakeling describes a non-fatal three days' fever, with a week's convalescence and certain sequelæ, due to the bite of the *Phlebotomus papatasii*. There is a tendency to inflammation of synovial and pleural cavities, and to neuritis and headache.

Skiagrams of Renal Calculi and of Fractures.—O. L. Rhys presents skiagrams, one of which shows multiple renal calculi, and the other of which shows fractures of the transverse processes of three lumbar vertebræ. These fractures had been produced by muscular violence.

Münchener medizinische Wochenschrift.

October 11, 1910.

Significance of Calcium Metabolism in the Origin of Rachitis.—Dibbelt pronounces in the course of a serial article on this subject as follows: The pathogenic causation of rickets lies in a disturbance of the calcium metabolism, represented by an increased excretion of calcium salts by the intestine. This leads to the skeletal alterations after the blood has become poor in calcium content. The attraction of the blood for lime salts is sufficient to deprive the bones of their lime content, to say nothing of preventing the deposition of lime in the skeleton. It appears that the blood must have its lime salts, although the skeleton suffers.

The Wassermann Reaction in Tropical Affections.—Baermann of Sumatra has investigated syphilis, yaws, lepra, and malaria of indigenous origin with the Wassermann reaction. So far as syphilis is concerned the findings seem to agree with those obtained in Europe. Of very great interest is the outcome of this test in frambesia, the relationship of which to syphilis is so problematical. Thirty-eight untreated cases gave 100 per cent. positive reactions. These cases all presented abundant eruption. Of ten cases with isolated lesions eight reacted positively. Of twenty-eight cases which had undergone one or two courses of mercurial treatment, 50 per cent. still gave positive findings. So-called tertiary yaws, untreated, gave about 67 per cent. positive findings. Hence it must appear that the old question of unicism vs. dualism, concerning syphilis and yaws, must be reopened. The parallel of the reaction is striking, and, for the time being, the unicists seem to have regained advantages lost through inoculation tests. The author is conservative and thinks that his material, however large, is too small for conclusions. It has further been alleged oftentimes that Wassermann's reaction is applicable chiefly to temperate zones; and that it possesses a vanishing significance for tropical diseases. This is in part borne out by findings in malaria of the tropics, in which a considerable per cent.—20 or more—of positive findings were obtained; and, still more strongly by lepra findings, where the positive percentages vary—being low or high, 18 to 80 per cent. without apparent causes.

Laceration of the Tentorium in Labor.—Beneke is inclined to believe that the mechanism of many fetal deaths and intracranial diseases in the living may be referred to laceration of the infants' tentorium cerebelli in labor. The sutures being still open, lateral compression of the skull would tend to cause this lesion and the results might be relatively mild or severe. In the latter case we should find immediate death or protracted asphyxia; in the former hydrocephalus internus as well as a structural basis for neuroses. These lesions of the tentorium, resulting in more or less hemorrhages, do not exhaust the intracranial pathology of the newly born infant, but represent an important factor in the same, if not the most important. Thus hemorrhage from the tentorium, from its basilar location, is able to influence powerfully the medulla and the nerves which originate therefrom, and likewise the fourth ventricle, and most of the sinuses. Hemorrhage of the vertex, often mentioned in textbooks, tends to produce at the outset only the general symptoms of intracranial compression. It is evident that a whole series of subjects, such as asphyxia neonatorum, deaths of numerous types soon after delivery (notably trophic deaths from lesion of the medulla), chronic hydrocephalus, congenital neuroses, idiocy, and so on, should derive new significance when studied from this etiological standpoint. At the same time the idea is by no means new, having been foreshadowed by some of the fathers of modern pathology.

Book Reviews.

Die Praxis der localen Anästhesie. Von Dr. Artur Schlesinger, Berlin. Mit 22 Textabbildungen. Berlin und Wien: Verlag von Urban und Schwarzenberg.

This handy volume of 160 pages fully covers the entire subject of local anesthesia in its many phases. The author traces the extraordinary progress that this subject has made, giving full credit to Corning's contributions, particularly to the latter's demonstration of the feasibility of regional anesthesia by means of cocainization of the nerve trunk. The main object of this book is to enable those who have no opportunity of learning by actual observation the various methods of local anesthesia to acquire the technique by meaus of graded exercises. At the same time the author seeks to satisfy the more difficult requirements of specialists in the most advanced methods of local anesthesia.

Un Nouveau Traitement du Tabes (Ataxie Locomotrice). Avec quelques considerations sur la repercussion centrale des irritations périphériques. Par le Docteur Helan Jaworski, de la Faculté de Médecine de Paris, et de la Faculté de Médecine de Lemberg (Autriche); Médecin et Chirurgien de la Faculté de Médecine de Lima (Pérou), et du Royaume d'Espagne. Paris: A. Maloine, 1910.

This "new treatment" is the one associated with the name of Denslow, and is sufficiently familiar to English-speaking physicians. In this work Dr. Jaworski endeavors to make the theory known to the French.

Department of Neurology, Harvard Medical School: Contributions from the Massachusetts General Hospital, the Boston City Hospital, the Long Island Hospital, and the Neurological Laboratory. Vol. IV. Boston, Mass., U. S. A., 1910.

This publication brings together in one volume articles published during the year in several medical journals. The various contributors have endeavored to maintain the standard of previous volumes, and some of the twelve contributions are timely and interesting.

Visiting Nursing in the United States. Containing a Directory of the Organizations Employing Trained Visiting Nurses, with Chapters on the Principles, Organization, and Methods of Administration of such Work. By Yssabella Waters, Henry Street (Nurses') Settlement, New York City. New York: Charities Publication Committee, 1909.

It may be said that the appearance of this work commemorates the fiftieth anniversary of the establishment of visiting nursing in Liverpool, England. During these fifty years there have been established in the United States alone 566 visiting nurse associations with a staff of 1,413 nurses, while in the past year 112 new organizations were formed. The purpose of this book is to show what is being done in this country through the services of the trained nurse, in district nursing, and in the more recent extension of her activities in tuberculosis, school inspection, social welfare, and other more general social work. There are a description and a history of visiting nursing, a chapter on principles, and a directory of all visiting nursing organizations in the United States. The book is practical, and may be used as a guide by those who wish to establish a nurses' settlement. The author has admirably embodied in this work the fruits of her experience as a trained nurse and as a settlement worker on the East Side of New York

The Science of Living or the Art of Keeping Well. By William S. Sadler, M.D.; Professor of Physiologic Therapeutics, The Post-Graduate Medical School of Chicago; Director of the Chicago Institute of Physiologic Therapeutics; Member of the Illinois State Medical Society, the American Medical Association, the American Association for the Advancement of Science, the American Health League, the Sixteenth International Medical Congress, etc. Illustrated. Chicago: A. C. McClurg & Co., 1910.

It is a pleasure to read a book so interesting, practical, and helpful. The work has been prepared primarily for those who are well and who wish to remain so. Health rules are presented with physiological explanations. Of great value is the section on foods, in which many common daily errors are discussed with reasons for their avoidance. The fuel value of foods is given, with a description of the prevalent adulterations and methods of detecting them. Other interesting and useful chapters are the cause of worry and the cure of worry. The text is free from fads and extremes, so much in vogue in many works of this nature. Results of the latest scientific discoveries in the field of hygiene are incorporated in the text in a simple, straightforward style. Numerous phases of the subject ordinarily overlooked in health books are given a place in this volume, which with a full index and illustrations lend value to the book. The retail price is $1.50 net.

Radium Therapy. By Dr. Louis Wickham, Médecin de Saint-Lazare, Ancien Chef de Clinique Dermatologique de la Faculté de Paris, Lauréat de l'Académie de Médecine; and Dr. Degrais, Chef de Laboratoire à l'Hôpital Saint Louis, Lauréat de l'Académie de Médecine. Translated by S. Ernest Dore, M.A., M.D. (Cantab.), M.R.C.P., with an introduction by Sir Malcolm Morris, K.C.V.O. Illustrated with 20 colored plates and 72 figures in the text. New York: Funk & Wagnall's Company, 1910.

The appearance of this book is at once a tribute to the discoverers of the new epoch-making element, and to the scientific skill of those who first saw and applied its therapeutic possibilities. With the matchless facilities of the Laboratoire Biologique de Radium at his disposal, Dr. Wickham has been enabled to contribute largely to the recent progress in radium therapy. The authors have been guided by the principle that assertions must be made with great caution, and always based on a sufficient length of time and number of cases. They have paid special attention to the study of measurements, filtration, and dosage. The first part of the work is concerned with physics—the description of the nature, origin, and available energy of radium. The second part deals with instruments and technique, describing the methods of treatment and the conditions of measurement and dosage. The third part is concerned with clinical therapeutics, and includes general considerations on reaction, together with chapters on carcinoma, cheloids, and disfiguring cicatrices, angiomata, pigmentary nevi, tuberculosis, chronic refractory affections of the skin (inflammatory and pruriginous), and various other diseases; and a chapter on the use of radium in gynecology. Numerous colored plates and figures in the text add to the value and beauty of the book.

La Medecine à Bord. Notes recueillies au cours de dix-huit années de navigation. Par Franck Clair, Médecin sanitaire maritime, Membre correspondant de la Société de Pathologie exotique, Membre de la Société de Médecine et d'Hygiène tropicales, Medailles d'honneur des épidémies en argent. Ouvrage couronné par l'Académie de Médecine (Prix Clarens). Paris: Vigot Frères, 1910.

Growth in the subject of maritime medicine has been coincident with the extraordinary development of international traffic on the high seas. A number of works on this subject have appeared within recent years, but none seems to have fulfilled its purpose so admirably as this book, which is intended to be at the same time a brief compendium of maritime pathology and hygiene, as well as a guide book for those ship surgeons who are just entering upon their vocation. In the first part of this book the author describes succinctly the affections most commonly observed at sea, dwelling especially upon those peculiarities created by the nautical environment, and upon those methods of treatment compatible with the resources that may be found aboard ship. The second part of the book deals with the organization of maritime medicine under the control of the state, somewhat after the pattern of the Public Health and Marine Hospital Service of the United States, which represents the best institution of its kind in the world.

Zur Transformation des Knochenkallus. Experimentelle Untersuchungen und ihre klinische Bedeutung. Von Dr. M. Zondek, Berlin. Mit 11 Abbildungen im Text. Berlin: Verlag von August Hirschwald, 1910.

In order to clear up some of the uncertainty existing as to the exact process of healing following fractures, Zondek broke the right hind leg in six mice, killed the animals after an interval of six to thirty-five days, and made a great number of serial sections at the seat of fracture. He finds that the production of cartilage in the interior of the diaphysis is due to pressure. It was greater on the concave than on the convex side of the bone. The change from cartilage into osteoid tissue progresses gradually from above and below toward the seat of fracture, and is slower in the lower fragment and on the concave side than in the upper fragment and on the convex side. His conclusion as to treatment is that the best results are obtained by a combination of the anatomical (correct adaptation) and functional methods. The work is in the form of a monograph of forty-one pages, and is most praiseworthy. The study of bone pathology involves so much labor that it is very generally neglected.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixtieth Annual Meeting, Held at Pittsburg, October 3, 4, 5 and 6, 1910.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 794.*)

THEODORE B. APPEL, M. D., OF LANCASTER, PRESIDENT.

Thursday, October 6—Third Day.

Oration on Obstetrics.—Dr. H. F. TOMB of Johnstown made this oration, saying that we should endeavor to obtain better fees, to have every one of these cases as a direct patient under the guidance of a physician from the very beginning of her pregnancy, to make an effort to obtain better nursing and, by procuring the better care and nursing, to get rid of the midwife and her class. To give to our labor cases more of our time and care, both during their labor and in the lying-in period, and to never discharge a case of this kind until we had made a thorough examination of her.

The Prophylaxis of Gonorrhea.—Surgeon M. F. GATES, U. S. N., read this paper, saying that in the U. S. Navy general preventive measures such as mental and physical exercises and diversions and instruction by lectures and leaflets had been employed to the fullest extent Prophylactic treatment after exposure had been used in the last few years with excellent results. If administered within eight hours of exposure protection was almost certain, but even after forty-eight hours it was sometimes of value.

The Abortive Treatment of Gonorrhea.—Dr. MACY BROOKS of Philadelphia read this paper, saying that a case cured within two or three weeks was to be considered aborted. Abortive treatment was seldom effective later than when the discharge was just becoming mucopurulent, and there was at most a slight burning on urination. Injections too strong or too frequent were harmful. A daily injection by the surgeon was sufficient. Should abortive treatment fail, treatment could be continued as in the usual case.

Treatment of Acute Gonorrhea.—Dr. W. F. DONALDSON of Pittsburg presented this paper, saying that when acute gonorrhea was recognized and treated more as a pathologic condition and less as a social disease it would take its place among curable diseases and not rank among the leading disseminators of death and destruction. If it were true that acute gonorrhea was curable, it was time that we cease to be alarmists and rather educate the public that the unfortunate with acute gonorrhea may with early, intelligent, and diligent treatment be cured. He would urge physicians to deal with patients infected with acute gonorrhea in such a sympathetic and dignified manner that in the course of time all such would early seek medical advice and follow the same until a cure had been effected.

Diagnosis and Treatment of Chronic Gonorrhea.—Dr. T. L. DISQUE of Pittsburg read this paper, saying that for the diagnosis of chronic urethritis it was necessary to determine the character of the discharge, make a microscopic examination of the discharge, investigate the urine and make a careful local examination of the urethra itself. In the treatment if gonococci were present disinfection by lavage with potassium permanganate was carried out until the discharge was stopped, then followed by instillations of silver nitrate. If there was infiltration of the submucosa dilatation and massage must be practised. Of internal remedies, the balsams and disinfectants are of value when the urine was turbid and the diluents when there was concentration and acidity.

Dr. H. M. CHRISTIAN of Philadelphia said that in the early stages of gonorrhea as a local treatment there was nothing better than permanganate of potash. Permanganate of potash would never cure a case of gonorrhea. To cure a case of gonorrhea something was required that acted upon the mucous membrane of the urethra like an astringent, to repair the damage done by the gonococcus to the mucous membrane. Personally he felt that all chronic gonorrhea was found in the prostate. He was coming more and more to let the anterior urethra almost out of the question, unless, of course, there was present in the anterior urethra a stricture or some involvement, but he believed that in 75 or 80 per cent. of chronic urethral discharge there was a prostatic involvement.

Dr. S. W. MOORHEAD of Philadelphia said that he had reluctantly come to the conclusion that the microscopical examination was in itself insufficient to establish whether gonococci were present in a discharge and that recourse should be had to cultures. This necessitates a large amount of laboratory work and equipment, but it was a work which ought to be done and which would have to be done in very many cases.

Dr. W. C. BRYANT of Pittsburg said that there was no doubt that acute inflammation was a beneficent process and while it might not last very long there was a time in treating some cases of gonorrhea, at least, when the urethra was better left alone. Permanganate should never be stronger than 1-5000.

Dr. DISQUE, in closing, stated that what Dr. Christian had said in regard to the rôle of the prostate was well taken. While the prostate was a marked feature in the prolongation of chronic urethritis and probably the greatest hiding place of the gonococcus, it was not the only one and we should not neglect other portions of the urethra or the genital tract.

The Clinical Results Following the Use of Vaccines and Sera in the Treatment of Gonorrhea and Its Complications.—Dr. W. H. MACKINNEY of Philadelphia read this paper, saying that the bacterial vaccines had not demonstrated their value in the treatment of acute or chronic gonorrhea or its acute complications. In metastatic infections, chiefly arthritis, they had given good results in a few cases, but the results could not be compared to those obtained from the serum. In the treatment of metastatic gonorrhea both the serum and the vaccine were of considerable value though they were not specifics.

The Question of Marriage Following Gonorrhea.—Dr. G. A. Holliday of Pittsburg read this paper, saying that gonorrhea was the married woman's most common disease. The double standard of morality must be frowned upon. The girl should be taught that venereal infection might ruin her health and, therefore, to demand a clean bill of health from her prospective husband. Most of the sterility in women was due to gonorrhea, and 50 per cent of infected women were sterile. Men should be instructed in prophylaxis. Physicians were responsible for a large percentage of innocently infected wives because they did not thoroughly treat gonorrhea and its complications in the male.

Officers of the Section on Surgery for 1910-1911: *Chairman*, Dr. J. Mayhew Wainwright, Scranton; *Secretary*, J. B. Lowman, Johnstown.

SECTION ON EYE, EAR, NOSE, AND THROAT DISEASES.

Dr. G. HUDSON-MAKUEN, Philadelphia, Chairman, made a few preliminary remarks.

Clinical Diagnosis of Laryngeal Neoplasms.—CHAS. PREVOST GRAYSON, Philadelphia, considered the relative importance of the clinical diagnosis, the significance of the personal and clinical history, the clinical features of the more common laryngeal growth and the methods of examination.

Histological Diagnosis in Laryngeal Neoplasms.—Dr. Braden Kyle, Philadelphia, said that a careful examination of the microscopic appearance should be made. The presence or absence of inflammatory tissue should be noted, and the patient should be kept under observation, so that all the clinical phenomena could be carefully observed. Portions of tissue should be removed for examination and diagnosis, and other conditions should be eliminated by time and the therapeutic test.

Systematic Tests in Cases of Laryngeal Neoplasms.—John W. Boyce, Pittsburg, said that these had but a limited field of usefulness. He thought that the therapeutic tests for syphilis were not rendered obsolete by Wasserman.

Treatment of Laryngeal Neoplasms.—Chevalier Jackson, Pittsburg, considered the medical treatment and treatment with the therapeutic ray and radium; also the surgical treatment, which he divided into the endolaryngeal method and external surgery.

Dr. Klotz, Pittsburg, was impressed with the doubtful diagnosis occasionally obtained. He said that the pathologist was at a decided disadvantage when trying to make a diagnosis in the case of an individual that he had not seen and knew nothing about, if he received only a small bit of the growth. He thought that there was a type of papillomatous growth that had malignant qualities. In his experience all laryngeal lesions of syphilis had given a positive Wasserman reaction.

Dr. Boyce said that he had had seventy-seven positive results from the Wasserman reaction in the late lesions of syphilis, and that the lesion of this disease that was confused with malignancy was always a late lesion.

Dr. Jackson said that the medical profession were prone to lean too heavily on the laboratory. They did not want to know the structure or arrangement of the cells, but wanted their specimens to come back positive or negative. No conscientious pathologist, however, could give a positive answer in every case. The clinicians were the ones that were responsible for the diagnosis.

Total Blindness from Toxic Action of Wood Alcohol, with Recovery of Vision Under Electricity.—Dr. S. Lewis Ziegler, Philadelphia, said that the patient had suffered total loss of vision suddenly, with blanching of the disks, about a month before treatment was begun. Negative galvanism stimulated the revascularization of the disks, and brought light perception at the end of the second month. The vision had steadily improved until it became two-sevenths of the normal, and the fields were gradually growing wider.

Dr. Samuel D. Risley, Philadelphia, said that the fact that the case had improved under the application of negative galvanism held out a ray of hope in regard to the treatment of some of these cases. Personally, however, he had never seen a case of this sort recover. The drug was so dangerous that he thought that the community should be protected more thoroughly against it than at the present time. He had never seen a case of wood-alcohol blindness in which there was not present atrophy of the optic nerve, except the case mentioned by Dr. Ziegler, in which galvanism produced benefit.

Dr. E. L. Jones, Cumberland, Md., related the case of a man who had been blinded by drinking ginger extract; negative galvanism was used, and when the vision had been considerably improved, the infection did not make any further progress. Dr. Jones did not at that time think it was the galvanism that had improved the patient's vision, but he had become convinced that it probably was the lucky accident of his having used galvanism that had prevented complete loss of sight.

Dr. Geo. B. Jobson, Jr., Franklin, said that he had not been so fortunate, as his patient had retrogressed after he had been using electricity for a certain length of time. He thought that in this case there was undoubtedly complete degeneration of the nerve fibers, and was inclined to think that it had commenced in the ganglionic centers and had spread to the nerve fibers by ascension.

Dr. W. H. Tassell, Coudersport, said that he had lived in a section of the State where 150 people worked in the manufacture of wood alcohol. During a period of five years he had seen no case of poisoning from that drug, either by inhalation or by local application. He thought, therefore, that the danger of the absorption of wood alcohol had been rather overestimated.

Dr. Ziegler said that those who worked in the products of wood alcohol got used to it and had no bad effects from it, unless the room in which they were working was closed. He did not think that any cases yielded to galvanism, except those in which there had not been total destruction of the nerve fibers.

Arterial Hypertension and Its Relation to Morbid Changes in the Eye.—Dr. Luther C. Peter, Philadelphia, said that a study of chronic interstitial nephritis and arteriosclerosis showed that in all cases in which eye changes were present arterial hypertension existed. Within certain limits hypertension bore a more or less definite relation to the severity of the eye changes. They were not due to toxemia, except in so far as toxemia increases blood pressure, but were direct outgrowths of arterial hypertension. Hypertension was one of the most frequent causes of subconjunctival hemorrhage and an active factor in the production of glaucoma.

Dr. Wendell Reber, Philadelphia, did not think that Dr. Peter had sufficiently emphasized the fact that beginning lesions in the retinal vessels were not so rare, and might often be among the earliest signs. He thought that the mechanical theorists had some basis for their belief, although autotoxemia was present in most cases.

Dr. S. D. Risley, Philadelphia, remarked that there was a growing recognition of the importance of a study of the tension of the blood stream, not only in ophthalmology, but also in other branches of medicine. He felt sure that within the last two months the lives of two patients had been saved in this way. He thought that the relation of blood pressure to glaucoma depended upon the kind of glaucoma, the age of the patient, and many other circumstances. In a large number of cases of glaucoma the ocular disease was but one of the local expressions of the symptom complex of arteriosclerosis.

Dr. Peter added that the same patient would show marked variation in blood pressure at different times. He said that toxemia intensified the blood pressure and that this was the cause of these changes.

Varix or Angioma Venosum of the Orbit.—J. Ferdinand Klinedinst, York, said that the tumor was of five years' duration; it was not perceptible when the patient was standing or sitting erect, but only when stooping or bending forward. There was no hereditary tendency to similar growths, no exophthalmos or impairment of vision. Nose, throat, and nasopharynx were normal. Cure was produced by injections of alcohol within the orbit.

Dr. M. V. Ball, Warren, said that he would be loath to follow Dr. Klinedinst's example in the treatment of a similar case, because he believed that there was considerable danger of causing cellulitis or trouble in the cavernous sinus.

Dr. Wendell Reber, Philadelphia, did not exactly share Dr. Ball's views, as he would be tempted to use alcohol, first warning the patient of the danger.

Dr. Klinedinst said that the patient was willing to undergo the operation, and that the treatment had been explained to him. So far as cellulitis was concerned, Dr. Klinedinst said that alcohol was a strong antiseptic solution, and that sterile instruments were used; he could, therefore, see very little danger of cellulitis.

Modern Advances in Syphilis.—Dr. ALEXANDER A. UHLE, Philadelphia, said that the discovery of the *Spirocheta pallida* was the greatest achievement. The inoculation of syphilis into apes and monkeys was of great value in determining a prophylaxis by the use of calomel ointment. He considered a positive Wassermann reaction a valuable aid in the early diagnosis of active or latent syphilis. A negative reaction was not so reliable. Repeated negative reactions in the absence of mercurial treatment were of value in determining a cure.

The Early Ocular Signs of Syphilis.—Dr. WENDELL REBER, Philadelphia, said that a primary sore may occur on the lid margin or conjunctiva, the only site where an initial sclerosis was found in ocular tissues. Secondary syphilis was most likely to reveal itself in ocular tissues as an iritis, choroiditis, keratitis punctata (descemetitis), or all three combined (uveitis). The vitreous frequently participated in the process. The optic nerve was said by some to be the most frequent seat of secondary syphilitic involvement.

Ocular Affections in Congenital Syphilis.—SAMUEL D. RISLEY, Philadelphia, made a study of the more usually occurring forms of eye disease in children of syphilitic parentage, paying especial attention to the association of ocular affections with other manifestations of impaired general nutrition, and their similarity to other specific dyscrasias.

Aural Manifestations in Syphilitic Disease.—Dr. S. MACCUEN SMITH, Philadelphia, said that primary syphilis of the ear was rare. The auricle was subject to the usual secondary eruptions, condylomata and ulceration. In the middle ear syphilitic inflammations occurred in connection with nasopharyngeal involvement. Strictures of the tube frequently resulted from ulcerations, causing marked deafness. Suppurative otitis media was common in congenital syphilis. Syphilitic involvement of the labyrinth caused nerve deafness, and was the most serious aural complication.

Syphilis of the Nose and Throat.—Dr. GEORGE C. STOUT, Philadelphia, considered this condition under the three headings of congenital, hereditary, and contracted; and each of these in the primary, secondary, and tertiary stages. He then took up the course, duration, pathology, diagnosis, prognosis, and treatment of the condition.

Dr. ALEXANDER A. UHLE, Philadelphia, said that mucous patches that will not respond to treatment with mercury alone might be made to do so by the addition of a few drops of potassium iodide early in the disease, probably by causing destruction of the nucleus of the round cell. From his personal experience he was convinced that the Wassermann reaction was one of the greatest advances that had yet been made in the study of syphilis. In a hundred and one reactions taken in the Philadelphia Hospital, but one case had been found in which the clinical and Wassermann diagnosis did not correspond. They employed the reaction as described by Wassermann himself and not any of the various modifications. The result can usually be relied upon, unless the patient has been taking mercury before the reaction is made.

Dr. WM. CAMPBELL POSEY, Philadelphia, said that he knew of no case of recent iritis that he could recognize as being due to gonorrhea or secondary syphilis by merely looking at the eye. He wished to ask Dr. Reber whether syphilitic inflammation of the iris was met with more frequently in patients with a gouty or rheumatic diathesis. He believed that most cases of pseudoglioma were due to inherited syphilis. He had seen a number of uveitis due to this disease, but had seen marked inflammation of the iris but rarely.

Dr. EDWARD STIEREN, Pittsburg, said that he had reported cases of presenile syphilitic cataract in which endarteritis was a causal factor. He thought that the deleterious influence on the center of the eye was occasioned by the obliteration of the caliber in the blood vessels.

Dr. WENDELL REBER, Philadelphia, thought it natural to look for a greater prevalence of iritis in those whose resistance was lowered by the gouty diathesis. He then related a case in which, while the patient presented none but the laboratory evidences of tuberculosis, he thought that there was late tuberculous interstitial keratitis. Ten years ago this case would have been diagnosed as syphilis.

Dr. JAY F. SCHAMBERG, Philadelphia, considered the remarks of Dr. Stout concerning the widespread prevalence of syphilis fully corroborated by the statistics. He also agreed with Dr. Stout regarding the greater prevalence of innocent infections than was usually believed, and said that there were likewise more professional infections. Physicians generally did not take sufficient precaution to protect themselves and their patients from possible syphilitic infection. Concerning the Ehrlich remedy conveniently known as 606, Dr. Schamberg said that judging from the opinions of the most competent syphilographers of Europe the medical profession was facing the announcement of the discovery of a remedy that had no equal in therapeutics.

Dr. S. D. RISLEY said that in his opinion Dr. Reber's case was not necessarily a tuberculous keratitis, but was one of that group referred to by him as due to impaired nutrition, the result of dyscrasia. This condition of affairs existed in the class of people formerly called scrofulous.

A Method of Preserving the Eye Usually Removed. EMMETT L. JONES, Cumberland, Md., described a treatment by massive subconjunctival injections of cyanide of mercury, plus varying drugs, to suit individual cases or conditions. These procedures were of value in preventing loss of vision in a wide variety of grave conditions, and in getting results not otherwise obtainable.

Dr. L. WEBSTER FOX, Philadelphia, said that he had been using sugar or salt in a good many cases, and had been encouraged by the results. A certain percentage of vitreous opacities had cleared up and the course of the disease had been shortened. He did not know what action it had other than a stimulating effect on the lymphatics of the eye, accelerating the absorption of inflammatory products, and thus preventing what might lead on to sympathetic ophthalmia.

Dr. JONES said that the cyanide of mercury facilitated the process of rapid healing. Conditions that would otherwise have taken days and even weeks to heal got through in a strikingly short period of time.

Pennsylvania State Pilots.—WM. CAMPBELL POSEY said that vessels coming from foreign ports are compelled to take on board a State pilot to guide them into the harbor. These pilots are often paid more for this service than is the captain of the vessel for bringing it over from Europe. He related the case of a Pennsylvania pilot who had frequently been tested and found color blind, but who was still retained in the service by the Board of Commissioners of Navigation. He then offered a resolution to be passed by the section, as follows: "Be it resolved, that the section request the House of Delegates to sanction the following—In the light of our present knowledge, the Holmgren and lantern tests are the best means to detect color blindness; and persons failing to pass these tests should be debarred from all forms of public service in which the recognition of color in signaling is an essential."

Dr. L. WEBSTER FOX, Philadelphia, seconded the resolution, and related his experience in examining this particular pilot.

Dr. E. B. HECKEL, Pittsburg, said that this case showed that the color blind may educate themselves to recognize colors by means of their intensities; yet that, when put to the test, their deficiency would become evident.

Dr. S. D. Risley thought that there was great danger inherent in such a case as this, more than in that of a man

who was obviously color blind. The latter would be turned down without trouble.

Temperature in Enlarged Tonsils and Adenoids.—Dr. J. Homer McCready, Pittsburg, gave a report of the temperature in two hundred operated cases of hypertrophoid tonsils and adenoids. Cases with temperatures of over 100 degrees were considered nonoperative. About 30 per cent. of the cases ran an afternoon temperature varying from 98.8 to 100 degrees. The temperature in most cases was due to slight tubercular involvement of the lungs, chronic bronchitis, gastrointestinal disturbances, etc. These conditions were caused primarily by diseased tonsils and adenoids.

The Indications for Removal of the Faucial Tonsils and the Dangers Connected with This Procedure.—Dr. Christopher C. Sandels, Pittsburg, said that the indications were simple hypertrophy interfering with normal respiration; local and general systemic infection due to diseased tonsils; glandular enlargement of the neck; recurrent tonsilitis, and tuberculosis of the tonsils. The dangers of the operation were from shock, traumatism and postoperative hemorrhage.

A Method of Removing the Faucial Tonsil Using a Soft Silver-Wire Snare.—Archibald A. MacLachlan, Pittsburg, described the use of the vacuum pump, operated by water pressure, to remove blood and secretions from the throat by suction during throat operations. The pillars were separated by scissors and blunt dissection. The base of the tonsil was snared outside its capsule with a soft silver-wire snare, threaded through a perforated shot, which does not cut, but compresses the blood vessels and tissue posterior to the capsule, as would a ligature. The shot was then compressed, the tonsillar tissue was compressed, the tissue was cut off with scissors at the median side of the compressed silver wire and shot. The wire was left on for a few minutes, and then cut loose, or, if much bleeding is expected, it was left on until it separates, about three days afterward. A smooth scar is left, unlike the usual scar when the wound heals by granulation.

The Tonsil and the Singer.—Dr. M. Delmar Ritchie, Pittsburg, called particular attention to the clinical aspect of a few of the more interesting questions that daily devolve upon the laryngologist. His conclusions were as follows: (1) Local measures have a larger field in the treatment of tonsillar disturbances in singers than in other classes of patients; (2) the small, submerged tonsil is frequently more disastrous to the vocalist than a larger one; (3) ordinarily a singer must be in good health to be in good voice; (4) the erroneous lay position that removal of the tonsils causes deterioration in vocal or auditory powers must be ascribed to the incomplete operation as done until within the last few years; (5) the voice is improved in essential qualities and range, if the pillars and adjacent muscles are uninjured by the complete operation of tonsilectomy.

Dr. J. S. Hegeman, Pittsburg, said that he had been able to follow up some of the cases which Dr. Sandels had operated on, particularly in children at the age of pubescence, and had found that the effect of the operation was almost magical. It had occurred to him that if a little preparatory treatment were undertaken a day or two before operation, the tendency to hemorrhage might be obviated. He thought that the necessity for complete tonsillectomy, instead of tansillotomy, could not be too often reiterated.

Dr. Victor Laurent, Pittsburg, thought that most of the benefit would come from removal of the adenoids, and not necessarily from removal of the tonsils, which are normally large in children. He admitted, however, that in diseased tonsils, tonsillectomy was the only thing to be done. One should be careful in operating upon professional singers. The additional space might make the voice larger, but it would also make it lower; and the surgeon would scarcely receive thanks for changing a high soprano, for instance, into a mezzo.

Dr. E. L. Jones, Cumberland, Md., thought that removal of the tonsils from adult singers, especially where there was disease of the tonsils or adhesions preventing the free action of the palate, was a good thing.

Dr. C. M. Harris, Johnstown, said that many of his professional brethren had no modern ideas regarding tonsil work. The operation they thought of was usually tonsillotomy. Too much stress could not be laid upon the proper separation of the pillars. He had no infectious symptoms beyond a slight rise of temperature in the first twenty-four hours, and he had grown to regard traumatism as a potent cause of infection.

Dr. G. Arthur Dillinger, Pittsburg, said that the majority of cases in which there is hemorrhage following operations on the tonsils were due to tearing of the tissues through lack of sufficient care. He used chloroform for these operations, except in cases in which there were very large adenoids. He could not see how removal of the tonsils could affect the voice, except to improve it, provided the pillars were not injured.

Dr. Joseph H. Hoffman, Pittsburg, said that the operation for adenoids improved the voices of children, but he could not say what the effect would be in adults.

Dr. F. Victor Laurent, Pittsburg, said that the changes in the voice came from injuries to the pillars and other anatomical structures. If the enlarged tonsil was merely causing a defect to the voice, all that was necessary was to clip the tonsil enough to remedy this defect.

Dr. G. Hudson Makuen, Philadelphia, said that he supposed it was a little radical to assert that every diseased tonsil should be removed, because the diseased tonsil might be serving as a protective agent. He asked whether Dr. MacLachlan was not afraid to leave the wire and clamp shot to be cut off afterward, lest the patient should swallow it.

Dr. McCready said that after excluding all other causes for a high temperature except the focus in the tonsil this would be an indication for its removal.

Dr. MacLachlan stated that the wire was not more than an eighth of an inch in diameter, and that after the shot was compressed it was cut off at the base of the shot, so that there was no sharp point. He did not think that even if the patient swallowed it there would be much danger, as it would be encased in fibrin.

Dr. Ritchie thought that there was a large field for the treatment of tonsils that were not diseased, but that they were in the way of professional singers, and said that if the voice was not improved by removal of the tonsils, it was because they were not entirely taken out with the capsule.

Herpes Zoster Ophthalmicus.—Dr. Elmer E. Wible, Pittsburg, said that this condition was characterized by a peculiar and beautiful unilateral distribution. Its etiology remains problematical. It simulates erysipelas and simple herpes febrilis in appearance. The serious sequelæ occurring occasionally, and protracted recovery, prompt the oculist to give a guarded prognosis. Its early recognition is important that prompt and proper treatment may be given.

Dr. Stanley S. Smith, Pittsburg, had had only two cases of this disease in fourteen years, one resulting in practical blindness, and the other in mechanically complete recovery.

Dr. E. B. Heckel, Pittsburg, said that as these cases were rather classic in appearance, there should be no trouble in making a diagnosis. He was then treating a case with cauterization by means of phenol and carbolic acid, with apparently good results.

Trachoma and Some Facts Concerning Its Existence in Western Pennsylvania.—Dr. Clarence M. Harris,

Johnstown, gave some historical data concerning trachoma and information about its geographical distribution, its existence and progress in the United States, its prevalence among the alien population, the lack of control of all cases, the economic loss occasioned by the disease, the influence of sanitary living upon it, and the question of a remedy.

The Progress of the Trachoma Campaign in Pennsylvania.—Dr. CLARENCE P. FRANKLIN, Philadelphia, emphasized the difficulties in obtaining reliable statistics, and the inertia of mind of ophthalmologists upon what they considered a non-vital subject. He then spoke of the investigations being conducted by the Bureau of Municipal Research of Philadelphia. He considered the outlook for the future of trachoma work in Pennsylvania more encouraging than it was two years ago.

Dr. E. B. HECKEL, Pittsburg, said that trachoma was a reportable disease in Pennsylvania, and that a person affected with it might be sent back to his own country at any time within two years if it could be proved that he had it before reaching the United States.

Dr. JOHN B. CORSER, Scranton, said that many persons with trachoma get into the United States by way of Canada.

Dr. JAMES THORINGTON, Philadelphia, said that the Committee on Trachoma had made a big step in the right direction in attempting to isolate these cases.

Mr. C. F. CAMPBELL, General Secretary of the Pennsylvania School for the Blind, said that if the voters could be made to realize how much each case of the disease cost the public to maintain they would insist upon proper efforts to stamp it out. He and others were trying to get the laymen to back the physicians up.

Dr. FRANKLIN said that another way in which persons with trachoma got into the United States was by shipping as sailors on vessels bound for Jamaica, and then deserting when these fruit steamers reached the United States. Any physician failing to report the disease was, he stated, subject to a fine of fifty dollars.

A Case of Detachment of the Retina Successfully Treated.—Dr. GEORGE B. JOBSON, JR., Franklin, said that the retina was detached in its lower and anterior part. Sclerotomy with puncture of the retina was performed. The patient was then put to bed, and received normal salt solution hypodermically once a day, and dionin locally three times a day, alternately for three weeks. The retina was then found reattached.

Dr. E. B. HECKEL, Pittsburg, spoke of the fact that this patient had been treated by an optician first, her glasses being changed without benefit, when she should have been referred at once to the oculist. He thought that one should remember that in this condition there may be a neoplasm behind the retina, shoving it forward. The fact that some cases of spontaneous reattachment had occurred would lead him to be careful about thinking that cure was the result of any particular method of treatment.

Dr. JOBSON said that he had used normal salt solution for the injections because he thought that a stronger solution might cause severe pain. He thought that it might act by endosmosis, increasing the vitreous tension, and in that way keeping the retina in its place by pressure.

Critical Observations on the Ehrlich-Hata Treatment.—The laity are demanding treatment for all forms and stages of syphilis as a result of the newspaper notoriety of the treatment but the physician must apply it only upon strictest indication, viz., cases of severe type, especially those refractory to mercurials; cases with mercurial intolerance; cases which relapse after or during mercury cure; incipient cases, before the roseola appears, and cases never treated with mercurials, etc. The arsenobenzol remedy may be used in combination with other specific treatment in suitable cases. Finally, the use of the remedy in parasyphilis must be made a matter of careful experiment.—*Berliner klinische Wochenschrift.*

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Twentieth Annual Convention, Held at Saratoga Springs, September 13, 14 and 15, 1910.

THOMAS D. CROTHERS, M.D., OF HARTFORD, CONN., PRESIDENT.

Report on Direct Continuous Currents, Including Electrolysis, Electrochemical Surgery, Ionization, and All Apparatus Connected Therewith.—Dr. G. BETTON MASSEY of Philadelphia said that the question of the value of zinc-mercury ions or copper-mercury ions in the treatment of obstinate sinuses had arisen in connection with three cases in his hands during the past year. In one case temporary benefit was shown, but the condition later proved to be malignant. In a case of sinus of the abdominal wall the treatment was moderately effective, but the patient did not persist in the treatment and was later operated upon. Better results were obtained in treating a case of rectal fistula.

Report on Phototherapy and Apparatus. — Dr. CHARLES R. DICKSON of Toronto, Canada, said that further observations served to confirm the theory which was now a well-established fact that light rays do penetrate the skin and underlying tissues and exert their influence not alone locally, as when concentrated in the treatment of local lesions even to the point of desiccation and cauterization, but were also taken up by the circulation and induced systemic changes which were not equaled by any other physical agent.

Report on Mechanical Vibration Therapy, Exercise Therapy, and Apparatus.—Dr. FRED H. MORSE of Melrose, Mass., said the committee had found nothing to report this year in the way of new designs of apparatus. A slight canvass made among physicians had shown that vibratory apparatus in use five years ago was still in use.

Report on Hydrotherapy, Thermotherapy, and Apparatus.—Dr. FRANCIS H. MUNROE of Newark, N. J., referred to the detailed report made by this committee in 1908. The report also dealt with the use of hot air currents in certain diseased conditions.

Report on Dietetics.—Dr. BYRON S. PRICE of New York read this report, which gave the present day opinion of authorities in experimental work with regard to foods and their effects when taken into the body, their relation to autointoxication, especially having in view the prevention of arteriosclerosis and allied conditions. The report considered in this relation the physical, chemical, physiological, and pathological conditions of food and of digestion and elimination. Also the scientific explanation why milk, farinaceous, and other foods acted unlike in different conditions, the very important part played by the lactose contained in farinaceous articles, and in milk, differences, etc.

Report on Standardization of Therapeutic Measures.—Dr. WILLIAM B. SNOW of New York said that a survey of the year's progress in physical therapeutics marked a movement toward a more general tendency to the adaptation of rational standardization, away from irrationalism and empiricism. The report discussed the various physical therapeutic measures in detail.

Report of X-Ray Treatment of Splenomyeloid and Lymphoid Leukemia, with Blood Findings in Each.—Dr. J. W. TORBETT of Marlin, Texas, reported two cases, one of each variety, in order to emphasize the importance of observing Pancoast's and Stengel's precautions in treating each class of cases. In the first case the patient died sixteen days after taking the first *x*-ray treatment. It would have been better to treat the arms and legs alone as Pancoast had advised. The second case showed some improvement under *x*-ray treatment.

Psoriasis.—Dr. Herbert McIntosh of Boston read this paper. He reported several cases of psoriasis in which the characteristic eruptions were removed by a combination of physical methods of treatment. In his practice he had usually associated the *x*-ray with the light treatment, in a desire to hasten the cure, though the *x*-ray could probably be dispensed with. One should not fail to counsel hygienic living, proper exercise, and regulation of the diet, excluding meat as being unfavorable to the progress of the cure.

Report on High Frequency Currents.—Dr. Frederic deKraft of New York read this report. He called particular attention to the bipolar utilization of the D'Arsonval current. This could be used in the cavities of the body, for instance, for destroying a papilloma of the bladder; in the nasopharynx, and also for its sterilizing effect on infected tissues, abscesses, pustular acne, etc. As a part of this report Dr. Frederic M. Law of New York detailed experiments that he had conducted to show the bactericidal effect of high-frequency currents.

The Treatment of Inflammation Not Complicated or Caused by Infection.—Dr. William B. Snow of New York read this paper. The systematic proper application of the static current, in the case of a sprained knee, for instance, at the first administration softened the exudation, relieved the pressure and consequently the pain, relaxed muscular tension, and restored motility and utility to the joint. The best means for relieving local inflammations in which infection did not enter as a factor were the application of the static wave current, the static sparks, the static brush discharge, or the direct vacuum-tube static current, singly or conjointly. In prostatitis and seminal vesiculitis the results had been most striking. Also in dysmenorrhea and subinvolution and urethral carruncles Neuritis, herpes zoster, intercostal neuritis, tic douloureux, and Bell's palsy had been successfully treated in the same manner. Other conditions treated in this way were anterior poliomyelitis, rheumatoid arthritis, traumatic arthritis, and phlebitis.

Electricity in the Treatment of Gout.—Dr. Frederic deKraft of New York read this paper. Treatment by drugs had been unsatisfactory. He recommended autocondensation with sufficient D'Arsonval current to produce perspiration. In his experience the pain and stiffness in the muscles were the last to disappear under the usual mode of treatment. The use of a powerful and thoroughly concentrated resonator effleuve accomplished a most valuable purpose by reason of its deep contracting effect on the tissues and the blood vessels. As improvement took place the static brush discharge might be substituted with benefit. Concentrated light was also of benefit. Diet and gentle exercise should not be neglected.

Some Laboratory Findings in Diseases of Metabolism Which Question That These Are Primarily of Metabolic Origin.—Dr. Anthony Bassler of New York discussed the etiology and symptoms of chronic intestinal putrefaction and its treatment. After emphasizing the importance of regulation of the diet, he mentioned his new method of treating such cases by the instillation of live bacteria, grown from the patient's or others' stools, and delivered in billions and trillions into the rectum at intervals of a few days. At the present time he had cases that were being successfully treated with different strains of bacteria.

The Etiology and Treatment of Eczema. — Dr. Herbert F. Pitcher of Haverhill, Mass., read this paper. He believed that the majority of cases were due to some metabolic or vasomotor disturbance, and the most prominent cause of that disturbance was overeating. The hygienic and dietetic treatment should be attended to. The internal treatment was symptomatic. The external treatment of acute eczema should be soothing and protective. The blue light should be used in the early stages, later the *x*-ray and the static brush discharge. The *x*-ray was the most important. It was the most valuable remedy for the relief of the intense pruritus which accompanied the disease. It was the last court of appeal in many cases of the chronic form, and it seldom failed if properly used. In the subacute form and in the vesicular and seborrheic varieties a very low tube should be used, the treatments lasting from ten to fifteen minutes. Where there was much induration the static brush discharge would hasten toward a more rapid resolution. The effleuve from the high frequency currents or from the vacuum tubes was also beneficial in this type.

Osteoarthritis of the Spine.—Dr. Frank E. Peckham of Providence, R. I., described this condition in detail. He emphasized the importance of finding the focus of the trouble and the cause before beginning treatment. Autointoxication was the cause of most such cases. In the treatment of this condition there must be produced elimination of toxic material from the tissues locally and a stimulation of the physiological processes to perform their duties in a more nearly normal manner. This might be accomplished by physiotherapeutic measures, no one modality alone usually giving as much benefit as a combination.

Report of a Case of Splenic Leukemia Successfully Treated by Modern Methods.—Dr. G. W. Strobell of Rutland, Vt., reported this case. Fowler's solution, Blaud's iron mass, and blue mass were used. *X*-ray treatments were made over the spleen, alternating with chlorine cataphoresis, the treatments each day concluding with static insulation. By the end of the fourth week the patient declared she had not felt so well for twenty years. The myelocytes were reduced from 50 to 15 per cent., and the size of the spleen was reduced two-thirds. At the end of the second month the spleen, which had been the size of a man's head, was scarcely to be felt.

Lumbago.—Dr. F. Howard Humphris of London, England, read this paper. Lumbago should be distinguished from the neurotic spine, from sacroiliac disease, from cancer of the spine, cancer of the sarcoiliac notch, from the pain from an enlarged prostate, from the backache which ushered in dengue, influenza, and other conditions of toxic origin, from Pott's disease, and from sacroiliac relaxation. The ideal treatment was to see that the bowels moved freely with mercury and a saline. Sodium salicylate and sodium citrate, of each 20 grains, should be given in a glass of hot water every four, five, or six hours. The 500-candle power light should be applied for fifteen or twenty minutes, followed by the static wave current for the same length of time.

The Treatment of Chronic Metritis with Descent or Displacement.—Dr. G. Betton Massey of Philadelphia read this paper. The form of treatment that he preferred in these cases, when not accompanied by inflammation of the adnexa, was the intrauterine employment of twenty to sixty milliamperes, positive, of the constant current, diffusing copper-mercury ions from the amalgamated electrode for four minutes about twice a week, each application being followed by a strongly contracting induction current from a coarse wire secondary.

The Treatment of Cataract by Electricity. — Dr. Samuel J. Harris of Boston discussed the history of cataract, the anatomy of the lens, the different varieties of cataract, their etiology, and treatment in detail. He reported a number of cases of cataract successfully treated by the direct or galvanic current, a special form of electrode being used over the eye. Mature cataracts were not suitable for this treatment, and he preferred to operate in such cases. But he had had experience in a large number of incipient cases, and many of these he had been able to cure. The subject was still in its infancy, but the rapid

progress so far made encouraged him to continue investigation along this line.

Oscillatory Desiccation in the Treatment of Accessible Malignant Growths and Minor Surgical Conditions.—Dr. William L. Clark of Philadelphia read this paper, drawing the following conclusions: A current from a static machine of large output with properly adjusted accessories is capable of producing desiccation in morbid tissue. We are able to destroy malignant growths without opening up blood or lymph channels. It is possible to get every gradation of current, from the most attenuated to the most intense, producing simple stimulation, desiccation or cauterization. It is obviously a styptic intense in effect, and a sterilizing agent in infected wounds, or following an extensive surgical operation where there is a suspicion of infection or malignancy it would appear to be ideal in instantly sealing up blood and lymph channels. In cancer of the breast where the axillary glands are involved a surgical procedure is indicated, but on the first appearance of recurrence it might be used in arresting further recurrence. It might be used in cancer of the cervix to supersede the curette and cautery as a palliative measure. We can apparently accomplish as much in a few seconds by this method in malignant growths as by the *x*-ray in weeks or months. In disfiguring neoplastic blemishes of the skin we have a potent weapon.

Reactions in Physical Treatments.—Dr. F. H. Morse of Melrose, Mass., read this paper. Physicians doing this work were often confronted with the statement from their patients that they felt worse the next day after treatment, but that they felt much better the second or third day than before treatment. This disturbance was unquestionably due to a sudden liberation of toxins, the lymphatics becoming overloaded before the emunctories could take care of the extra work suddenly thrown upon them.

Remarks on the Electrical Treatment of Interstitial and Hemorrhagic Fibroids of the Uterus.—Dr. G. Betten Massey of Philadelphia read this paper. He said it was our duty to use this method if possible in those patients whom it might save from the risks of an operation. Most important, particularly in the hemorrhagic cases, was the association with the Apostoli treatment proper of the *x*-ray applied through the abdominal wall. From an experience in a number of cases he was convinced that it was a valuable adjunct in large tumors. Its use filled in the time between the all-important intrauterine treatments, shortening the total time required for the treatment.

X-Ray and Light in Infections.—Dr. F. C. Tice of Roanoke, Va., read this paper. He reported a number of cases of hay fever treated with bland oil atomization and an insulated low vacuum high frequency tube to each nostril, with prompt cures, and cases of acute infection treated with the light and *x*-ray.

Infantile Paralysis.—Dr. Almerin W. Baer of Chicago, Ill., drew attention to the prevalence of the disease and to the many cases of deformity and paralysis that continued unrelieved in spite of all treatment commonly employed. He found that contractions and deformity could be relieved and that the muscles would regain their tone and function, even after many years, by the use of the direct current applied to the spine, followed by the static breeze and sparks, treatment being given three times a week for a number of weeks.

Modern Malpractice in Gynecology.—Dr. Arthur W. Yale of Philadelphia, Pa., presented a plea for greater conservatism in gynecological surgery. A few years ago tubes and ovaries were removed indiscriminately where now removal would not be contemplated nor tolerated, but the conservative movement had not yet gone far enough, and such operations were not to be attempted in cases curable by electrical and physical methods of treatment. That much pelvic disease was readily curable by such means was not well appreciated by many surgeons.

Electric Anesthesia in Human Surgery; Electric Sleep by Unipolar and Wireless Currents; Displacement Currents.—Dr. Louise G. Robinovitch of New York gave an account of painless amputation of the toes under local anesthesia due solely to passing through the leg a constant current of low amperage and low voltage interrupted 10,000 times per minute. The patient had no uncomfortable sensation. The speaker described experiments in which she could at will cause strong contraction in specimens of muscle from a frog placed at a distance and without any connection with the instrument. Again, by wireless methods animals were caused to continue asleep for several hours and as long as the wireless current was being generated.

A Noteworthy Case of Sciatica.—Dr. J. Willard Travell of New York gave the full history of a case of sciatica of nine months' duration, which during the last three months received constant and thorough treatment in one of the large hospitals along the usual lines without appreciable improvement. Sedatives were given regularly at night and the patient could not sleep. Treatment was begun with light, the static wave current, and static sparks on the third day after leaving the hospital, and all medication was stopped. The patient was able to sleep in bed after the third treatment and was entirely and permanently relieved of all pain after the seventh treatment, treatments being given daily.

The Physics of Light Therapy.—Dr. Thomas D. Crothers of Hartford, Conn., gave an exhaustive study of the theories of light, of the many forms and modifications of light, and of the diverse ways in which light was utilized in the treatment of disease.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Regular Meeting, Held October 7, 1910.

Dr. Willy Meyer, Chairman pro tem.

Aneurysm of the Common Carotid.—Dr. J. C. A. Gerster presented a woman, sixty years old, who had been in this country but a few years and from whom it was difficult to get a good history. She was married and had had several children, a number of them dying of tuberculosis. It was not possible to get anything suggestive of any specific trouble. The patient had suffered no inconvenience from her aneurysm and came to the dispensary because of scabies. An interesting feature of the case was the presence of a complete heart block, the number of beats falling to 50 and lower.

Diverticulum of the Esophagus Cured by Operation.—Dr. Edward W. Peterson presented a man, forty-eight years old, a Russian. His family history was negative. His trouble began eleven years ago when he had slight dysphagia and regurgitation of food. His trouble in swallowing became worse and, about five years ago, he was admitted to the Massachusetts General Hospital where a diagnosis of stricture of the esophagus was made and a gastrostomy proposed but refused. Last July he found difficulty even in swallowing water, and he applied for admission to the Post-Graduate Hospital. A fullness was found in the upper end of the sternum and he regurgitated food that had been taken several days before. He regurgitated more during the night than during the day. When the esophagus was examined with a bougie an obstruction was found about nine inches from the incisor teeth. After giving the patient bismuth and apple sauce he was fluroscoped. A pouch was found which contained about four ounces; when the patient regurgitated, less difficulty was found in getting some of the fluid into the stomach. An

operation was proposed and performed. The patient was out of bed on the second day following, and left the hospital on the eleventh day. Before operation he weighed 147 pounds; on the day out of bed he weighed 139 pounds; he now weighed 173 pounds.

Dr. De Witt Stetten said that in May, 1909, he operated upon a similar case and had presented the patient before the Section one year ago. The diverticulum was exposed and removed and the patient was in perfect health to-day, free of all bad symptoms. When he first published this case he said he advocated doing a preliminary gastrostomy as being a safe method of attacking these sacs; but since he learned of Dr. Peterson's case, and had read of Dr. Charles Mayo's cases, he was not now so keen about gastrostomy.

Dr. A. V. Moschcowitz referred to the technique in operations upon the esophagus, especially when the operations were done for the removal of foreign bodies. There was great danger of leakage and he warned against the use of gauze in the wound for drainage.

Dr. R. H. M. Dawbarn advocated closing the esophageal wound and then feeding the patient by rectum and skin; he did not even allow water to be swallowed. When there was such a complete rest to the parts he did not believe that leakage could occur.

Dr. Edward W. Peterson said that he used the cigarette drain but did not introduce it so that it would touch the line of sutures. He gave his patients nothing by the mouth until the third day; they were fed entirely by rectum. Semi-solid food was given about the fifth day.

Cases of Inguinal Hernia.—Dr. A. V. Moschcowitz presented three cases of inguinal hernia that had been cured by operation. The interesting feature in these patients was that all were old men with very large hernias, the hernial opening in each instance permitting the entrance of the closed fist. One man had such an enormous hernia that he could only be made comfortable at night by using a sheet which he used as a sling to support his hernial contents, the bed post acting as the base for support.

Case of Stricture of the Esophagus.—Dr. Willy Meyer presented a boy upon whom he had operated six years ago. The child had swallowed lye and was brought to the hospital and admitted. The introduction of silk thread by way of the mouth was comparatively easy in adults, but very difficult in young children. In this instance, however, he succeeded in passing the filiform. It was much easier to catch the filiform with forceps when the stomach was filled with water than with air. The child made a complete recovery. He was now nine years of age, and was operated on when he was but three. To-day he could swallow nicely. In such work Dr. Meyer said that one should use care and not injure the mucosa of the mouth or stomach. Continuous swallowing on the part of the patient did not permit the stricture to recur.

Result After Eight Years Implantation of Silver Filigree for Large Ventral Hernia.—Dr. Willy Meyer presented a woman, fifty-three years old, upon whom he had operated March 1, 1900. In 1894, a vaginal hysterectomy was performed for myoma. Five weeks later, bilateral oophorectomy. After another month, extirpation of the left kidney on account of ureterovaginal fistula. Soon after being out of bed, a ventral hernia appeared at the site of the median incision. A radical operation was performed with a good result. When she came under Dr. Meyer's care in 1900 she weighed 250 pounds and had an enormous irreducible omento-intestinal hernia, with the aperture about midway between the symphysis and the umbilicus. Surgical help was demanded. This hernia had been pronounced by several surgeons as being inoperable. With the patient in the Trendelenburg position reduction of the hernia was accomplished with difficulty. The aperture was found to be round and larger than the palm of the hand. Autoplasty was out of the question. In order to shut out the peritoneal cavity, the omentum was drawn down tautly and stitched to the peritoneum near the border of the gap. The parictal peritoneum was then closed on top of the omentum. There was primary union throughout. Five months later, however, she vomited severely and felt something give away at the hernial orifice. On June 29, 1901, an operation was performed. The omentum had torn loose from the right lower circumference of the aperature. Reduction of the intestines was done and the omentum was again stitched to the border. After sufficient undermining of the subcutaneous fat layer, a ready-made silver filigree pad, four by six inches, was placed upon the defect. It rested upon the omentum and adjoining abdominal wall, where it was stitched to the underlying fascia. The wound soon closed and had remained so up to date. In view of her weight (250 pounds) it was thought best to keep her on her back for eight weeks. The rupture had been radically cured. The wire pad caused her little discomfort. A little over three months after this operation, while washing dishes, she struck the region of the protected hernial opening against the corner of the sink. A sudden, intense pain almost made her faint. She must have torn the continuous suture at the time, causing one of the corners of the well fastened filigree pad to come loose. Now there could be felt a slight omental protrusion. Nevertheless, the patient felt well and experienced little discomfort from this cause. Dr. Meyer intended to reopen the scar and repair the defect.

Silver Wire and Linen Thread for the Cure of Hernia.—Dr. Joseph Wiener said that to Goepel belonged the credit of having first made use of the ready-made filigree. The filigree should be so pliable that it would bend with respiratory movements. The meshes should not be too close and the wire should not be too heavy. Why there should be a sentimental objection to putting a so-called foreign body into the wound, in the shape of silver sutures or a filigree, he had never been able to understand. And why some men preferred to do most extensive plastic operations for the cure of herniæ, which often failed to give a permanent cure, in place of the simple and reliable procedure of using a filigree, it was hard to understand. If the proper wire was used, if the filigree was properly made, and if it was properly introduced, it would very seldom become necessary to remove it. During the past eighteen months chromic catgut for use in hernia cases had been entirely discarded. Catgut, no matter how prepared, was not safe to use. He called attention to a material which was easily prepared, which was always sterile, which was never quickly absorbed, and with which the knots never opened spontaneously, namely, Pagenstecher linen. He had used this in over one hundred operations, most of them herniotomies, without a recurrence. The linen was wound on glass spools, boiled for fifteen or twenty minutes, and preserved in 95 per cent. alcohol. Hernias formed so large a proportion of the surgical cases, and yet it seemed that they did not receive as much thought and study as they deserved. Dr. Wiener asked if it was not time to call a halt on the promiscuous use of chromic gut in herniotomies. Had they not been worshipping a fetich too long? The startling number of immediate recurrences after the Bassini operation with chromic gut were surely worthy of consideration. They could not be argued away. The following conclusions were offered: (1) Chromic catgut was an unreliable suture material. (2) Pagenstecher linen was an excellent suture material. (3) Silver wire, in some form, was a very desirable suture material in many recurrent cases; and at primary operations where the tissues were poorly developed. (4) Immediate re-

currence, in uninfected cases, was usually due to chromic gut. (5) There would occur fewer recurrences if chromic gut was entirely discarded.

Dr. R. H. M. Dawbarn said that in the large hernias there was trouble in reducing the contents, and when reduced the patient was very uncomfortable as a rule.

Dr. Charles Goodman disagreed with the statement that linen thread was the best material in these cases.

Dr. Franz J. A. Torek said that he operated upon patients with inguinal hernia by a method of his own. The introduction of the silver wire was not such an important point, but merely a side issue. He had been using it for seven years and was convinced that its use was not objectionable. He had not used the filigree in any case; his experience made him believe that the use of the filigree was not desirable; he had already removed three ready made filigrees. In one instance there had occurred a break in the ready made filigree and a point stuck through the skin; in the other two cases there had occurred a recurrence of the hernia through the middle of the filigree. In all three cases attempts at reduction of the hernia were accompanied with much pain. With regard to the cause of the rupture of the filigree he said it should be remembered that the filigree was not pliable, and that it was introduced into a body which changed in shape a great deal and, therefore, it seemed that it must sooner or later break. An important part of a well constructed filigree was that it should be made of thin wire and be very pliable.

Dr. A. V. Moschcowitz limited his remarks to inguinal hernia, the use of linen thread and the silver cable. He said that he was very orthodox regarding the use of, and continuing the use of chromicized catgut. Personally he had operated upon a large number of cases of hernia and was perfectly well satisfied with his results in the cases that he had been able to follow. On the contrary he was heretic enough to say that the Bassini operation was not at all satisfactory. Kocher did not employ the Bassini method at all. After studying the results of this operation here and abroad one would find a large number of recurrences. Kocher did his own operation, merely tying off the sac. It was a mere ligation of the sac.

Dr. Robert T. Morris asked what the result would be in those cases in which linen thread was used if an infection happened. He said he had used the silver filigree and he had seen two or three cases in which it became necessary to close sinuses. Some of them did close after injecting pure carbolic acid followed by alcohol. Nevertheless this represented one of the undesirable features of an unabsorbable suture material. He asked what became of the linen thread in those cases in which infection occurred. Concerning the chromicized catgut, he said he would like to feel that it was a reliable suture material but he agreed with the reader of the paper that it was better to turn to the kangaroo tendon or its substitute. This material lasted a long time in the tissues, was remarkably benign, and seemed to possess no irritating qualities.

Dr. Willy Meyer said that the case he showed was the second of its kind on this side of the Atlantic. He had little occasion now to make use of the filigree or other foreign material. Silver wire he thought to be preferable to the filigree. He preferred the autoplastic operation in cases in which it could be used. The method used in the case presented was for the inoperable cases only.

Dr. Joseph Wiener said that the filigree he made would give and would never break when properly made. He had one patient who was performing severe physical labor and had worn the filigree without inconvenience five or six years. It took him about ten minutes to construct the filigree. It should not have any rim. One should be careful in suturing not to draw the sutures too tight, and simply make an approximation of the edges. He did not believe that silk was as good a suture material as linen; he had seen a great many instances in which the silk thread had to be removed, and in only one case did he have to remove linen thread. He believed that the published reports regarding the number of recurrences following the Bassini operation had been underestimated. It was not right to compare the results of operations done on children with those done on adults. In the former the recurrences were not more than two per cent. while in the latter they were about eight per cent. As time went on he believed that chromic catgut would have to give way to linen thread. With regard to what occurred when infection took place, in one hundred cases in which the linen thread was used this occurred in but one case; here there was a fat necrosis and he was compelled to remove the linen thread, which was done with eucaine as the local anesthetic. He had so little experience with infections when linen thread was used that he could not answer the question raised by Dr. Morris. When kangaroo tendon or its substitute was used, vomiting or coughing might open the knots; this would not happen if linen thread was employed as a suture material.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

South Carolina State Board of Medical Examiners.

June 14, 15, *and* 16, 1910.

ANATOMY.

1. Name the bones of the lower extremity.
2. Name the muscles that rotate the eye.
3. Give origin and distribution of the pneumogastric nerve.
4. Locate the liver, with its relations.
5. Give the divisions and termination of brachial artery.

SURGICAL ANATOMY.

1. Name the various boney prominences or landmarks which are easily felt and recognized in the head and face which afford the means of mapping out the important structures comprised in this region.
2. Of what importance would ossification in the epiphyseal end of the femur be if found in a dead child? Why should we preserve the epiphysis in excision of the knee?
3. Where is congenital dislocation most often found? Name location of displacement. How recognized?
4. Which is the most common form of strabismus? What muscle requiring division?
5. Why is thecal (or sheath) abscess of the thumb and little finger usually followed by abscess of the forearm? What precaution should be taken in amputation of the fingers?
6. Of what importance is the fibrous septum between the two halves of the tongue?
7. In fracture of the neck of the femur internal to the capsular ligament, what produces eversion? What produces shortening?
8. Where is the subclavian artery best compressed? Where best ligated, and line of incision?
9. What condition found in paralysis of ulnar nerve?
10. What marked symptom do you have in paralysis of the musculospiral nerve?
11. What regions of the eye are called filtration area and dangerous area, and why?
12. Why do we use the Trendelenburg position (head and body lowered)? Why do we use the Fowler position (head and body elevated)?

PHYSIOLOGY.

1. Name the uses of the blood.
2. Causes of the first and second sounds of the heart.
3. What result would follow extirpation of the thyroid gland?
4. What is ptyalin, and describe its action.
5. What are the functions of the skin?

HYGIENE AND STATE MEDICINE.

1. State what constitutes a good drinking water, and state the diseases transmitted by drinking water.
2. What effect has alcohol on the temperature?
3. What are the injurious effects of the excessive use of tobacco?

4. Give amount of air space that should be allowed per head in sleeping apartments.
5. Period of incubation of smallpox, yellow fever, and parotitis.
6. What hygienic and sanitary precautions should be taken to control spread of uncinariasis?
7. (*a*) Plague (bubonic plague); period of incubation and general measures to be taken for prevention of same. (*b*) Cholera; incubation, etiology, and means of prevention.
8. Under what conditions have beriberi developed, and what hygienic measures should be taken to control same?
9. What effect has altitude on respiration?
10. Define a disinfectant. Name three, and give a recognized method of fumigating a room.

MATERIA MEDICA.

1. What would be a cathartic dose of calomel, and its physiological effect?
2. Dose of sulphate of morphine, with physiological effect.
3. Dose of elaterium, and physiological effect.
4. Name two vasodilators, with dose of each to effect.
5. Name two vasoconstrictors, with dose of each to effect.

THERAPEUTICS.

In treating the following diseases, give dose and frequency of drugs used, with their physiological effect. If other methods than drugs are used, mode and physiological effect.

1. Typhoid fever. 2. Scarlet fever. 3. Chronic malaria. 4. Erysipelas. 5. Dysentery, acute catarrhal. 6. Rheumatic fever. 7. Peptic ulcer. 8. Enterocolitis of infants. 9. Cholera infantum. 10. Acute nephritis.

CHEMISTRY.

1. Define physical change and chemical change. Give familiar example of each.
2. What is the chemical relation between animals and plants? Which performs the office of reduction? Which of oxidation?
3. What is a chemical formula? What part of a compound does a formula represent? Give formula for the following: Hydrogen peroxide, common table salt, lunar caustic, aqua fortis, oil of vitriol.
4. In what two ways can electricity be produced? Give illustration of each.
5. What is the difference between galvanic and faradic electricity?

PRACTICAL URINALYSIS, MICROSCOPY, AND TOXICOLOGY.

1. What is the specific gravity of normal urine? What condition would continued low specific gravity indicate? What continued high specific gravity?
2. What is the average amount of urine voided in twenty-four hours? What conditions may vary this amount?
3. How would you make a chemical analysis of the urine for life insurance?
4. How would you make a microscopical examination of the urine?
5. What is the difference between a simple and a compound microscope?
6. How does the knowledge of microscopy aid in practical diagnosis?
7. Under what two heads may poisons be classed? Give an example of each.
8. Give symptoms and chemical antidote for opium poisoning.
9. Give symptoms and chemical antidote for acute silver nitrate poisoning.
10. Name and describe the condition which the continued use of silver nitrate as a drug is liable to produce.

BACTERIOLOGY AND PATHOLOGY.

1. Describe briefly the bacillus of tetanus; modes of infection, and best methods of prevention.
2. Describe briefly the bacillus typhosus. Name sources of infection, sources of elimination, and what is meant by typhoid carrier.
3. Give pathology of lobular pneumonia.
4. Describe the pathology of interstitial nephritis, and give the most common accompanying pathological conditions.
5. Give the symptoms, pathology, and termination of inflammation.

MEDICAL JURISPRUDENCE.

1. Give the symptoms of chronic cocainism.
2. Give dose of bichloride of mercury and symptoms of acute poisoning by same.
3. Describe post-mortem findings in acute poisoning by Paris green.
4. Define illusion, hallucination, and delusion, and what is meant by delusion of persecution.
5. In a case of suspected infanticide, how would you determine whether infant was born alive?
6. What conditions influence time of appearance and disappearance of rigor mortis, and what is meant by cadaveric spasm?
7. How would you determine whether a wound was received before or after death?
8. Give the usual causes of death in cases of burns.
9. What conditions simulate death, and what are the most important certain signs of death?
10. What precautions would you observe in submitting stomach and contents for analysis?

PRACTICE OF MEDICINE.

1. Give a description of herpes zoster, mentioning the diseases with which it may be confounded and their diagnostic differences, and give the treatment of an acute case of the affection.
2. What are the causes, signs, and symptoms of a dilated right heart? Describe the remedial measures you would recommend.
3. Discuss the clinical significance of pain at the epigastrium.
4. In what diseases may pus occur in the urine? What treatment would you recommend in diseases mentioned?
5. Describe a case of Bell's paralysis.
6. Mrs. A., aged 30, has had a temperature for ten days ranging from 100° in A.M. to 103° in P.M. There are no clinical symptoms or signs of disease except the continuous temperature. What diseases would you consider in making a diagnosis? Give briefly these diagnostic differences.
7. What are the causes, symptoms, and treatment of ptomaine poisoning?
8. Describe an ordinary case of measles.
9. Discuss the clinical significance of a convulsion occurring in a child under two years old.
10. (*a*) At what age would you expect an infant to commence to cut teeth? What are the causes of delayed dentition? (*b*) A child two and a half years old has never walked. How would you investigate this case to find out the reason for his not walking?

OBSTETRICS AND GYNECOLOGY.

1. Give the signs of pregnancy and the differential diagnosis of pregnancy.
2. Define podalic version, give indications for, and describe technique.
3. Give symptoms of toxemia of pregnancy, prophylaxis of, and treatment of.
4. Give symptoms of threatened abortion and of inevitable abortion, and treatment of each. Also treatment of incomplete abortion.
5. Give the diagnosis, symptoms, and treatment of placenta prævia before labor and after labor had commenced.
6. Give the diagnosis of L. O. A. and L. O. P. presentations.
7. Give the diagnosis of face presentations and varieties and prognosis.
8. Give and explain the methods of examining the uterus.
9. Name and describe the various displacements of the uterus and the common symptoms produced by each.
10. Mention the causes of cystitis in a woman and the treatment.

SURGERY.

1. What are the indications for trephining? Describe the operation.
2. Describe ligation of the brachial artery in the middle of the arm.
3. How would you treat a compound fracture of the lower third of radius and ulnar when one or more tendons are severed?
4. Empyema: Diagnosis and operative treatment.
5. Carbuncle: Definition, progress, and treatment.
6. Inguinal hernia: Differentiate between oblique and direct; describe radical cure of oblique variety.
7. Stone in the bladder: Diagnosis and operative treatment.
8. Shock: Definition, symptoms. How would you prevent shock in operations?
9. Gangrene: Definition, cause, and treatment.
10. Give the several steps in the operation of amputation of the thigh at the junction of upper and middle third.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

SOUTH CAROLINA STATE BOARD OF MEDICAL EXAMINERS.

June 14, 15, *and* 16, 1910.

ANATOMY.

1. Os innominatum (ilium, ischium, and os pubis), femur, patella, tibia, fibula, os calcis, astragalus, cuboid, scaphoid, external cuneiform, middle cuneiform, internal cuneiform, five metatarsals, and fourteen phalanges.

2. Rectus superior, rectus inferior, rectus internus, rectus externus, obliquus superior, and obliquus inferior.

3. PNEUMOGASTRIC NERVE. *Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric.

4. See Cunningham's "Anatomy" (1909), page 1109; or Gray's "Anatomy" (1908), page 1334.

5. See Cunningham's "Anatomy" (1909), page 830; or Gray's "Anatomy" (1908), pages 655 and 657.

SURGICAL ANATOMY.

1. Nasion, glabella, inion, lambda, external angular process, parietal eminence, external auditory meatus, zygoma, mastoid process.

2. The importance of ossification of the epiphyseal end of the femur is that by it we can be aided in determining the age of the child. In excision of the knee it should be preserved, because it is here that the greatest amount of growth in the length of the bone occurs.

3. Congenital dislocation occurs most often in the hip joint. The displacement is usually on to the dorsum of the ilium. It is recognized by the waddling gait and extreme lordosis.

4. Convergent strabismus is the most common. The internal rectus muscle should be divided.

5. See Gray's "Anatomy" (1908), pages 494 and 486.

6. The fibrous septum often limits an acute inflammation or abscess to one-half of the tongue; in the anterior half of the tongue the lymphatics do not communicate across the septum, and so in malignant disease of the tongue, when not extensive and when confined to one side of the anterior half of the tongue, may be removed by a hemisection of the tongue.

7. In fracture of the neck of the femur, internal to the capsular ligament, "the *shortening* is brought about by the glutei, the hamstrings, the tensor vaginæ femoris, the rectus, sartorius, and iliopsoas, the adductors, gracilis, and pectineus. The *eversion* is mainly due to two causes: (1) The weight of the limb, which causes it to roll outwards, as is seen in persons insensible or asleep, the line of gravity passing through the outer part of the thigh; (2) the fact that the compact tissue on the posterior aspect of the neck is much more fragile than that on the anterior aspect. Thus the cervix is often more extensively fractured behind than in front, or the fracture may be impacted behind but not in front, and in either case the limb will tend to become everted. As a third cause may be mentioned the action of the iliopsoas, the adductor and pectineus muscles, and of the small rotator muscles, all of which tend to roll the femur outwards."—(Treves' *Surgical Applied Anatomy.*)

8. The subclavian artery is *best compressed* where it passes across the upper surface of the first rib; pressure is to be made at the outer border of the sternomastoid and just above the clavicle. It is *best ligated* in its third portion. The *line of incision* is transversely over the clavicle, from the anterior border of the trapezius to the posterior border of the sternomastoid, and with its center about one inch internal to the center of the superior border of the clavicle.

9. In *paralysis of the ulnar nerve* "there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction of the hand; there is inability to spread out the fingers from paralysis of the interossei; and there is inability to adduct the thumb. The fingers cannot be flexed at the first joints, and cannot be extended at the other joints. A *claw-hand* develops, the first phalanges being overextended and the others flexed. Sensation is lost or impaired in the skin of the ulnar side of the hand anteriorly and posteriorly, involving the little finger, the ring finger, and the ulnar half of the middle finger posteriorly, and anteriorly involving the little finger and the ulnar half of the ring finger."—(Gray.)

10. The marked symptom in paralysis of the musculospiral nerve is *wrist-drop* (the hand is flexed at the wrist, and lies flaccid).

11. "The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The *dangerous area of the eye* is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other."—(Gray.)

12. In the lymphatics of the peritoneum those of the diaphragm are more rapid in absorption than those of the pelvis. Hence to stimulate, the patient should have the foot of his bed raised (Trendelenburg position), so that the fluid (salt solution) may be conveyed more readily to the diaphragm, where absorption is more rapid. To retard the too rapid absorption of pus in the abdominal cavity, the head of the bed should be raised so that drainage may be directed toward the pelvis, where absorption is slower (Fowler's position).

PHYSIOLOGY.

1. USES OF THE BLOOD. The *red corpuscles* carry oxygen from the lungs to the tissues.

The *white corpuscles* (1) serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

The *plasma* conveys nutriment to the tissue; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

2. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

3. *After extirpation of the thyroid gland:* The face becomes white, puffy, and loses all expression; the mental and intellectual faculties become dulled, and may terminate in idiocy; the heart becomes slowed, blood pressure lowered; body temperature may be subnormal; albuminuria and dyspnea may be present; the puffiness of the face extends to the neck and supraclavicular fossæ; the tongue is enlarged, and speech is slow and measured; the extremities become enlarged and movements are slow, labored, and clumsy.

4. *Ptyalin* is a ferment found in the saliva. Its action is to convert starches into dextrin and sugar in an alkaline medicine.

5. The *functions of the skin* are: Protection, excretion, secretion, regulation of the body temperature, absorption, sensation, special sense of touch, respiration.

HYGIENE AND STATE MEDICINE.

1. *Characteristics of a good drinking water:* (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water.—(From Bartley's *Chemistry.*)

Diseases which may be transmitted by drinking water:

Typhoid, cholera, dysentery, diarrhea, indigestion, goiter, vesical calculi, intestinal worms, lead poisoning.

2. *Alcohol* if applied to the skin, evaporates quickly and cools the surface. Taken internally, it first slightly raises the body temperature and later on it lowers it.

3. "The continued use of tobacco, by smoking or chewing it to *excess*, produces granular inflammation of the fauces and pharynx, atrophy of the retina, dyspepsia, lowered sexual power, sudden faints, nervous depression, cardiac irritability, and occasionally angina pectoris. Used by the young, it hinders the development of the higher nerve centers and impairs the nutrition of the body by interfering with processes of digestion and assimilation."—(Potter's *Materia Medica*, etc.)

4. One thousand cubic feet of space should be allowed each adult, with provision for ventilation.

5. Period of incubation of *smallpox* is about twelve days; of *yellow fever*, about two to five days; of *parotitis*, about fourteen days.

6. *Prophylaxis of uncinariasis* consists in: (1) Boiling the drinking water; (2) washing of the hands before meals; (3) not going barefooted; (4) disinfection of the stools of all infected persons.

7. See French's "Practice of Medicine" (1907), (*a*) pages 284 and 287; (*b*) pages 292, 289, and 295; or Osler's "Practice of Medicine" (1909), (*a*) page 242; (*b*) pages 230, 228, and 232.

8. See French's "Practice of Medicine" (1907), pages 412 and 416.

9. *At an altitude*, inspiration becomes deeper, owing to the need for air, which cannot be satisfied with normal inspiration; inspiration is also more difficult; expiration is easier and quicker; the number of respirations per minute increases; the percentage of CO_2 in expired air is increased.

10. *Disinfectants* are agents which restrain infectious diseases by destroying or removing their specific poisons. *Three:* Sulphur dioxide, chlorine, and formaldehyde.

To *fumigate by sulphur dioxide:* For each 1,000 cubic feet of space, three pounds of sulphur are burned, care being taken to prevent accidents. In all cases all apertures and crevices of the room should be closed, all closets, drawers, or other receptacles opened; and after the fumigation the room should be well ventilated and thoroughly cleansed with a solution of corrosive sublimate.

MATERIA MEDICA.

1. Cathartic dose of calomel is about five grains. *Physiological effect* is increased peristalsis, increased secretion of intestinal glands, and stimulation of the liver.

2. Dose of sulphate of morphine is gr. 1/8 to 1/6. *Physiological effect* is analgesic, hypnotic, diaphoretic, narcotic; at first it stimulates brain, heart, and respiration; afterwards it depresses them.

3. Dose of elaterium is 1/10 grain of *elaterin*. *Physiological effect* is the production of profuse, watery stools; also much prostration, and nausea, and gastrointestinal irritation.

4. *Two vasodilators:* Nitroglycerin, dose (of spirit), ♏j; and amyl nitrite, dose (by inhalation), ♏iij.

5. *Two vasoconstrictors:* Ergot, dose (of fluid extract), ♏iv; adrenalin chloride, dose (of solution), ♏vij.

THERAPEUTICS.

1. See French's "Practice of Medicine" (1907), page 112; or Osler's "Practice of Medicine" (1909), page 90.

2. See French's "Practice of Medicine" (1907), page 324; or Osler's "Practice of Medicine" (1909), page 138.

3. See French's "Practice of Medicine" (1907), page 248; or "Osler's "Practice of Medicine" (1909), page 24.

4. See French's "Practice of Medicine" (1907), page 221; or Osler's "Practice of Medicine" (1907), page 213.

5. See French's "Practice of Medicine" (1907), page 258; or Osler's "Practice of Medicine" (1907), pages 6 and 246.

6. See French's "Practice of Medicine" (1907), page 230; or Osler's "Practice of Medicine" (1907), page 226.

7. See French's "Practice of Medicine" (1907), page 751; or Osler's "Practice of Medicine" (1909), page 477.

8. See French's "Practice of Medicine" (1907), page 785; or Osler's "Practice of Medicine" (1909), page 500.

9. See French's "Practice of Medicine" (1907), page 783; or Osler's "Practice of Medicine" (1909), page 511.

10. See French's "Practice of Medicine" (1907), page 895; or Osler's "Practice of Medicine" (1909), page 600.

CHEMISTRY.

1. A *physical change* is such a change as does not alter the composition of a substance; a *chemical change* does alter its composition.

"A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism when under the influence of an electric current. Under the influences of these *physical forces* the iron suffers no change in composition, and, on cessation of the action of the inciting force, the iron returns to its original condition. But if the iron be heated in an atmosphere of oxygen both the iron and a part of the oxygen disappear, and a new substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action*, causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action."—(Witthaus' *Manual of Chemistry*.)

2. In *vegetable life* the metabolic changes are chiefly synthetic; the plant absorbs water and carbon dioxide, liberates oxygen, and builds up complex substances.

In *animal life* the metabolic changes are chiefly analytic; the animal takes as food complex substances and splits them into simpler substances.

Plants perform the office of oxidation; animals, that of reduction.

3. A chemical formula is a collection of symbols (and figures) used to denote one molecule of a chemical compound. Hydrogen peroxide. H_2O_2; common table salt, NaCl; lunar caustic, $AgNO_3$; Aqua fortis, HNO_3; oil of vitriol, H_2SO_4.

4. *Static electricity* is produced by friction; *galvanic electricity* is produced by chemical action in a galvanic cell.

"*Static* or *frictional electricity* is generated for practical purposes by an electric machine, consisting essentially of a plate or wheel of glass, or some similar substance, revolved by a mechanical contrivance against some material capable of producing positive electricity on the plate. This positive charge is carried from the plate by metal combs or rods to the prime conductor; the negative generated on the rubbing cushions may be collected on a conductor, but is generally carried to the ground by a chain."

Galvanic electricity: "Zinc placed in a vessel containing dilute sulphuric acid is gradually dissolved, evolving hydrogen gas. Platinum is not acted on by dilute sulphuric acid. If plates of both metals be placed in sulphuric acid and water, and connected by a piece of wire as a conductor no bubbles of gas are evolved on the zinc, but escape from the platinum plate. If the wire be placed near a magnetic needle this will be turned from its course (deflected); when the ends of the divided wire touch the tongue a tingling and metallic taste are perceived. All these phenomena disappear if the connection between the plates is broken, and reappear when restored, and are manifestations of electricity generated by the action of the acid on the metals, traveling through the wire to which it imparts its properties. The zinc, platinum, and sulphuric acid may be replaced by many other materials. Electricity will be generated whenever two solid conductors, usually in plate or cylinder form, are connected by a conductor, and placed in a liquid having the power of acting chemically on one of them. Such an arrangement is called a voltaic or galvanic cell; the liquid the electrolytic or exciting agent; and the solids the electrodes; and all are called the elements of the cell. In a galvanic cell the electrolytic agent is split into two parts, called ions; and these ions, charged with + and — electricity, respectively, unload the charges on the plates. The conductor restores the electrical equilibrium. In the zinc, platinum and sulphuric acid cell the acid is split up into hydrogen and SO_4, the H_2 escapes from the platinum plate while the SO_4 combines with the zinc, forming zinc sulphate, which dissolves in the water."—(McGlannan's *Epitome of Chemistry*.)

5. The galvanic current is constant and continuous; it always flows in the same direction; it has pronounced chemical and thermal effects.

The faradic current is a rapid succession of momentary impulses; the direction is not constant: the chemical and thermal effects are almost imperceptible.

PRACTICAL URINALYSIS, MICROSCOPY, AND TOXICOLOGY.

1. The specific gravity of normal urine is about 1015 to 1025. Continued low specific gravity might indicate: Diabetes insipidus, chronic interstitial nephritis, or contracted kidney. Continued high specific gravity might indicate: Diabetes mellitus, fevers, or chronic parenchymatous nephritis.

2. The average amount of urine voided in twenty-four hours is about forty to fifty ounces. This amount may be *increased* by ingestion of large amount of liquids, in diabetes mellitus, diabetes insipidus, in granular atrophy

of the kidneys, in hysteria, chorea, or epilepsy. It is *decreased* when the amount of perspiration is increased, in fevers, acute nephritis, chronic parenchymatous nephritis, shock, cardiac disease, after hemorrhages or diarrhea.

3. *An analysis of urine* includes: Estimation of total quantity passed in twenty-four hours, color, odor, reaction, specific gravity, total solids (by aid of Haeser's coefficient). Then examine for albumin by Heller's test, or by heat and nitric acid; then for glucose, by Moore's test, with potassium hydroxide, or with Fehling's solution, which contains copper sulphate, sodium hydroxide, and Rochelle salt; then for blood with potassium hydroxide solution; then for bile pigments by Gmelin's test; then for indican, using lead acetate, hydrochloric acid, ferric chloride, and chloroform. Then quantitatively for urea, using solution of sodium hypobromite; for chlorides, with silver nitrate solution; for sulphates, with barium chloride solution. Microscopical examination should then be made for casts, cylindroids, crystals, and tubercle bacilli.

4. See French's "Practice of Medicine" (1907), page 1202.

5. *A simple microscope:* "With this an enlarged, erect image of an object may be seen. It always consists of one or more converging lenses or lens-systems, and the object must be placed within the principal focus. The simple microscope may be held in the hand or it may be mounted."

A *compound microscope:* "This enables one to see an enlarged, inverted image. It always consists of two optical parts, an *objective*, to produce an enlarged, inverted, real image of the object, and an *ocular*, acting in general like a simple microscope to magnify this real image. There is also usually present a mirror, or both a mirror and some form of condenser or illuminator for lighting the object. The stand of the microscope consists of certain mechanical arrangements for holding the optical parts and for the more satisfactory use of them."—(Gage's *The Microscope.*)

6. A knowledge of microscopy aids in diagnosis: In blood examinations in anemias, chlorosis, leukemias, and malaria; in urinary examinations in nephritis; in Widal's test for typhoid; in examining sputum or urinary sediment for tuberculosis; discharges for tuberculosis, gonococcus, or diphtheria bacillus; cerebrospinal fluid for meningococcus.

7. Poisons may be classed as: (1) True poisons, as strychnine; (2) corrosives, as nitric acid.

8. *Opium poisoning. Symptoms:* In opium poisoning there may be three stages: (1) a period of excitement, in which the patient is active, talkative, and has hallucinations; (2) a period of drowsiness, in which the patient is sleepy, but may be aroused; his face is pale, lips livid, pupils contracted; this passes into (3) the stage of coma, from which the patient cannot be aroused, the reflexes are abolished, the pupils are very contracted, the pulse is slow and irregular, and the respirations are infrequent and shallow.

Treatment consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment, to keep the patient awake; artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter.

There is no antidote.

9. SILVER NITRATE POISONING. *Symptoms:* Pain; vomiting of white, cheesy matter, which becomes black in the sunlight; cramps; purging; depression; convulsions; coma or collapse. *Antidote:* Solution of sodium chloride.

10. The condition is known as *Argyria.* It is characterized by a blue or black discoloration of the skin and mucous membranes; it is due to deposits of silver in the rete, sweat glands, and about the hair follicles, where it becomes black on exposure to sunlight. The pigmentation is permanent.

BACTERIOLOGY AND PATHOLOGY.

1. The bacillus of tetanus is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

Modes of infection: By wounds and abrasions (often slight), and in compound fractures; also by punctured wounds of hands or feet, and wounds in which earth or other foreign matter is driven into the tissues. *Prophyloxis* consists in thorough opening and cleansing of all wounds soiled with earth, or in which foreign bodies are present; also all "Fourth of July wounds."

2. *Bacillus typhosus* is a rod-shaped organism, with rounded ends, is from 2 to 4 microns in length, and about three-fourths of a micron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

Sources of infection: Food, water, flies, fingers. *Sources of elimination:* Feces, urine, skin (in rose spots), and sputum. A *typhoid carrier* is a person who, not having typhoid fever at the time, retains the typhoid bacilli in his system, and excretes it in feces and urine, and so "carries" the disease.

4. See French's "Practice of Medicine," page 902; or Osler's "Practice of Medicine," page 695.

5. See Rose and Carless's "Surgery" (1908), pages 37, 31, 34; or Da Costa's "Surgery" (1908), pages 84, 73, and 83.

MEDICAL JURISPRUDENCE.

1. *Symptoms of chronic cocainism:* "In chronic cases there is much disturbance of digestion, emaciation, insomnia, hallucinations, enfeeblement of mind and general ill health. The symptoms much resemble chronic opium poisoning in many respects. As cocain is sometimes used in a vain effort to cure the morphin habit, it often happens that the symptoms of the two merge into each other so gradually as scarcely to be distinguished. A common symptom during the later stages of cocain poisoning is a sensation as of insects crawling over the surface of the body. Occasionally these cases end in dementia or some form of mania."—(Riley's *Toxicology.*)

2. BICHLORIDE OF MERCURY. *Dose:* Gr. 1-20. *Symptoms of acute poisoning:* "The nauseous, metallic taste is experienced during the act of swallowing. Within a few moments this is followed by an intense, burning pain in the mouth, throat and stomach. The mouth and tongue are whitened and shriveled. There are vomitings of a white material, containing shreds of mucous membrane, and tinged with blood, and bloody stools. Salivation occurs if life be sufficiently prolonged. Death sometimes occurs early from collapse, accompanied by convulsions, or in deep coma; but in most fatal cases life is prolonged for from three to six days."—(Witthaus's *Essentials of Chemistry and Toxicology.*)

3. *Postmortem findings in acute poisoning by Paris green:* "They are confined to the stomach and intestines. The stomach is inflamed, whether As has been taken by the mouth or by other channels of absorption. The mucous surface is coated with a layer of mucus, tinged with blood or bile, and sometimes containing white crystals of As_2O_3 or green particles of Paris green. The color of the mucous membrane is brownish red, interspersed with darker streaks or patches between the rugæ. The small intestines are sometimes inflamed throughout their length, but more usually the inflammation is limited to the duodenum."—(Witthaus's *Essentials of Chemistry and Toxicology.*)

4. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion.* If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion.* If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination.*

A *delusion of persecution* is such a *delusion* in which the patient believes himself to be constantly pursued or tormented.

5. If respiration has taken place, its lungs will float on being put into water; if respiration has not taken place, the lungs will sink. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration, they fill the whole cavity.

6. The onset and duration of rigor mortis depend upon the previous degree of exhaustion. In death from exhausting diseases, there is an early onset, while in those dying suddenly, as from accident, it may be delayed for

twelve hours or more. Its duration is very variable; it is shortened by heat, and prolonged by cold; it generally lasts about twelve to twenty-four hours; in death by lightning or electrocution it may only last a few hours; in other cases, several days.

Cadaveric spasm is a violent muscular contraction often observed in persons who have died violent deaths; it is found in suicides, who have a weapon grasped in their hands; or in drowned persons, with grass or weeds in their hands.

7. A *wound inflicted during life* is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

8. *The usual causes of death in cases of burns* are: Shock, asphyxia, inhalation of flame, and fright.

9. *Death may be simulated* by: Coma, epilepsy, trance. *Signs of death:* Cessation of respiration, absence of heartbeats, insensibility, loss of power to move, change in the eyes, pallor, loss of body heat, rigor mortis, putrefaction, and adipocere formation.

10. The contents should be enclosed by ligatures at the esophagus and duodenum. All is then placed in a *clean* and *new* glass jar, closed with glass or cork cover or stopper. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing-wax gets into the jars.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1907), page 994.

2. See French's "Practice of Medicine (1907), page 599; or Osler's "Practice of Medicine" (1909), page 820.

3. *Pain at the epigastrium* may denote: Neuroses, ulcer, cancer, erosions, or catarrh of the stomach; duodenal ulcer; gastralgia; appendicitis; pancreatic disease; diseases of the vertebræ; pleurisy or pneumonia; and the morphine habit.

4. "Pus in the urine (*pyuria*) is generally due to some acute or chronic inflammatory process present in the urinary tract, such as pyelitis, renal abscesses, cystitis, prostatitis, urethritis (gonorrhœal or simple), and genito-urinary tuberculosis, or it may come from some extraneous source, as the discharge into the urinary canal of the peri-nephritic, pelvic or other origin, or from the bursting of a vulvo-vaginal abscess. Cancer of the bladder or other urinary organs is also a frequent source of pyuria."

For *treatment* see Rose and Carless' "Surgery" (1908); or Da Costa's "Surgery" (1908), in Index, under disease mentioned.

5. See French's "Practice of Medicine" (1907), page 1008; or Osler's "Practice of Medicine" (1908), page 1019.

6. Tuberculosis, and simple continued fever; and see French's "Practice of Medicine" (1907), pages 441, 386, and 368.

7. See French's "Practice of Medicine" (1907), page 965; or Osler's "Practice of Medicine" (1909), page 380.

8. See French's "Practice of Medicine" (1907), page 326; or Osler's "Practice of Medicine" (1909), page 141.

9. See French's "Practice of Medicine" (1907), page 1123; or Osler's "Practice of Medicine (1909), page 1056.

10. (*a*) An infant may be expected to commence to cut teeth at about the sixth month. The *causes of delayed dentrition* are: Rickets, malnutrition, idiocy, and cretinism. (*b*) Possible causes are: Rickets, Pott's disease, cretinism, infantile paralysis, birth palsy, muscular atrophy, hydrocephalus, congenital dislocation of hip. See these diseases in French's or Osler's "Practice of Medicine."

OBSTETRICS AND GYNECOLOGY.

1. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Subjective signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

For *differential diagnosis of pregnancy,* see Williams' "Obstetrics" (1909), page 190; or Hirst's "Obstetrics" (1909), page 204.

2. The *indications for podalic version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother; and (7) in any case where speedy delivery is imperative. And see Williams' "Obstetrics" (1909), pages 432 and 437; or Hirst's "Obstetrics" (1909), page 830.

3. TOXEMIA OF PREGNANCY. The symptoms are: "Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptoms. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions."—(King's *Manual of Obstetrics.*)

"*The prophylactic treatment* consists in frequent and regular examination of the urine. After the first appearance of albumin, daily quantitative examination of the urine should be made. The diet should be milk; the bowels should be kept freely open by means of calomel and salines; the skin should be kept active by hot baths, followed by vigorous rubbing. Diuretics, such as Basham's mixture, digitalis, and caffein, should be administered. During pregnancy, if the percentage of albumin increases in spite of the treatment, abortion or induction of labor is indicated.

"*The treatment of the attack* consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluid extract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5, repeated frequently enough to keep the pulse at about 60 beats a minute), to control the convulsions, and free purgation by croton oil (gtt. 2 or 3 in sweet oil or glycerin), free sweating by the hot pack and sometimes depletion by venesection to eliminate the poison. The after-treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference."—(Gould and Pyle's *Pocket Cyclopedia.*)

4. See Williams' "Obstetrics" (1909), page 617; or Hirst's "Obstetrics" (1909), page 276.

5. See Williams' "Obstetrics" (1909), page 813; or Hirst's "Obstetrics" (1909), page 577.

6. See Williams' "Obstetrics" (1909), pages 254 and 266; or Hirst's "Obstetrics" (1909), pages 395 and 404.

7. See Williams' "Obstetrics" (1909), page 274; or Hirst's "Obstetrics" (1909), page 409.

8. The patient should be free from corsets and constricting bands; the bladder and rectum should be empty. *External palpation:* The patient should be in the lithotomy position, on a suitable table or bed. The examiner stands on one side, and palpates the lower abdomen to determine any enlargement of the uterus. *Vaginal touch:* The examiner separates the labia with the thumb and finger of one hand; and two fingers of the other hand well lubricated are introduced into the vagina. Pressure is made on the perineum until the posterior fornix is reached, when the palmar surfaces are turned forward and the size, position, and condition of the cervix are determined. Then with the palmar surface of the external hand gentle pressure is made on the abdomen and the two hands are approximated. Thus the size, consistency, and position of the uterus are determined. *Rectal examination:* In virgins and in some cases of extreme retroversion one finger

is introduced into the rectum and with the other hand on the abdomen a more satisfactory bi-manuel examination can be made. *Intrumental examination:* In the lithotomy position, by the use of a bi-valve, a tubular or Ferguson speculum, the condition of the cervix can be inspected. This is best accomplished in some cases by use of the Sims position and the Sims speculum. At the same time in rare and selected cases by steadying the anterior lip of the cervix with a bullet forceps the uterine sound may be passed to determine the size and position of the uterus.

9. *The common displacements of the uterus are:* Retroversion, retroflexion, anteflexion, and descent or prolapse. The following symptoms may follow displacements of the uterus: Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be *general symptoms,* as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.

10. Cystitis. *Causes:* Retention of urine, tumors, foreign bodies, calculus, ammoniacal urine, gonorrhea, tuberculosis of genito-urinary tract, pus in the urine.

Treatment: Rest in bed; the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz-bath; irrigation of the bladder with an antiseptic solution; hot fomentation and vaginal douches are often helpful; sometimes intravesical medication is necessary.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 758; or Da Costa's "Surgery" (1908), page 734.

Indications for trephining: "Intracranial hemorrhage; abscess; fracture; foreign body; evacuation of cerebrospinal fluid through the lateral ventricle; as a preliminary step to osteoplastic resection and to linear craniectomy; epilepsy; bullet and other wounds; small tumors; drainage of frontal sinus; drainage of mastoid antrum and cells; thrombosis of venous sinuses."—(Bickham's *Operative Surgery.*)

The Treatment of Leprosy.—R. García Rijo reviews the different treatments of leprosy. In his practice he has employed the oil of chaulmoogra (*Gynocardia odorata*) in capsules and in frictions without good results. The drug has also a very bad taste. The red mangrove in extract has also been extensively employed by García Rijo, and although it has advantage over chaulmoogra oil in that it is easily taken, the results are far from satisfactory. He has also employed ichthyol and eucalyptus, but with no results. The arsenical preparations have been used in several cases, especially the arsenate, cacodylate, and metarsinate of sodium, and he has obtained satisfactory results, even to the extent of claiming to have cured one case. He has been using atoxyl lately, and he gives the histories of five cases cured or greatly improved by the injections of this drug. He concludes that in spite of the small number of cases he thinks himself right to believe that this drug has a very marked influence on leprosy, especially on the nodular forms. He knows the dangers connected with the drug, and therefore recommends great caution in using it.—*Crónica Médico-Quirúrgica de la Habaña.*

THE RELATION OF THE ACID-FAST TUBERCLE BACILLUS TO OTHER FORMS OF BACTERIAL LIFE.*

BY STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

THREE years ago at the International Conference, von Behring and Much reported that they found in all young tubercle, prebacillary coccal forms of the causative agent of tuberculosis. Their findings have been confirmed by several workers. Some years previously Auclair, and Calmette, and Arloing, and Courmont grew non-acid-fast bacilli from old growths of tubercle bacilli; and the author reported the growing of non-acid-fast cocci from the spleens of guinea pigs injected with an almost avirulent strain of human tubercle bacilli. These announcements aroused only a perfunctory interest. The teachers and the text-books continued to assert that the cause of tuberculosis is the acid-fast tubercle bacillus, and that the acid-fast tubercle bacillus is always derived from an acid-fast tubercle bacillus, and that only acid-fast tubercle bacilli can be developed from acid-fast tubercle bacilli.

For the purpose of again showing the inaccuracy of these assertions, and in the hope of inducing the Conference to take a livelier interest in the whole matter, and perhaps of inducing the Inner Council to recommend "The Relation of the Acid-Fast Tubercle Bacillus to Other Forms of Bacterial Life" as a subject for general discussion at the next meeting, I wish to report some observations which, though often incomplete, seem to me important and illuminating.

The young growths of tubercle bacilli, human, bovine, or avian, on glycerin-broth, glycerin-agar or glycerin-broth-potato, are consistently acid-fast and stain entire, and are of a uniform size. As the bacillary scum on the surface of the glycerin-broth in air-tight flasks grows old and heavy, and perhaps a shade darker, smears will disclose the fact that many individual bacilli have become abnormally long, and have taken on a filamentous appearance. Later, say at the end of six months, some bacilli will disclose a beaded or granular content, and some will have lost in part or entirely their resistance to the acid. With the ordinary Ziehl-Neilsen staining, or the Gabbett modification of it, many bacilli will appear blue or unstained. But these changes in the bacilli composing the scum will be slight as compared with those undergone by the bacilli that from time to time have fallen or have been shaken to the bottom of the flask. No change will be noticed in the gross appearance of these heaps, but the microscope will promptly show that they contain a large proportion of bacilli that have lost their acid resistance. Many fields will be blue, but sprinkled with short red rods, and these short red rods will be single, surrounded by a large blue linear halo, or they will be in small nests separated by slender, often broken, actinomycotic blue lines.

Growths of tubercle bacilli on blood serum and glycerin-agar cannot be kept alive so long as the growths in flasks of glycerin-broth because both the medium and the bacilli dry up. But if one examines a good four-weeks' growth of tubercle bacilli on glycerin-agar, one will find already a few non-acid-fast or poorly acid-fast individuals; and at the end of eight or ten weeks, if the culture is not dead, one or two c.c. of plain bouillon poured into the tube, will, after forty-eight hours in the thermostat, cause a remarkable change in the microscopic picture. Many short well-stained acid-fast bacilli will be seen, but they will be single or in pairs, and with Ziehl staining they will stand out in strong contrast to the pale pink or blue matrix in which they lie.

I have found glycerin-potato a very satisfactory medium for the study of the old tubercle bacilli. The growths of most strains of the tubercle bacillus are more luxuriant on this medium than on glycerin-agar or blood serum, and they do not dry up so soon. The bacilli in the scum that form on the surface of the liquid, and the bacilli that grow on the surface of the potato, preserve well their integrity and their normal staining characteristics, even after the potato has lost half its bulk by evaporation. Many of the bacilli that fall to the bottom of the fluid soon lose wholly or in part their resistance to acid, and after some weeks' immersion, often do not crackle in the flame.

Sterile water or plain broth poured into these old tubes will cause a swelling of the potato and of the growth, and in forty-eight hours the growth will be found to contain: (1) Comparatively few acid-fast rods imbedded in a non-acid-fast matrix made up of lines, granular and non-granular, arranged in ovoidal masses suggesting naked yeast cells; or, (2) Comparatively few tubercle bacilli of recognizable shape in a matrix that is made up of amorphous acid-fast granules of varying size, some suggesting acid-fast yeast shapes, and others, acid-fast cocci. In spite of these changes in the microscopic picture, the bacterial heaps on the potato will retain their gross appearance of pure cultures of tubercle bacilli.

These changes in moistened old growths of tubercle bacilli are easily demonstrated. Are these changes in appearance merely post-mortem or antemortem changes? Are these acid-fast and non-acid-fast coccal shapes and yeast shapes and slender streptothrical vines that make up the various matrices, alive or dead, and, if alive, are they capable of development into something different from tu-

*Read before the IX International Antituberculosis Conference, held in Brussels, October 5-8, 1910.

bercle bacilli? And, if the answer to the last question is in the affirmative, what relation to the tubercle bacillus does this "something different" bear, friendly or inimical?

I would answer that these new bacterial forms are alive and are capable of independent growth in their new forms, and that some of them at least bear a friendly and adjuvant relation to the tubercle bacillus, and that as to the others, I have not yet sufficient evidence to justify an opinion. I have reached these conclusions as the result of many scattered laboratory experiments during the last ten years. Let me hurriedly describe one or two late ones:

January 26 to a dozen ripe cultures of typical and virulent tubercle bacilli, six to ten weeks old in milk and on glycerin-agar, and on glycerin-broth-potato, I added 3 c.c. of 5 per cent. glycerin-broth, or 2 per cent. sugar-broth. On February 17 I found that the growths of tubercle bacilli in the milk had undergone no change. They were still growing in great acid-fast strands. In the glycerin-agar and the glycerin-broth-potato tubes there were left a few t.b. of good shape and staining, but the growth consisted mostly of granular clumps, some acid-fast and some non-acid-fast, but which in many places were of perfect yeast shapes. The suggestion of yeast cells was strongest in the tubes into which the glycerin-broth had been poured. Grossly there was not the slightest sign of any other kind of organism than tubercle bacilli, yet every loopful from the crumbling bacterial mass was found to be made up chiefly of the granular round masses that bore no longer any resemblance to tubercle bacilli. Some weeks later I added to each of twenty-five glycerin-broth-potato cultures of two strains of tubercle bacilli aged from four weeks to eight weeks, enough plain broth to immerse half of the potato. The younger cultures underwent very slight change. The tubercle bacilli in ninety-six hours were still almost all acid-fast and continued afterwards to display the characteristics of normal tubercle bacilli. All of the eight-weeks old cultures underwent very striking metamorphoses; the bacterial masses were found in ninety-six hours to be largely non-acid-fast and often unstained bacillary and coccal and yeastoid and filamentous shapes.

Sub-cultures on glycerin-broth-potato from the four-weeks'-old cultures to which the broth had been added, gave pure cultures of acid-fast tubercle bacilli. Sub-cultures from the eight-weeks'-old cultures to which broth had been added resulted in seven cases in a growth of pure acid-fast tubercle bacilli, with an entire disappearance of the non-acid-fast matrix; in four cases in a persistence of the non-acid-fast linear-matrix and its development into a weak growth of a granular non-acid-fast rod of the size and shape of tubercle bacillus; in two cases in a weak development of acid-fast and non-acid-fast bacilli in the same tube; in three cases in no growth of any kind. In no case did the yeastoid or coccal shapes in the original moistened matrices persist in sub-cultures.

Five years ago to a flask of not very virulent tubercle bacilli in glycerin-broth, and five-months'-old, I added twice at a week's interval, 25 per cent. of 2 per cent. sugar-broth. In four days the bacterial scum had become reddish in hue and contained many swollen tubercle bacilli, and many bacilli of the shape and size of tubercle bacilli that were only very slightly resistant to acid. Sub-culture on glycerinized or sweetened media gave good red growths in forty-eight hours of an acid-fast rod that looked like the acid-fast bacillus that Moeller grew from timothy grass. At present, when grown at room temperature, it loses much of its acid-fast property, although still crackling sharply in the flame, and still preserving its chromogenic powers. Its acid resistance may be even now restored almost entirely by cultivating it at 37° in milk, or in a less degree by cultivating it at 37° in glycerin-broth or on Loeffler's serum.

Some years later in studying old glycerin-broth cultures of this same slightly virulent strain of tubercle bacilli, I found that if they were planted in milk and grown for three weeks in the milk, and the resulting rather filamentous and granular but perfectly acid-fast bacilli, were planted on glycerin-broth-potato, the result was a very weak growth with a swelling of the contained coccal granules, and that a further sub-culture resulted frequently in a yellowish soft growth about the planted crumbs, made up of coccal forms, acid-fast, partly acid-fast, and not acid-fast, and identical in appearance with the coccal granules in the remaining swollen tubercle bacilli. These cocci were readily sub-cultured. They lost their partial acid resistance when grown at room temperature; but retained it if kept at 37°. They did not change milk. They crackled in the flame. They caused the formation of tiny nodes in injected guinea pigs from which the animal quickly recovered. They did not vaccinate the injected animals against subsequent injections of tubercle bacilli. Cultures killed by heat caused mild reactions in injected tuberculous patients.

I thought at first that the explanation of these phenomena lay in the fact that this strain of almost non-pathogenic tubercle bacilli had been cultivated so long—nearly twenty years—that it had retrogressed towards its saphrophitic form, and that therefore its behavior was not a fair indication of what the virulent tubercle bacillus would do under similar circumstances. In these last years I have pursued the subject somewhat, and although I have failed with a good many strains of virulent tubercle bacilli to break down the old granular tubercle bacilli into partly acid-fast cocci, and have frequently failed to develop chromogenic quick-growing cultures of acid-fast bacilli from old glycerin-broth cultures of tubercle bacilli, I have been entirely successful with three different virulent strains, one isolated by the late Dr. Leonard Pearson of the University of Pennsylvania, one isolated by Dr. Nathan Raw of Liverpool, and one isolated by the writer, from cases of human pulmonary tuberculosis.*

Avian tubercle bacilli, which at the ordinary ages of three to six weeks' stain solid, and are of normal size and shape, will appear in ten-months'-old glycerin broth cultures to have lengthened out into acid-fast filamentous forms, punctuated with less acid-fast coccal forms. After many trials, I succeeded three years ago in growing these granular filamentous forms of avian tubercle bacilli, in a

*A technique which has been suggested for securing the quick-growing acid-fast rods is that the tubes containing luxuriant four-weeks'-old growths of human tubercle bacilli on glycerin-broth-potato be put at room temperature for a few days—not less than two days—and that then there be made generous plants in tubes of glycerin-broth or preferably lactose- or glucose-broth, that the tubes be shaken for a few minutes every day for a few days after the third day, and finally that sub-cultures be made on any of the ordinary glycerinized or sweetened media.

series of half a dozen sub-cultures. When these filamentous tubercle bacilli were planted in glycerin-broth and permitted to sink to the bottom of the flask, the resulting growth and sub-cultures were red and of a partly acid-fast coccus, which in fluid media grew in small clumps of rosaries.

Bovine tubercle bacilli in my hands have acted somewhat differently. In old pure glycerin-broth cultures they swelled at one end or in the middle. In the swollen parts a less acid-fast coccal granule developed. Planted in plain or sweetened broth, these granules became free and grew as cocci, which were readily sub-cultured, but except in old sub-cultures showed not even a partial acid resistance.

Concerning the several bacterial forms that I have derived from old cultures of tubercle bacilli, it is to be noted that none of them digests milk or changes its reactions to litmus, and that most of them preserve some of the acid-fast property of the tubercle bacillus, and that so far as my incomplete investigation has disclosed, all of them have a power to cause slight reactions, that have many of the characteristics of tuberculin reactions.

I realize thoroughly that when I claim that culturable bacterial forms other than tubercle bacilli can grow from old tubercle bacilli, I will be met with a first cry of "contamination." That is a charge that is usually hard to refute, but it is not so difficult here:

1.—Because of the appearance and development of the coccal granules in the old bacillary forms before their extra-bacillary appearance and development;

2.—Because of the convincing pictures of the relationship between the free and contained cocci shown in the second and third sub-culture on hard glycerinized or sweetened media;

3.—Because of the ease with which the transition from the acid-fast slow-growing tubercle bacillus to the chromogenic quick growing purely acid-fast or not acid-fast bacillus can be followed on smears;

4.—Because of the slight viability of the non-acid-fast rods and cocci derived from the old or moistened cultures of tubercle bacilli. It was only by quick and frequent sub-culturings that they could at first be kept alive. They could not have lived forty-eight hours in the media on which the tubercle bacilli were growing.

5.—Because every culture of tubercle bacilli that gave me these strange coccal and bacillary growths was capable before sophistication and when planted on favorable media, of growing pure sub-cultures of acid-fast tubercle bacilli.

A second criticism of such results as are outlined in this paper is, "Their improbability. The facts within our knowledge of tuberculosis and bacteriology do not warrant a belief in them." For the present, a sufficient answer to this criticism is: Our knowledge of the causation of tuberculosis is limited to the two facts, (1) That the acid-fast tubercle bacillus is found in most cases of tuberculosis, and (2) That the acid-fast tubercle bacillus can cause tuberculosis in susceptible animals. Neither of these facts is impugned by the findings related in this paper.

On the other hand, in support of the probability of these findings are the following:

I. Much's well-confirmed claims that pre-bacillary and pre-acid-fast stages of Koch's organism are recognizable by special staining method, in all young tubercle.

II. The work of Arloing and Courmont, Auclair and their associates in deriving homogeneous liquid cultures of non-acid-fast or poorly acid-fast tubercle bacilli from old growths of acid-fast tubercle bacilli.

III. The remarkably persistent similarity in the so-called "secondary" bacterial flora in any given case of breaking down tubercle.

IV. The fact that the non-acid-fast "secondary" organisms, whether isolated from the wall of a pulmonary cavity or from tuberculous bone, or any other tuberculous area, and whether they have the cultural and tinctorial characteristics of the streptococcus or the diphtheria bacillus or whatever their form may be, have no pathogenic effect on healthy animals. (Ravenel.)

V. By the fact that the new tuberculin tests, particularly the von Pirquet skin test, frequently give positive reactions, when careful autopsies disclose no sign whatever of tuberculosis, as the word is at present understood.

VI. By the fact that caseous material and effused pleural fluid that reveal no tubercle bacilli to the most diligent examination, so frequently produce prompt and severe tuberculosis when injected into guinea pigs.

VII. By the behavior of the non-pathogenic acid-fast bacilli when subjected to the influence of somewhat unfavorable or unaccustomed environment. Cantacuzene of Bucharest has shown that Moeller's timothy bacilli, when injected intraperitoneally into rabbits, lose for the first generations their waxy capsule, and that it is only after some days or weeks that they become acid-fast again. The Grassberger bacillus, at least the strain I have of it, grows entirely acid-fast in milk, and almost entirely non-acid-fast in glycerin-broth or in glycerin-agar.

VIII. By the suggestive frequency with which quick growing acid-fast bacilli are found in the nasal secretions of lepers, and inhabitants of leprous districts (Karlinski); and by the number of observers who when trying to cultivate the slender slow-growing leprosy bacillus from leprous nodes, have instead secured only growths of a quick-growing acid-fast bacillus which has been discarded because it does not produce leprosy. (Levy, Czaplewski, Bordonni-Uffreduzzi, Bornet, Spronck, and others.)

IX. By the fact that in spite of the comparative harmlessness of the ordinary acid-fast organisms isolated from grass and hay and butter, etc., most of the experiments have shown that the blood of the animal injected with these acid-fasts agglutinates tubercle bacilli, and vice-versa.

X. By the findings of A. Moeller, who reported as long as 1900, that from all the ripe tuberculous nodes of affected cattle and hogs he was able to isolate besides the tubercle bacillus an acid-fast bacillus, that was thicker than the bovine tubercle bacillus and that grew in orange red colonies at room temperature as well as at 37° and that in fact closely corresponded to the acid-fast quick-growing bacillus that I have derived from old cultures of human tubercle bacilli.

XI. By the following disjunct facts of my own observations:

1.—Acid-fast bacilli, often closely simulating tubercle bacilli in appearance, can be developed in difficult media from the acid-fast spores of such ordinary non-acid-fast bacilli as *Bacillus mycoides*, and *Bacillus subtilis*.

2.—When *Bacilli typhosi* are grown at room temperature for a month in plain broth and sub-cultured in weakly nutrient but normally saline broth

(equal parts of physiological salt solution and plain broth), a large proportion—sometimes one-half—will be acid-fast. A similar striking development of acid resistance will be shown by many strains of Klebs-Loeffler bacilli when grown at room temperature for two weeks in equal parts of sugar-broth and salt solution.

3.—Glycerin-broth cultures killed by heat, or filtered, of cocci or streptococci or yeast cells isolated from tuberculous pus, have the power to induce in tuberculous patients, a mild reaction closely simulating the tuberculin reaction.

4.—From the blood of a hospital patient suffering from acute endocarditis, I isolated a bacillus that grew in chains, of which one link of three was acid-fast. There was no history of rheumatism or other infection. At autopsy, the only finding was of a small, old but caseous tuberculous area in the right apex. This bacillus did not cause tuberculosis in injected guinea pigs.

5.—From the effused fluid of three cases of tuberculous pleurisy kept at room temperature for four days, I have found a bacillus that was sometimes acid-fast, and sometimes not; that is, in every field stained by Ziehl, individuals uniform in shape and size would be, some red, some partly red and partly blue, and some entirely blue. Sub-cultures on various media resulted in growths of an entirely non-acid-fast bacillus.

6.—M. T., a bright girl of ten years, after a prodromal period of lassitude and depression and aversion to study, and of slight fevers, began to cough. The first specimens of sputum showed no acid-fast organisms. Two weeks later there appeared an occasional thick, weakly acid-fast rod, in clumps or lines of rods of similar size, but not acid-fast. In frequent examinations of sputum, these acid-fast rods were seen to increase in number, actually and relatively, and to become more and more slender and soon to be indistinguishable from the classical tubercle bacillus. Both lungs became rapidly involved and the patient died with all the symptoms of an acute pulmonary tuberculosis.

7.—M. M., a nun, who had been under treatment for several months for apical and laryngeal tuberculosis, and who had had characteristic tubercle bacilli in her sputum, showed suddenly marked amelioration of symptoms and coincidently the tubercle bacilli in her sputum became very thick and few. The next specimen of sputum and dozens of specimens since contained no acid-fast organisms, but were almost pure cultures of a non-acid-fast granular bacillus, that both with the Neiser stain and with alkaline methylene blue, appeared to be perfect diphtheria bacilli. It is now six years since her improvement began. She has been teaching school for five years, and has had from sixty to eighty pupils in her class. Twice during that time, at the close of the school year, she has had return of cough and laryngeal distress, and a return of a few acid-fest bacilli in her sputum.

8.—H. S., a consumptive, with an afternoon temperature which for months ranged from 102° to 104°, and in whose sputum there are ordinarily a dozen or more orthodox tubercle bacilli in every field, has three times given me sputa which contained no perfect tubercle bacilli, but did contain thicker poorly acid-fast bacilli, in small clumps or strings of non-acid-fast bacilli of similar shape and size. The specimens that contained the normal tubercle bacilli contained none or few of the unusual acid-fast rods.

9.—K. A., a tall, athletic girl of twenty years, skylarking with her brother, had the rug on which she stood pulled with such unexpected force that she fell at full length, striking the right side of her head violently on the hardwood floor. No bones were broken, but within a week she was conscious of queer trouble about the hurt temporal area. There was no evidence of inflammation of the bone, but she had spells of pain and tinnitus and dizziness. In spite of a great variety of treatments, none of them operative, she grew worse slowly for weeks, then the whole side of her head took to aching, and she developed a very irritating cough. That lasted without any expectoration for several weeks. As the cough increased, the pain in the head and all the ear symptoms grew better, and she regained her lost weight. The cough was very annoying. Finally she had a small hemoptysis, and ever since has been able to raise small amounts of sputum which almost invariably contained clumps of slender filamentous bacilli that, stained with Ziehl, varied in color in most clumps from a bright red to a pale pink, and sometimes to a pale blue, and sometimes to unstained forms. Clinically, she is suffering from a mild pulmonary tuberculosis. She reacts promptly to tuberculin.

10.—K. H., a young woman in whose ear-wax were the ordinary acid-fast cerumen bacilli, used an ear spoon so vigorously as to start an inflammatory process in one ear. When that healed the glands under the angle of the jaw swelled and one suppurated. The pus contained short, straight, acid-fast bacilli, but injected into a guinea pig caused no tubercle. She did not react to the von Pirquet tuberculin test. Plants of the pus on plain agar or plain broth gave no growths, but plants of the pus on glycerinized media gave a pure, soft growth of a short, slow-growing granular bacillus that crackled in the flame, and of which one of the contained granules, was frequently distinctly acid-fast. A vaccine made from this organism caused local reaction, but had no curative effect. The glands remained swollen for several months, but they melted away very quickly with small doses of old tuberculin.

11.—I have tried for many years to get a pure culture of acid-fast bacilli from the smegma of a patient on whom they often grew in apparently pure culture. I have always failed, but I have repeatedly convinced myself from closely observing the changes undergone by very generous plants of these bacilli on various media, that the planted bacilli grew, but grew non-acid-fast. The resultant growths were granular, gram-positive bacilli, that did not change milk; that throve only on glycerinized or sweetened media, and that developed some slight acid resistance when grown on human blood agar.

12.—Aspirated creamy pus from the swollen cervical gland of a young woman of tuberculous family, repeatedly digested milk, but revealed no bacterial forms, either intracellular or extracellular. Sub-cultures, made from the milk gave invariably a slow, red growth of a partly acid-fast coccus arranged in chains, which was morphologically and tinctorially identical with the coccus derived from old avian human tubercle bacilli. This organism had no power to digest or otherwise change milk.

13.—The tubercle bacilli, when in great numbers in sputum, preserve well their shape and acid resistance after many months at room temperature, if

protected from the air. But in specimens to which equal parts of milk have been added, the tubercle bacilli in a short time at room temperature lose their outline in more or less acid-fast granular clumps that strongly suggest the matrices described in the moistened old growths of the pure culture of tubercle bacilli. And in the clumps there develops a larger granular non-acid-fast streptothrical rod.

14.—From the very tuberculous livers of six guinea pigs, dead six to ten weeks after injection with pure human tubercle bacilli, I have recently isolated pure cultures of very feeble yeast cells by crushing the liver substance and planting on plain potato. These yeasts did not grow at all on other media that was not sweetened or glycerinized, and gave only very faint growths on any media. The livers of an equal number of control guinea pigs gave no growth when subjected to the same technique.

15.—Several times in the last few years I have found in the little cheesy nodes of guinea pigs that had been injected with coccal acid-fasts, bacilli of perfect t.b. shape. Yet plants of these crushed nodes, on various glycerinized media, gave only pure cultures of the coccal forms that had been injected.

Perhaps the tentative deductions from such a paper as this may be best put in the form of questions:

1. Is not the acid-fast tubercle bacillus simply a most highly specialized acid-fast bacillus that has acquired the faculty of resisting the lytic power of the animal cell? And like all other acid-fast bacilli, was it not derived originally from a non-acid-fast bacillus?

2. Does not the hope for the infected animal lie, not in killing the invader outright, but in depriving him of his acid-fast armor and weapons?

3. Does not the great sensitiveness of the tubercle bacillus to change of environment *in vitro*, afford a key to the solution of nature's cures of tuberculous animals?

4. When the infected animal is cured by change and fresh air, is it not because in the new environment the tubercle bacillus has difficulty in perfecting its acid-fast development and therefore grows non-acid-fast or poorly acid-fast, or breaks up into cocci, which may or may not win the next battle with the cells? (If the cells win, the patient recovers. If the cells lose, the coccal and rod forms quickly break down surrounding tissue entrenchments; then slowly, as *in vitro*, begins again the victorious progress of the acid-fast tubercle bacilli.)

5. Is not all the literature concerning the organisms of the secondary invasion or of mixed infection in tuberculous areas a huge blunder because of its failure to recognize the fact that the so-called secondary invaders are practically always derivatives of the struggling acid-fast tubercle bacillus?

6. Do not the facts here related of the devolution of the acid-fast tubercle bacillus into culturable cocci and non-acid-fast bacilli, harmonize with and complete the theory involved in the important communications of Much and his followers, and Foulerton and others, and make the further and thorough study of the points at issue, altogether the greatest need in the present tuberculosis problem?

212 Orange Street.

THE DIAGNOSTIC AND THERAPEUTIC VALUE OF LUMBAR PUNCTURE.*

By LEON LOURIA, M.D.,
BROOKLYN, N. Y.
ATTENDING PHYSICIAN TO THE JEWISH HOSPITAL.

When, in 1891, Quincke of Kiel introduced the practice of lumbar puncture, he little dreamed of the extensive possibilities and developments which this simple surgical procedure would acquire. At first regarded as a startling mode of invasion of one of the most vulnerable parts of the body, it has, through its widespread application, become one of the easiest resources in the hands of the general practitioner. Indeed, the latter may now perform lumbar puncture with as little hesitation as a simple paracentesis of the pleural cavity, and with even greater and richer rewards in diagnosis and treatment.

It is my purpose in this paper to review the recent advances made in the theory and practice of lumbar puncture, to indicate its increasing sphere of usefulness in a wide range of diseases, and to report a few examples of my own experience with this diagnostic and therapeutic measure.

It is quite natural that the subarachnoid space should be the last of the great body cavities to yield its secrets to the prying needle. One need only recall a few of the simple anatomical relationships of the cerebrospinal axis and of its enveloping membranes to appreciate the fact that the cerebrospinal fluid may undergo a host of changes in response to the multitude of pathological conditions to which the brain and spinal cord may be subject—changes that are nutritive, toxic, vascular, traumatic, or inflammatory—and even in response to similar conditions affecting remoter parts of the organism.

The cerebrospinal fluid possesses not only the lubricating function which is similar to that of the pleural and pericardial fluids, but, unlike the latter, it forms a substantial water jacket whose elasticity amply protects the cerebrospinal axis from the injurious effects of sudden jars. In addition, it fills the ventricles of the brain, and serves the important hydrostatic function of permitting such changes in the volume of the brain and spinal cord as result from a varying blood supply. The cerebrospinal fluid thus plays a happy physiological rôle: the brain, enclosed within an unyielding bony box, is capable of receiving a richer blood supply only by virtue of the fact that part of the cerebrospinal fluid within its ventricles may readily be shifted into the subarachnoid space of the spinal cord.

Access to this space is most easily accomplished by the introduction of a hollow needle, four to ten cm. long, and having a lumen one to one and a half mm. in diameter, between the spinous processes of the third and fourth or fourth and fifth lumbar vertebræ, or, preferably, between that of the fifth lumbar vertebræ and the sacrum. The site of puncture is usually on the level of an imaginary line joining the crests of the ilia. The needle is inserted in the interspinous space just below this level, in children in the median line, and in adults a few millimeters to one side of the median line; in children to a depth of two cm., in a horizontal direction, and in adults to a depth of four to six cm., slightly inward and upward. The operation is performed under strictest aseptic precautions, under local anesthesia with

*Read before the Williamsburg Medical Society, April 11, 1910.

ethyl chloride, and sometimes, in extremely neurotic individuals, under general anesthesia. The patient should preferably lie on his left side with his knees drawn up and his back strongly arched. The sitting posture is recommended for children by Pfaundler[1], but this position has the disadvantage and danger of permitting occasionally a sudden change in the pressure of the cerebrospinal fluid. As soon as the needle reaches the subarachnoid space, as evidenced by a diminished resistance to its passage, and by the issuance of the cerebrospinal fluid usually drop by drop from its free end, the latter is attached by means of a piece of rubber tubing twenty to forty cm. long to one of the several forms of apparatus for recording the pressure of the fluid. The simplest of these, originally introduced by Quincke, consists of an upright glass tube, ten to fifteen cm. long, and two mm. in diameter, with its upper end bent into an inverted U; in this tube the height of the cerebrospinal fluid, and hence its pressure, is measured in terms of millimeters of water by means of a scale. More accurate than this device is the use of a mercurial manometer, such as that recommended by Pfaundler. This consists of a Sahli mercurial manometer connected with the needle by means of rubber tubing and disconnected after the pressure is read. This device has recently been modified by G. E. Erbright[2], who, by means of the interposition of a T-shaped nickel-plated tube, with a suitable arrangement of valves between the needle and the manometer, is able to record the pressure, collect the fluid, and regulate its speed of outflow, without removing the manometer. Still more recently W. Kausch[3] has invented an instrument by means of which lumbar puncture, the injection of fluids into the subarachnoid space, and the estimation of the pressure of the fluid may all be accomplished without the escape of any of the latter from its containing membrane.

A "dry tap" is an indication that the needle has not reached its proper destination, or that its lumen is occluded (to avoid this contingency a stylet is used with the larger needles), or that the exudate is too thick to flow, or that the pressure of the cerebrospinal fluid is negative, as may occur when the cerebral portion of the subarachnoid space is shut off from the spinal portion by means of inflammatory adhesions or a new growth. The needle may wound the plexus of veins beneath the dura, in which event a few drops of blood will succeed the puncture, to be followed by the clearer cerebrospinal fluid. This event is to be differentiated from a true hemorrhagic condition of the cerebrospinal fluid by the fact that in the latter the blood is evenly distributed throughout the fluid. When the flow of the fluid is sluggish Curschmann[4] recommends the application of ice to the extremities as a means of promoting the flow. Not more than thirty c.c. of fluid should be removed at any one time, nor should the pressure of the fluid be allowed to fall below the normal.

In health the cerebrospinal fluid is colorless like water, of alkaline reaction, and of low specific gravity (1005 to 1007). It is continually under a tension consisting of two components, namely, hydrostatic and elastic pressures, the former depending upon the perpendicular position of the cerebrospinal axis, and the latter upon the elastic tension of the fluid within the body. The normal pressure is from 60 to 100 mm. of water (10 to 35 mm. of mercury). Chemically this fluid contains a small amount of albumin in the form of globulin (.02 to .05 per cent.), glucose and a trace of another copper-reducing substance, probably pyrocatechin, fat, cholesterin, chlorides, sulphates, phosphates, sodium lactate, traces of cholin, and occasionally urea. There is a larger amount of potassium as compared to sodium. The freezing point is — 60° to — 65° C. Microscopically the fluid shows an average of five cells per millimeter, chiefly leucocytes and endothelial cells. The amount of cerebrospinal fluid present in the body has not been determined.

The pathological conditions that cause variations in the appearance and composition of the cerebrospinal fluid are so numerous that one cannot make a comprehensive survey of them without an attempt at classification, as follows:

1. Diseases of the meninges; (a) acute inflammatory or infective meningitis, meningococcic, tuberculous, pneumococcic, streptococcic, staphylococcic, influenzal, typhoid, colon bacillus, etc.; (b) chronic inflammatory, tuberculous, or secondary to trauma, toxemia, or intoxications (alcoholic); (c) syphilitic meningitis; (d) acute traumatic meningitis, serous, or hemorrhagic, epidural, and subdural hematomata, pachymeningitis externa hemorrhagica; (e) malignant disease of the meninges; (f) epidural and subdural abscess; (g) meningismus (infections, intoxications, and reflex irritations).

2. Diseases of the brain and cord; (a) acute inflammatory, acute encephalitis, acute poliomyelitis, acute myelitis, abscess of the brain or cord, sinus thrombosis; (b) chronic productive, paresis, tabes; (c) malignant disease of the brain or cord; (d) cerebrospinal syphilis; (e) hemorrhage into the brain or cord; (f) functional neurosis, epilepsy, tetany, chorea.

3. Pressure upon the brain or cord by fracture, hemorrhage or new growth.

4. Ependymitis, acute or chronic, resulting in hydrocephalus.

5. Constitutional diseases: (a) chlorosis, (b) uremia, including eclampsia of pregnancy; (c) cutaneous affections.

A clear conception of the changes wrought in the cerebrospinal fluid by any of the above conditions is rendered possible by the consideration of a few general principles.

The pressure of this fluid is increased by all causes that add to its volume. These may be enumerated as follows: Ependymitis, congenital or acquired, causing hydrocephalus; the various inflammatory diseases of the cerebrospinal axis or its membranes; tumors of, or hemorrhage into, the brain, or fracture of the skull, that by pressure interfere with the proper drainage and consequent absorption of the cerebrospinal fluid; hydremic conditions of the blood, such as exist in chlorosis, in which there is an increased transudation into the ventricles and subarachnoid space; toxic conditions of the entire organism, such as uremia and lead encephalopathy, causing an irritation of the meninges and an increased secretion of fluid. Dependent upon the kind and severity of the disease, the pressure of the spinal fluid varies all the way from 200 to 800 mm. water (15 to 60 mm. Hg.)

The accompanying table, adapted from Pfaundler and Schlossman,[5] shows some of the marked differences of pressure in children as measured in millimeters of mercury:

	mm. Hg.
Normal infants	10 to 20.
" older children	15 to 25.

	mm. Hg.
Tuberculous meningitis—	
State of irritation and pressure	50 to 100.
State of paralysis	Not increased.
Meningococcic meningitis	Up to 50.
Suppurative "	Up to 40.
Serous "	Increased.
Chronic internal hydrocephalus	Up to 60.
Cerebral tumor	Sometimes increased.
Meningismus	Slight increase, maximum 45.
Functional neuroses	Usually increased
Sinus thrombosis	Often increased.

The cerebrospinal fluid is clear and transparent in acute and chronic serous meningitis, in syphilitic meningitis, often in meningococcic meningitis, and in paresis, tabes, hydrocephalus, uremia and chlorosis; and in tuberculous meningitis, clear, with a faint, cloudy coagulum that forms on standing. It may be slightly blood-tinged in hemorrhagic meningitis, malignant disease of the meninges, or of the brain or cord, and in fracture of the skull, or it may contain an abundant admixture of blood, in hemorrhage into the brain or cord. It may be slightly opalescent from a slight admixture of cellular elements, or may contain a considerable amount of pus, as in the various forms of infective meningitis, meningococcic, pneumococcic, staphylococcic, influenzal, etc.

On chemical examination the cerebrospinal fluid presents striking and characteristic changes in various pathological conditions. The copper-reducing substances, sugar and pyrocatechin, which are normally present to the extent of from .002 to .006 per cent., are completely absent in inflammatory conditions of the meninges, and gradually return as these conditions improve. Even in serous meningitis sugar and its accompaniment may be absent. The absence of these copper-reducing substances goes hand in hand with the process of exudation.

The estimation of the amount of albumin, which is normally present in the form of globulin to the extent of .02 to .05 per cent., is of diagnostic value in various morbid conditions. The following table, adapted from Simon,[6] shows the wide range of variations in the content of albumin:

Chronic hydrocephalus	Traces.
Serous meningitis	.05 to .075 per cent.
Tumors of the brain	Traces to .08 per cent.
Chronic hydrocephalus the result of hyperemia	.1 to .7 per cent.
Tuberculous meningitis	.1 to .3 per cent.

Mott and Halliburton[7] found that in paralytics the amount of albumin is increased threefold, and that nucleo-albumin, which is absent in health, is present in small amount. Two recent tests have been devised for the easy determination of this excess of globulin, namely, the Noguchi reaction and the ammonium sulphate ring test. The Noguchi reaction consists in boiling two parts of spinal fluid with five parts of a 10 per cent. solution of butyric acid in saline solution for a few seconds, and then adding one part of a normal sodium hydrate solution, and again boiling briefly. A granular or flocculent precipitate is obtained on standing. The ammonium sulphate ring test[8] is performed as follows: Two c.c. of a saturated solution of ammonium sulphate are placed in a test tube and 1 c.c. of cerebrospinal fluid is superimposed upon its surface as in the Heller test for albumin. A positive reaction consists in the formation of a thin, clear-cut grayish white ring between the two liquids, like a thin sheet of paper. This ring should form within three minutes and within half an hour its surface should show a delicate mesh appearance resembling a fine cobweb.

According to L. Merzbacher,[9] in paresis there is a marked increase in the amount of globulin, which increase is not found in tabes or in the other syphilitic or parasyphilitic conditions. This chemical difference is of diagnostic importance, for in all of these conditions a lymphocytosis is the rule. J. Billström[10] found this globulin increase in 100 per cent. of thirty-four cases of general paralysis, employing the technique of Nonne and Apelt for the fractional precipitation of albumin. This increase was also found in five out of seven cases of congenital syphilis in which the cerebrospinal fluid was examined by Tobler.[11] In suppurative and hemorrhagic conditions of the meninges there is also an increase in the globulin content of the cerebrospinal fluid. The following table constructed from figures given in Pfaundler and Schlossman[12] shows the differences in the content of globulin in children:

Normal finding	.02 to .05 per cent.
Tuberculous meningitis—	
State of Irrita'n and Pressure	.1 to 7 (aver. 2) per cent.
State of paralysis	Average 4 per cent.
Meningococcus meningitis	Increased up to 1 per cent.
Acute serous meningitis	1 per cent.
Chronic internal hydrocephalus	Normal.
Cerebral tumor	Often increased, exceptionally to 8 per cent.
Meningismus	Rarely slightly increased to 1 per cent.
Functional neuroses	
Sinus thrombosis	Oft'n somewhat increas'd

In tuberculous meningitis there is a gradual increase in the amount of globulin in the course of the entire process. It is to be noted that the globulin content is greater than 1 per cent. in exudations or tumors, and greater than 5 per cent. only in tuberculous and suppurative meningitis.

Within recent years some significance has been attached to the investigation, in various diseased conditions of the nervous system, of the amount of cholin which is normally present in traces. This has been detected in larger amounts by Donath[13] in cases of epilepsy, paresis, tabes, cerebral abscess, and other diseases. Coriat[14] found that the largest amounts of cholin are present in paresis.

From the diagnostic viewpoint, the cytological examination of the cerebrospinal fluid reveals the most important changes. In the acute infective forms of meningitis there is a polynucleosis of varying degree. This is strikingly seen in epidemic meningococcic, pneumococcic, staphylococcic and influenzal meningitis. In the tuberculous form lymphocytosis is the rule. In the later stages of the acute infective forms, where recovery occurs, there is a progressive increase of the lymphocytes together with a progressive diminution of the polynuclear leucocytes,[15] while in the tuberculous variety, if there is a mixed infection, polynucleosis occurs. A lymphocytosis is of eminent diagnostic significance in differentiating cerebrospinal syphilis and paresis, in which it is an almost constant accompaniment, from other diseases of the nervous system, chiefly functional, that may otherwise closely resemble them. In twelve out of fourteen cases of congenital syphilis, Tobler[16] found pronounced lymphocytosis. The importance of this lymphocytosis is emphasized by Waterman[17] in differentiating paresis from other psychoses, and in differentiating cerebral tumors from gummatous growths. An increase of lymphocytes is also found in multiple sclerosis, mumps, and herpes zoster. In a very small proportion of the cases of malignant disease

of the brain and cord, cancer cells may be isolated from the cerebrospinal fluid. Thus Sicard and Gy[18] report the finding of sarcomatous cells.

The bacteriology of the cerebrospinal fluid, while more difficult of investigation than the cytology, gives precision in the diagnosis of tuberculous meningitis, in which the tubercle bacillus is found in the spinal fluid in from 50 to 75 per cent. of the cases, and also renders possible the differentiation of the various acute infective forms from one another. The isolation of typhoid and influenza bacilli from the cerebrospinal fluid enables one to regard, as the result of a true meningitis, a set of symptoms that might otherwise have been regarded as a mere expression of meningismus. The diphtheria, and the colon bacilli, the streptococcus, staphylococcus, and the Bacillus pyocyaneus, have all been demonstrated, though rarely, in the spinal fluid. The tubercle bacilli are usually found by examining a portion of the fine fibrinous network that forms near the surface of the cerebrospinal fluid. This examination is facilitated by the process of inoscopy,[19] or the preliminary digestion of the fibrinous network by means of pepsin. Fürbringer[20] found tubercle bacilli in 70 per cent. of his cases.

The important diagnostic applications of lumbar puncture find a lesser rival in the therapeutic uses of this procedure. Although there are some observers who still cherish a sceptic attitude toward the therapeutic efficiency of lumbar puncture, yet the accumulating experiences of the last few years are sufficient to prove that tapping of the subarachnoid space may be distinctly curative, may serve to prolong life, or may relieve distressing symptoms. These effects may be attributed to one or more of the following agencies: (1) drainage, (2) diminution of the abnormally increased pressure upon the brain and cord (decompression), (3) the production of passive hyperemia of the brain or cord, and (4) as a preliminary step in the process of injecting antitoxic sera into the subarachnoid space.

There can be no doubt that in the acute infective forms of meningitis the drainage of the purulent fluid, loaded with microorganisms and toxins, is at any rate justified upon the ground of general surgical expediency. Unfortunately, in most of these cases, this procedure alone is insufficient to prevent a fatal outcome. Nevertheless, beginning with Lenharz in 1905, a number of clinicians have extolled the curative value of repeated lumbar punctures in meningococcic meningitis. J. v. Bokay[21] reports ten recoveries out of seventeen cases in children from this procedure, and attributes the happy result not only to the mechanical reduction of the cerebrospinal pressure, but also to the removal of bacteria and toxic substances from the body. He emphasizes the importance of repeated punctures, and states that in children no more than 30 c.c. of fluid should be withdrawn at any one time. As a step preliminary to the injection of antitoxic sera, lumbar puncture is indispensable. The Flexner serum has already amply proved its efficiency in meningococcic meningitis. It is quite possible that drainage of the infected fluid may account for those recoveries, unfortunately too few, that have been reported of influenzal meningitis. According to E. Schlesinger,[22] when tubercle bacilli of comparatively attenuated virulence are found in the cerebrospinal fluid the outcome following lumbar puncture may possibly prove favorable. He cites five cases that have been published in which recovery occurred. Sokoloff[23] reported in 1897 that a primary tuberculosis of the meninges may be cured by lumbar puncture. Similarly, Freyahn[24] reported cures. Stewart observed at least one case of ultimate recovery in which the tubercle bacillus had been demonstrated in the cerebrospinal fluid. There is one type of meningitis that is without question cured by lumbar puncture, namely, serous meningitis.

Drainage of the cerebrospinal fluid, if not curative, may, at any rate, serve to prolong life. This is true of the above forms of infective meningitis and hydrocephalus. In the latter condition the beneficial effects in diminishing the size of the skull and improving the mental condition have been plainly evident in a case reported by A. Gasparini.[25] In meningitis, the relief of the distressing symptoms, as accomplished by the process of decompression, furnishes one of the happiest services that lumbar puncture is called upon to perform. The severe headaches, vomiting, stiffness and pain in the back, the convulsions and other manifestations of increased intracranial pressure, are distinctly relieved by the removal of even a small quantity of cerebrospinal fluid. There can be little question that lumbar puncture has decided value in relieving the symptom-complex known as meningismus, which frequently accompanies the acute infectious diseases. This condition is often the manifestation of a true serous meningitis, caused by the bacteria or toxins of the primary disorder. The value of lumbar puncture in relieving the meningeal symptoms of typhoid fever has been frequently demonstrated, and it is now generally recognized that a serous meningitis is frequently responsible for the marked nervous manifestations of this disease. An excellent recent contribution to this subject is that made by R. Stein,[26] who reports three of his own cases of serous meningitis complicating typhoid, and also reviews the extensive literature. He believes that in typhoid fever spinal puncture has not been performed as frequently as its application seemed to warrant. Rocaz and Carles[27] extol the value of this procedure in the meningeal forms of typhoid fever in children, on the basis of eight favorable cases that they report. They also suggest that spinal puncture might be of service in the treatment of severe and prolonged headaches occurring during adult life. There is abundant evidence that the relief afforded by lumbar puncture is pronounced in the headaches and insomnia caused by syphilitic disease of the meninges, in the cerebral manifestations of uremia, and in the headaches of chlorosis.

During the past nine years many observers have reported the beneficial effects following lumbar puncture in cerebral uremia. A. E. Russell[28] states that there is evidence to show that the cerebral manifestations of uremia are dependent upon cerebral anemia produced by an increase in intracranial tension resulting from cerebral edema. The symptom-complex of cerebral uremia is almost identical with that of cerebral compression, namely, headache, vomiting, drowsiness, coma, convulsions, optic neuritis, *etc.* One of the first cases reported was that of a nephritic, in whom severe headache of one year's duration was completely relieved within two hours by lumbar puncture.[29] The frequency of cerebral symptoms in the course of chronic nephritis, and the discovery at autopsy of organic inflammatory changes in the meninges, have led R. Lépine[30] to discuss the possibility of the existence of a true uremic meningitis. In a case of uremia

with marked meningeal symptoms, M. A. Chauffard[31] has observed a distinct polynucleosis in the spinal fluid. Although this was only transient and therefore not a valid indication of the existence of a uremic meningitis, nevertheless it is an interesting contribution to our incomplete but growing knowledge of the meningeal states of uremia.

The opinions as to the value of lumbar puncture in the treatment of eclampsia of pregnancy have been varying. Audebert and Fournier[32] collected forty-four cases of the latter treated by spinal puncture and found that it undoubtedly benefits the cerebral factor of the fits. They state that lumbar puncture, which should be combined with the other more recognized measures, should be employed even when the coma is profound, but should not be delayed until too late. Thiess[33] states that seven of his fifteen patients treated by lumbar puncture died, a mortality of over 42 per cent. The pressure of the cerebrospinal fluid was unusually high in all but one case. The prognosis seemed to be better in the cases with lowest pressure. An effect from the lumbar puncture was evident in only a few of the cases. Profound coma was apparently relieved in some instances.

According to F. C. Eve,[34] the efficacy of lumbar puncture as a curative agent in certain obscure diseases of the brain has been suggested by the beneficial results that follow this procedure in a case of tetany. He states that the removal of spinal fluid, even when its pressure is normal, causes cerebral hyperemia, which in a variety of acute and subacute cerebral affections that have resisted other treatment, or have tended to become chronic, may have the same therapeutic efficiency as Bier's passive hyperemia in other parts of the body. Narbut[35] also reports a case of tetany cured by the removal of 50 c.c. of a sterile spinal fluid.

P. Savy[36] advises lumbar puncture in all cases of nervous disturbances possibly to be attributed to trauma of the skull, even if a long interval has elapsed since the primary injury. He attributes the good effects that he has observed in one case to the removal of decomposing blood, that accounted for the symptoms by its toxic effects rather than by its compression. R. Malatesta[37] similarly reports marked relief in nine cases of trauma of the head, and states that in all cases of such injury, in which expectant treatment is justified, lumbar puncture will permit the diagnosis of intracranial hemorrhage, and by repeated puncture the course of the latter will be determined. The puncture permits the escape of decomposing extravasated blood that produces toxins causing stupor, fever, and delirium, and at the same time relieves the compression. Babinsky and Charkow[38] report eight cases of optic neuritis of intracranial origin treated by spinal puncture with success in nearly all. They also recommend this procedure in post-traumatic and inflammatory intracranial effusions. When tumor is present, lumbar puncture is only palliative and alternative to trephining. L. Stephenson[39] also reports the good effect of lumbar puncture in optic neuritis. L. C. Ager[40] states that lumbar puncture is fully as useful in infantile spinal paralysis as in meningitis, and believes that by means of this procedure the improvement may be accelerated in the later stages.

As a means of relieving the severe and persistent headaches occurring in chlorosis, lumbar puncture was first advocated by Lenharz.[41] In the severe forms of this condition there is an increase in the amount and pressure of the cerebrospinal fluid, the pressure amounting to from 200 to 400 mm. of water. Lenharz reports that lumbar puncture relieved the headaches in one-half of his cases. Pruritus is another condition that has apparently responded to the therapeutic application of spinal puncture. P. Ravaut[42] states that a number of patients suffering from pruritus were cured by the withdrawal of from 6 to 8 c.c. of fluid. He ascribes the results observed to the modification of the blood-supply in the cord due to the withdrawal of the cerebrospinal fluid, with a consequent influence on the peripheral nervous system, thus confirming the theory of the angioneurotic origin of certain dermatoses and of pruritus.

It is hardly necessary to discuss *in extenso* the subject of the marked reduction in mortality that has followed the use of Flexner's serum[43] after a preliminary lumbar puncture in the treatment of meningococcic meningitis. It may not be amiss to allude to the fact that the use of antitetanic serum by injection into the subarachnoid space of the cord has not been found any more efficacious than hypodermatic injection of this serum.[44] The production of spinal anesthesia by means of cocaine and stovaine has demonstrated its practical utility in selected cases, and one need only refer for detailed information on this subject to Kroner's[45] recent admirable review of the literature.

There are very few fatalities that have been recorded as the result of lumbar puncture. In fact, so safe is this procedure generally considered that Waterman[46] performs lumbar puncture even in the out-patient clinic and in the office. It is desirable, however, that the patient be kept in bed for at least twenty-four hours following this operation. In spite of a faultless technique one may expect occasional disagreeable effects. In a large series of lumbar punctures, Klein[47] has observed no more serious results than occasional headache and slight nausea. Other writers have reported transient by-effects such as hemorrhage into the cord, lesions of the nerves, vertigo, headache, vomiting, irregular pulse, and pains in the limbs. H. Wolff[48] describes a case in which, five days after a lumbar puncture, abducent paralysis developed, and this he attributes either to the formation of an intracranial hematoma, or possibly to the entrance of blood into the spinal canal. Giarré reports a transitory unconsciousness that occurred in a case of hydrocephalus as the result of a too rapid drawing off of the fluid. Gumprecht reports two cases of death from respiratory paralysis occurring in children following lumbar puncture, in which the symptoms had pointed to brain tumor. The same author reported a case of the breaking of the needle owing to the sudden movement of the patient. The latter had pain and partial paralysis for a time, but no permanent ill effects.

According to W. Kaupe,[49] exceptional caution is necessary on suspicion of a tumor of the brain, on account of danger of hemorrhage into the tumor tissue, of variations in the intracranial pressure, and of the shutting off of the fluid in the ventricles from the rest of the cerebrospinal fluid. While as a rule harmless in tuberculous meningitis, lumbar puncture has been known to hasten the fatal termination. In cases of hydrocephalus it may do harm if the foramen of Magendie is occluded. It is important to note that in no case of lumbar puncture should too large an amount of fluid be allowed to escape, nor should the fluid ever be aspirated. According to Siemerling, a sharp fall of pressure and sudden

severe headaches are danger signals in brain tumor.

In reviewing the records of the Jewish Hospital of Brooklyn, of the eighty cases in which we have employed lumbar puncture for diagnostic or therapeutic purposes, I have selected a few whose brief histories here appended strikingly illustrate our own success with this measure in the diagnosis and treatment of many of the conditions mentioned in his paper.

Case I.—Acute serous meningitis secondary to autointoxication. M. H., male, age 16, admitted April 7, 1909. He was sick for ten days, with severe headache, fever, general malaise, and diarrhea. On admission he was very drowsy and apathetic and slow to answer questions. The head was retracted, the pupils were equal and contracted, the reflexes exaggerated, and the Kernig and Babinsky reflexes were present. The temperature was 102°; pulse, 100; respiration, 26. Between April 7 and April 9 the temperature ranged from 102° to 103.2.° and the pulse from 100 to 120. On April 9, lumbar puncture was performed and 15 c.c. of clear fluid were withdrawn under high pressure. The fluid was sterile. After that date the temperature gradually subsided, reaching normal April 10 and remaining normal, with a marked improvement of the patient's condition until his discharge from the hospital on April 14. In this case the beneficial effect of the lumbar puncture was quite apparent.

Case II.—Acute serous meningitis. A. M., 11 years old, was admitted August 15, 1909, with history of headache, fever, and vomiting, and presenting some rigidity of neck and Kernig's symptom. Two lumbar punctures were performed, 10 c.c. and 20 c.c. of cerebrospinal fluid, respectively, being removed. No bacteria were present. There were a large number of endothelial cells, indicating an irritative exfoliation. August 19, four days after admission, all the meningeal symptoms disappeared, thus attesting the curative effect of the lumbar punctures.

Case III.—Nephritis, uremia, hemorrhagic meningitis. R. S., female, age 55 years, was admitted with normal temperature, pulse, and respiration, with Kernig's sign, retraction of the head, and tenderness about the cervical vertebræ. She was at times apathetic and complained of severe headache and nausea. Although the kidneys responded to treatment the headache persisted. Two lumbar punctures were performed and cerebrospinal fluid was removed. The first contained blood. Both fluids were otherwise normal, except for increased quantity and high pressure. Immediate improvement followed.

Case IV.—Uremia. C. F., female, age 39 years, was admitted to my service on July 3, 1909. She was semiconscious and responded to questions. The cheeks were puffed and there was puffiness of lower eyelids. Pupils were equal and reacted equally to light. The reflexes were present and not exaggerated. On July 3 there were severe headache and nausea; on July 4, slight drooping of left upper eyelid. On July 6 there was involuntary micturition. On the same day there occurred convulsive twitchings of the extremities, lasting for seven minutes, and associated with unconsciousness. July 7, patient was in a stuporous condition, irrational at times and with loss of control of the bladder and rectum. On the same day lumbar puncture was performed, and there were removed 33 c.c. of a slightly flocculent fluid, which contained 100 per cent. lymphocytes, albumin 2 mm., and no sugar. There were no tubercle bacilli found and cultures were sterile. July 8, patient was much brighter. There were internal strabismus and conjunctivitis of the left eye. Eyegrounds examined by Dr. W. S. Simmons showed extensive recent hemorrhages in the right retina; left retina was normal. Lumbar puncture was again performed and 35 c.c. of a reddish and cloudy fluid were removed. This contained albumin, 4 mm. ring, no sugar, and traces of blood. Cultures were sterile and the cytology was pus. Prompt improvement followed both lumbar punctures. This case was undoubtedly one of a true meningitis complicating uremia, and strikingly exemplifies the form recognized by the French clinicians as uremic meningitis.

Case V.—Syphilitic meningitis. E. W., female, age 35, admitted with frontal headache, double facial neuralgia, pain and rigidity of the neck, projectile vomiting, and Kernig's symptom. On the date of admission lumbar puncture was performed and 30 c.c. of clear fluid under high pressure were removed. The fluid was sterile and lymphocytes were present. There were an immediate and marked improvement and relief of the symptoms. Two days later, 25 c.c. of fluid under high pressure were again removed with a slight relief of symptoms. The Wasserman reaction proved to be negative. An examination of the eyes showed choked discs and retinal hemorrhages, which were clear evidence of increased intracranial pressure. The history of acquired lues was absolutely denied but hereditary syphilis was suggested by the presence of insanity in one brother and imbecility in the child of another. The diagnosis in this case could only be based with some probability upon the cytology of the cerebrospinal fluid: the excess of lymphocytes in the otherwise normal fluid was presumptive evidence of specific meningitis. She was accordingly given mercury and iodides and responded promptly to the treatment. The physical examination and the clinical history of this patient had been such that without the lumbar puncture no diagnosis could have been made with any degree of plausibility.

Case VI.—Traumatic serous meningitis. L. R., 16 years old, admitted March 28, 1909. Three days before admission, while playing baseball, he was struck by a ball on the left temple, was unconscious for a few minutes, was soon able to walk, and was brought home. Since the injury he complained of dizziness, was apathetic, had severe headaches, and vomited at frequent intervals. Soon after admission a lumbar puncture was performed and 45 c.c. of clear and sterile fluid were removed under high pressure. The effect was prompt: his dizziness began to clear up, the headaches diminished, and otherwise general improvement was evident.

Case VII.—Serous meningitis. R. F., 56 years old, admitted to the hospital March 27. I saw her for the first time on the morning of the same day. She was in a semicomatose condition, her face was puffed and bluish, her temperature 100.2°, pulse 110, respiration 26. Pulse was of high tension. She would answer questions quite rationally, but while talking would fall back in a heavy sleep from which she could, however, be aroused. Immediately upon admission a lumbar puncture was performed and about 50 c.c. of clear fluid obtained under high pressure. The pathological report was as follows: Fluid is clear with a few fine fibrin flakes. Albumen light with one mm. ring. Sugar pseudo reaction. Cytology revealed lymphocytes. No bacteria. Cul-

ture sterile. Following the puncture, improvement was quite marked, cyanosis less pronounced, respiration less labored, pulse stronger, patient less drowsy and otherwise more comfortable.

Case VIII.—Acute traumatic myelitis. S. W., male, three years old, was admitted August 2, 1907, with the history that on the evening of July 27 he had been kicked by a boy in the neck. For the next two days he had fever, was restless, could not walk, and had severe headache. The head was retracted. On admission he was in a condition of extreme opisthotonos. A slight Kernig's sign was present. Lumbar puncture was performed and 22 c.c. of a sterile fluid were obtained, showing 2 mm. ring of albumen, and a slight reduction of Fehling's solution. The diagnosis of this case was traumatic myelitis, and improvement promptly followed spinal puncture.

I have cited the above eight cases out of a large number in which lumbar puncture was performed in the various services of the Jewish Hospital. I have not referred to the cases of cerebrospinal and tuberculous meningitis in which the application of lumbar puncture is a routine procedure. My object has been to call attention to the employment of Quincke's method in cases presenting meningeal or cortical irritation, cases in which the withdrawal of cerebrospinal fluid not only had a decided therapeutic value, but also rendered possible the interpretation of many symptoms in the course of different diseases.

In concluding this modest sketch, I shall be content if I have succeeded in showing the valuable rôle that lumbar puncture is called upon to play.

From the survey of the literature and from my own experience, I believe I may be justified in drawing the following conclusions:

1. Lumbar puncture is a simple operation, practically devoid of danger if performed with due aseptic precautions.

2. Quincke's needles ought to be added to the armamentarium of every general practitioner.

3. The latter should not hesitate to perform lumbar puncture in any case in which symptoms point to meningeal or cortical irritation.

4. The cytological and chemical examination of the cerebrospinal fluid can be performed by the physician himself or in any well equipped laboratory.

5. An early application of lumbar puncture will clinch the diagnosis in many cases, in some will bring decided relief, and in a few will even effect a cure.

Finally, I must express sincere gratitude to my associates in the medical service, to the pathologist and his assistants, and to the past and present internes of the Jewish Hospital for their cooperation in the clinical investigations.

INSUFFICIENTIA PYLORI.

By Mark I. Knapp, M.D., LL.B.,

new york.

Anatomically speaking the stomach represents an inverted, tapering bag with the widest part up and the narrowest part down. The narrowest part, the pylorus, is the lowest part of the stomach and this fact plays the chief role in the genesis of insufficientia pylori. The chief anatomical structures of the stomach are the muscular and mucous coats. The function of each of these differs from the other. The muscularis does the muscular work, this is the dynamic function, and the mucous membrane does the chemical work of the stomach. Both functions are equally necessary and there is a supposition, not founded upon truth, that the muscular function is the more necessary. The dynamic function is effected by the contracting muscle fibers; this and the following relaxation of such fibers is termed peristalsis. Although different ef-

fects are produced by such contraction, the force itself is elicited from the self-same source, viz., the contraction and relaxation of the muscularis of the stomach. The closing of the pylorus, the grinding up of the food and the propulsion of the food into the intestines is caused by the same agency, viz., the alternate contraction and relaxation of the muscular fibers. The introduction into the stomach of certain chemical agencies excites the mucosa which again excites the muscular layer. The excitement invariably causes contraction of the muscularis and the duration of the contraction depends upon the degree of the irritation. The contraction of the muscularis is, therefore, the answer to an irritation of the mucosa. Contraction is the active response to irritation; relaxation of the muscle is not an active process. Contraction of a muscle fiber, and the shorter the contracted muscle fiber is arranged in a circle the contraction, the shortening, of such a fiber will produce a shortening of the diameter of the space formed by the circular arrangement of the muscle. Hence a contraction of the circular fibers will cause a shortening of the diameter of the space formed by the circular arrangement of the fibers of the muscle of the stomach, which means that the caliber of the stomach cavity will be diminished at the point where the muscle contracts. The stronger the irritation the stronger the contraction; the stronger the contraction the shorter becomes the contracted muscle fiber, and the shorter the contracted muscle fiber the shorter the diameter if the muscle fiber is arranged circularly. Since one layer of the muscle fibers of the stomach is arranged circularly, hence, the diameter of the stomach aperture—the caliber—of the stomach will be diminished in direct relation to the irritation. Thus an irritation of the stomach produces a diminished caliber of the stomach cavity. Save, possibly in very violent irritations, the contraction of the circular fibers of the entire stomach does not happen all at once, *en masse*, but the contraction proceeds upon successive bundles of the muscle fibers. We speak of the wormlike contractions. The contractions are rhythmical and travel towards the pylorus and, when the contracting cause and impulse have reached the pylorus, this also contracts in identically the same manner, *i.e.* the caliber of the pylorus is diminished. But, as the normal aperture of the pylorus is only about ¼ inch, the contraction produced here causes the entire aperture to disappear; it has the effect of an annular contraction which is spoken of as the closure of the pylorus. This should be well remembered. The closure of the pylorus is caused by the peristaltic contraction of the stomach reaching the pylorus, *no other agency closes the pylorus.* What causes peristalsis of the stomach causes closure of the pylorus, the peristaltic wave having reached that section of the stomach called the pylorus. The relaxation of the contraction causes the pyloric aperture again to reappear. It is absolutely wrong to speak of an "opening of the pylorus"; there cannot be an opening, there is a relaxation, a recoil, when the contraction ceases. The relaxation, the reopening, of the pylorus is of a passive nature and ensues when the force of the contraction is spent. Let us not speak of an "opening" of the pylorus, but of a "relaxation" of the pylorus: the pylorus does not open, the pylorus relaxes. The thorough understanding of that distinction has its clinical significance. The relaxation results as a matter of course after a contraction. The contraction of a muscle constricts the vessels which run between the muscle fibers or hems the onward flow of their blood, thus damming back the blood and dilating the vessel beyond the constriction. The stronger the contraction, or the more persistent the contraction, the greater will be the interference with the circulation. The very small vessels will occasionally not be able to stand the pressure and stretching occasioned by the constriction just mentioned, and will burst, causing appreciable hemorrhage. It would seem that the varicose veins of the stomach owe their presence to the strong contractions and consequent constrictions produced thereby. The contractions are caused by irritation of the mucosa and the intensity of the irritation determines the degree of the contraction. Such irritation may be present already the first day of our life, produced by fermentation of the mother's milk and which may be due to only overfeeding. If we reflect over such condition we can easily deduce that prolonged pyloric contraction in an infant a few days old may cause agglutination and this give the so-called congenital stenosis.

When food or drink is introduced into the stomach peristalsis ensues. The peristalsis drives the food toward the pylorus, also it closes the pylorus. The force and the duration of the closure of the pylorus depend upon the irritation produced by the ingested matter. The stronger the irritation and the longer its duration the firmer is the closure of the pylorus. The effect is that the ingested matter is thrown against the closed pylorus, but it recoils back into the stomach cavity with the relaxation of the gastric muscularis. This constant throwing back and forth of the chyme causes its maceration, and the longer this continues the greater and the finer will be the grinding up of the food. This might be termed gastric mastication. This gastric mastication goes on in every healthy individual to a greater or lesser extent and is best illustrated in birds. Birds eat grains for the breaking up of which they have no other means than their stomachs and when we look at a bird's stomach we see the immense thickness of the muscular layer, whilst the mucous layer compares with the human. Here we have an illustration teaching that the stomach is capable of grinding up of the food as well as an illustration of the fact that such work depends on dynamic power, wherefore the muscular coat is so much thicker than the muscular layer of the human stomach. The grinding, the cutting up of the food is begun by the teeth and completed by the muscularis of the stomach. The more thorough the dental mastication the less masticating work will be exacted from the stomach. Here it will be necessary to dwell on the fact that the grinding up of the food represents solely mechanical work of the muscularis of the stomach and that such grinding up of the food is not produced by the chemical action of the juices of the mucosa. This I have repeatedly and invariably found in experiments with artificial digestion. Although the anticipated chemical results took place, the artificial chyme was never finely divided. But a very fine subdivision of the artificial chyme did result after I had stirred it up with a glass rod. In two cases I was able to demonstate that the very fine subdivision of the chyme was not due to chemical action. In these cases I aspirated a large quantity after the test breakfast: the solids settled on the bottom of the beaker as a

fine "floury layer," yet these contents were absolutely neutral (no mucus was present).

The discussion so far is intended to impress that the distinct layers which make up the body of the stomach have distinct functions, that the chemical function is performed by the mucosa and the mechanical, the dynamical, is performed by the muscular layer. Any changes of a chemical nature must be located in the mucosa, any changes of a dynamic nature must originate in the muscularis. Those acquainted with the physical appearance of chyme do know that the healthy chyme is very finely divided and ground up. This is a fact and no philosophical theory. Another fact is that we, as a rule, do not cut up the food so finely with our teeth. Therefore this fine subdivision must have taken place somewhere between the teeth and the pylorus, and, as the food does not remain long enough between the mouth and the stomach, hence, the grinding up could not take place between the mouth and the stomach. Nothing else remains but to acknowledge that the grinding up of the food into that fine floury condition occurs in the stomach. Having thus reasoned out something everyone knows we have to answer the question how does that grinding up take place. The answer must be that the grinding up is effected by the food being acted on mechanically before it can escape from the stomach. Therefore, we must assume that there must be some means which stop the escape of the food and that during such time the chyme is grasped by two surfaces between which the grinding is done. If the food could escape at every contraction of the stomach we could never have the finely divided chyme. The fact that such chyme is present evidences the presence of something which stops the escape into the intestine and this something is the pylorus. Grain is ground up by the bird and this proves that the stomach can do it provided the muscle is strongly enough developed, as we find it in the bird. We must imagine that the grinding up is effected by the food being thrown against a closed pylorus by the contracting muscle and, as the pylorus is still contracted when the stomach recoils, the food drops back into the cavity of the stomach, only to be acted on again by the contracting peristalsis of the stomach. The elements which enter into producing that grinding up are the stomach walls and the pylorus. The fineness of the chyme will depend on the power of the grindstone and the duration of the grinding. The stronger they contract the finer the product and, *vice versa*, the lesser the power of contraction the coarser the chyme. Conversely, the finer the aspirated chyme the greater was the peristalsis and the coarser the chyme the less active was the peristalsis. We thus must judge the mechanical, the dynamical ability of the stomach by the state of the subdivision of the chyme. A chyme finely divided proves greater peristaltic action than a coarse chyme. Also, the finer the subdivision the oftener must the same particles have been subjected to the grinding action of the contracting muscles of the stomach wall. In order that this prolonged action could be exercised the chyme must have remained within the stomach, which means that an effective barrier must have presented itself at the outlet of the stomach which should prevent the escape of the ingested food from the stomach into the bowel. In other words, in order to finely grind up the food the pylorus had to remain contracted whilst the food was being thrown back and forth. The natural inference is that in order to produce the floury looking subdivision of the chyme the chyme must not escape from the stomach, it must be kept back in the stomach and this results when the pylorus remains tightly closed for a sufficiently long time. Conversely, the fine floury subdivision does show that the pylorus remained closed for a long period, during which the peristalsis of the stomach continued unabated. Clinical experience also teaches that finely divided chyme and large quantities thereof go together. And the explanation is that the same agency that causes the fine subdivision of the chyme is also responsible for the largeness of the quantity, namely, the pylorus remaining closed longer than is usual. The prolonged contraction of the pylorus retains a larger quantity of chyme in a given time. Also, through and because of the prolonged throwing of the food back and forth the chyme is finely ground up into the floury condition. Clinically the condition of the subdivision of the chyme must be taken to be the expression of the muscular activity and, *vice versa*, the coarser the chyme the less active was the muscularis. It also stands to reason that the longer the pylorus remains closed the less chyme will pass through it in a given time and therefore the greater will be the quantity left in the stomach the longer the pyloric contraction lasts. It must needs follow that the relation between the contracted pylorus and the quantity aspirated from the stomach is that the longer the contraction of the pylorus lasts the more chyme will be aspirated. But as the duration of the pyloric contraction depends upon the irritation we must conclude that the stronger the irritation the longer the closure of the pylorus, the greater the quantity of chyme in a given time; the quantity of the chyme depends upon the state of the closure of the pylorus. This reasoning leads us to the conclusion that the larger the quantity we aspirate the longer was the pylorus contracted and, inasmuch as the closing of the pylorus is effected by peristaltic motion and as a prolonged closure would mean a more protracted, stronger and severer irritation of the pylorus, therefore, the larger the quantity we aspirate the stronger was the pyloric contraction, the stronger was the peristalsis. Therefore the quantity within the stomach depends upon the peristalsis, the motility of the stomach. The more irritating the ingesta or the more readily the mucosa responds to irritation, the quicker, the more prolonged will be the closure of the pylorus. The longer the pylorus remains closed, the less chyme can be emptied beyond the pylorus, the more chyme will remain in the stomach in a given time. Consequently, the quantity of the chyme depends entirely on the relative state of the pylorus. *Whenever a large quantity of chyme is aspirated and the solids settle on the bottom in a layer of very fine subdivision, the "floury layer," we are dealing with increased peristalsis and a prolonged, spastic contraction of the pylorus and the pylorus is then in the condition of "stenosis pylori ab irritatione."* This last mentioned condition is the one which, in the first days of our life, may result in the coalescence of the spastically apposed and inflamed mucous surfaces, thus producing total occlusion of the pylorus. The greater the peristalsis, the motility, the stronger the contraction of the pylorus and the larger is the quantity aspirated. *When after a test breakfast we aspirate a large quantity such fact shows not only that there is no atony but proves the presence*

of the very contrary condition, the presence of hypertony.

Having come to the conclusion that a large quantity of chyme depends on an increased peristalsis the inference therefrom necessarily is that the negative of this proposition will be the cause of negative results. That is that diminished peristalsis will be the cause of a diminished quantity. When the increased irritations of the pylorus, when the repeated spastic contractions finally begin to weaken the pylorus, then a gradual relaxation of the pylorus sets in. This weakening and relaxation progresses until the stage has been reached when stomach and duodenum form one continuous canal, showing no line of demarcation and the ingested food passes from the stomach into the bowel by mere gravity. The transition period from the just setting in of pyloric relaxation until the supervening of absolute relaxation may occupy years in its formation, so that between the stenosis pylori ab irritatione and the complete insufficiency of the pylorus all the intervening gradations are seen. We must not assume that a complete insufficiency takes place over night. Accordingly, we find gradations as to quality and quantity of chyme corresponding with the degree of the insufficiency; the chyme gets coarser and the quantity gets less. A chyme which looks "spongy," "mushy," after being aspirated shows the early stage of the beginning of insufficiency and the quantity of such spongy chyme gives a guide in the estimation of the progress of the insufficiency. A spongy appearance of the aspirated chyme shows that the weakening of the pylorus has already begun.

We have accepted the Ewald-Boas test breakfast as the standard of comparison and, accordingly, wait one hour after the ingestion of the roll and water. The presence of chyme after one hour is interpreted one way and the absence of such chyme is interpreted a different way. Einhorn called attention to this last-named condition and introduced a distinct type of a gastric pathological condition based upon the absence of chyme after one hour and termed such condition achylia gastrica. Einhorn teaches not only that there are no contents or a scarcely appreciable quantity one hour after the test meal, but adds that such stomachs have no secretions at all and also adopts the synonyms of anadenia gastrica and atrophy for his achylia. Such teaching is erroneous. Those cases in which, according to Einhorn, the diagnosis achylia should be made because of the assumption of the absence of all glandular secretions show mostly good digestion and the presence of the expected chemical changes, if we aspirate the stomach sooner than one hour after the eating of the test breakfast. Such being the fact, we cannot call a stomach atrophic or suffering from anadenia if we find good digestion at an earlier period. If it is achylia gastrica or anadenia gastrica one hour after the test breakfast it is so at all times.

The existence of insufficiency of the pylorus is now recognized by others besides me, viz., Boardman Reed, A. L. Benedict, Palier, and others, but these still cleave to the achylia gastrica as well. Now, achylia gastrica and insufficiency of the pylorus are absolutely incompatible; there is no room for both; either the one or the other must go. I do not deny the existence of atrophy of the mucous membrane of the stomach, but I do deny the existence of achylia gastrica. Of course, I do not claim to have discovered insufficiency as such and in my first article I mention Ebstein as the real discoverer. But Ebstein is wedded to the idea that insufficiency is either due, as in his case, to retrogressive changes after cancer or to the mystery of all medical ignorance, to nervousness. What I claim is that insufficiency is the natural sequence of a previous pyloritis, that insufficiency follows the previous stenotic condition of the pylorus, that insufficiency of the pylorus is one of the most frequent causes of what so indefinitely and with bad grace is called indigestion, that insufficiency of the pylorus is hitherto the most baffling cause of many of the otherwise inexplicable phenomena of man's misery. It was my dissatisfaction with the result of the orthodox treatment of achylia gastrica that caused me to inquire into the conditions of the stomach. Had my patients recovered under the treatment advised for the achylia I am almost sure I would still be an ardent supporter of achylia. But, unfortunately, there is no cure for achylia.

Diagnosis.—When, one hour after the test meal has been eaten, the aspiration yields either no contents at all or one or two cc. of coarse pieces imbedded in mucus the diagnosis of insufficientia pylori is to be made. If no contents at all are aspirated it becomes our duty to search further, and this with double purpose. First we must ascertain the degree of the relaxation of the pylorus, and, secondly, we must make sure whether there is no glandular activity left in the stomach. This is accomplished by giving the patient repeated test meals, one day after the other and shortening the time of waiting between the eating of the test meal and the aspiration by 15 minutes. If we can aspirate no contents even 15 minutes after the eating of the test meal we have the patient come the following morning and, after the test meal, have the patient lie down on his left side for 15 minutes. Very often the stomach, which had no contents the previous day, after 15 minutes, will yield some contents now, when the posture of the patient is changed from the upright to the horizontal. But also this may prove unsuccessful and the patient is made to come again the following day and is now given a coffee test meal, which consists of 200 c.c. of a black infusion of coffee (the coffee should be made strong) and 35 gm. of plain, unbuttered, fresh roll (the roll should be only of flour and water). After this coffee breakfast the patient again lies down, as on the previous day, for 15 minutes. If there is no complete insufficiency, if the pylorus is still capable of answering to stimulation, the coffee will do it. I will here insist that the test meal shall be of nothing else than roll and water and that the test meal shall be eaten in the office of the physician. The roll should be exactly weighed and the water, 300 c.c., shall be exactly measured by the physician. Under no circumstance, if the physician expects to get good results, satisfactory to himself and patient, should the patient be allowed to have a slice of bread and a glass of water or tea at home and come thus prepared for the examination. Such a procedure is a fraud upon the patient and upon the general practitioner who seeks the advice of the specialist. First of all it is the duty of the specialist to positively ascertain whether or not the stomach is actually empty after the prescribed fast of 14 hours. The stomach may or may not be empty; the stomach may have food from the day or even days before; it may be a case of gastroxynsis; the stomach may contain a quantity of mucus; it may

contain quantities of mold. The patient is entitled to get all this information, he pays for it. So is his physician entitled and both the patient and the physician are deceived if they do not get such information. Again, a slice of bread in one case need not necessarily be of the same weight as the slice of bread in another case. The same holds good with respect to the quantity of water. Under no condition should the patient get anything else than water; the black tea, which a good many allow, does cause contractions of the stomach and, besides, already introduces organic acids. Absolute exactitude should be demanded of the specialist; guesswork can be done by the general practitioner himself without the aid of the specialist and without paying for it. One must not expect exact results from inexact methods, unless he intends to palm off on the patient or general practitioner the famous diagnosis, "nervous dyspepsia." Furthermore the very exercise of the walk or ride from the patient's house to the physician has its influence upon the action of the stomach.

The fact that I could aspirate some contents, if the patient lay on his left side, when there had been no contents the day before when the patient was in the usual sitting posture shows that the posture had a decided influence. One surely would not dare assert that the "hypermotility" which is made to explain the absence of the chyme in the stomach, operated only in certain positions of the body. My intention in changing the position of the body is to change the lowest point of the stomach. In the sitting or standing posture the pylorus is the lowest, but when one lies down on the left side the lowest point of the stomach is shifted to the fundus. Therefore, the ingesta gravitate to the fundus in the last-mentioned position, but they do gravitate past an open pylorus in the normal sitting or standing position. We have in this change of position a positive proof of the operation of the purely physical principle of gravitation in an open pylorus. This fact must be impressed on the physician, that the mere change in the posture produces a vital change in the gastric manifestations. Sitting or standing, the picture of achylia; lying down and there is evidence of digestion. It is hardly conceivable that the gastric mucosa, atrophic in one position of the body, magically regains the lost glands if the posture of the patient be changed. To counteract gravity is why I place the patient on his left side. To find chyme then when there was none when the patient was sitting sufficiently testifies to the correctness of the view that the escape of the ingested matter through the pylorus was not due to anything else but gravity. If nothing else, this test alone is sufficient to prove the existence of the insufficiency of the relaxed condition of the pylorus. Another test for the diagnosis of the insufficiency is the inflation of the stomach by carbon dioxid or ordinary air. The first is done by giving the patient half a teaspoonful each of tartaric acid and bicarbonate of soda; each chemical is given in half a glass of water separately, and each is drunk separately, one after the other. Ordinarily the gas evolved will distend the stomach. But if there is insufficiency the gas escapes beyond the stomach and fails to distend the stomach. The same result is obtained by inflating the stomach by means of the double rubber bulb.

Insufficientia pylori has had to stand the test of time and until the appearance of Moullin's article ("Pyloric Stenosis and the Conditions of the Pylorus During Life," *Lancet*, Jan. 19, 1907), five years after my first publication. Moullin tells us that he has made it a practice to examine the condition of the pylorus whenever the opportunity presented itself during laparotomies. He writes: "For some time past, whenever I had occasion to open the abdomen for the purpose of operating upon the stomach, I have made it a practice to examine the pylorus as thoroughly as I could. I found that the size of the pylorus varied from that of a channel, which could easily admit three fingers, to that of a tiny orifice. The former was in a patient of whom the pylorus was so indefinite that it was difficult to find. The sphincter could scarcely be felt, and the stomach and intestine seemed to form one continuous canal without a break." Moullin, apparently, was not interested in insufficiency, but he says: "Between these two (the channel wide pylorus and the pylorus in which the orifice could scarcely be felt) I have met with every grade." In other words, based on actual experience of laparotomies and autopsies, and therefore based on indisputable evidence of facts, not theories, Moullin asserts exactly what I had repeatedly stated, that there is a channel wide pylorus, hence there is the actual presence of the insufficiency which I have been preaching since 1902, and that there are several stages of insufficiency, at which conclusion I arrived not from autopsies, but from reasoning and deductions from clinical facts.

As to the etiology of this disease we need think only of that: what will cause a pyloritis will subsequently if not checked terminate in an insufficiency. The chief causes are: 1. Organacidia gastrica; 2, Chronic alcoholism, and 3, deficiency of teeth. In a recent article "Does zymosia gastrica solve the problem of tuberculosis?" (*N. Y. Med Jour.*, Aug. 7, 1909), I have found in a series of 100 unselected cases that came to the Tuberculosis Clinic of the New York Board of Health 78 patients to have insufficiency of the pylorus. Whether tuberculosis enters as an etiological factor is as yet hard to say. But it is surely worthy of note that 78 per cent. did have such a condition and therefore, in a case of pulmonary tuberculosis complicated by digestive disturbances, insufficiency of the pylorus might be presumed to be present. Anything which will cause an irritation of the pylorus will, if long continued, produce an insufficiency.

The symptoms of this condition can be summarized under two headings:

1. Symptoms which arise from causes within the alimentary canal and, 2, causes from without the alimentary tract. The causes operating within the alimentary canal may be of either a chemical or a physical nature or of both. The causes which operate outside the gastrointestinal canal are of a physical nature and due, mostly, to pressure exercised upon the neighboring organs. It is to be observed that the insufficiency per se gives no symptoms whatsoever. The symptoms are elicited from the fact that the relaxed pylorus permits of the passage of food from the stomach into the intestines in a condition entirely not contemplated in the anatomical make up of the body. True, medicine borrows from the charms of poetry and assumes that the bowel will assume "vicariously" the office of the stomach. But such assumptions have no basis of facts to support them. A little meditation over facts, as they are, will preclude such violence to be pepetrated against the laws of chemistry. The stomach digestion is acid, the intestinal

digestion is alkaline. Foods, being in their last analysis only chemical compounds must need be acted on differently by acids than by alkalis. The component chemicals of what makes up food and which are acted on by acids could not possibly yield the same result as when acted on by alkalis. The rudimentary laws of chemistry are set against such familiarity as exchange of courtesies. Neither has anyone yet been able to prove the existence of an alliance between the stomach and the bowel. If the food now enters the bowels without having been properly prepared certain changes must occur in the food for the very reason that such food elements which require the acid or pepsin digestion cannot be acted on by the alkaline digestive juices of the bowel without deleterious manifestations. This so-called intestinal indigestion is manifested because of the formation within the bowels of noxious chemicals of a solid, liquid or gaseous nature. Their effect is irritation of various degrees of the mucous membranes and distension of the bowels.

In accordance with the severity of the irritation the symptoms will vary from a slight and undefined uneasiness to rawness, burning, severe pains, spasms and colics. The overproduction of gases within the bowel gives the sensation of hollowness and sinking, if the quantity be moderate, and the sensation of painful stretching, fullness, dead weight, if the quantity of the gas is large. The causes for the symptoms which operate outside the intestinal canal are due to the laws of physics and are produced by pressure upon adjacent structures or by pulling. This latter condition obtains when the bowels, due to their being overdistended, pull away from their moorings and in so doing pull taut the mesenteric attachment to the spine, producing pain in this region which is referred by the patient to the loins.

Summarizing, the symptoms usually are as follows: Headache, vertigo, anorexia, nausea, dryness in the throat, burning in the mouth, bitter taste, especially in the morning, eructation, singultus, a choking sensation in the throat, weight, pressure, weakness or pain in the region of the stomach, shaking or running around in the bowels, flashes of heat and cold, constipation or diarrhea, painful breathing, palpitation, fainting or fainting sensation, sharp pains above the heart, tenesmus, pain in the sacral region. Of all these symptoms I wish to explain in detail the cause of the diarrhea, fainting, sharp pain in the region of the heart, and the tenesmus. These symptoms are complained of most frequently and have been so variously and erroneously interpreted. It is usually assumed to be due to "nervousness." But the true cause for the diarrheas, which in one of my cases had lasted for over 8 years and gave the patient admonitions of the presence of his bowels of from 10 to 20 times a day, is the presence and formation within the bowel of organic acids, which acids also produce the tenesmus and the pain in the sacral region. The palpitation, fainting, the sharp pain over the region of the heart, are due to pressure against the heart by a strongly inflated bowel or stomach or of both through the diaphragm. The heart is somewhat pyramidal in shape with the apex down and rests upon the dome-shaped diaphragm. A distension of the bowels or stomach pressing upward against the diaphragm will and does produce the pressing of the heart against the unyielding chest: the heart is squeezed, like in a vise, and the heartbeats now become perceptible both subjectively to the patient and objectively upon the abdomen. The sharp pain in the heart is due to the compression of the coronary artery produced by its being pressed against the chest wall; just as soon as the pressure ceases after copious eructations the pain in the heart also ceases. The fainting and faintness are likewise due to compression of the heart by the gases just mentioned. There is one more symptom, very frequently present in insufficiency of the pylorus, that is the excitability, the "nervousness" of the patient. My explanation to my patients, which has always satisfied them, is this: We must realize that the nervous system is not a special and separate organ and that it does not get its nourishment from outside the body, but, on the contrary, is part and parcel of our own bodies, deriving its nourishment from the same sources as the rest of the body. If now, the nourishment is bad, because of the insufficiency, how could we expect the nervous system to make an exception and not suffer with the rest of the body? Why, it stands to reason, without delving into the many occult mysteries that the nervous system suffers equally with the rest of the body, because of getting no better nourishment. It is not a case of "nervousness" but of the suffering of the nervous system together with the rest of the body.

The prognosis is very favorable. Once the disease is recognized and the proper medication instituted there is no failure. Indeed, betterment occurs too soon, often within 36 to 48 hours without the use of any of the so-called symptomatic treatment. My experience has proven that getting better too soon is not good for the patient. But I could not possibly or conscientiously do otherwise. I always warn my patients not to overbear and not to get "fresh," to use a select expression. Patients who had suffered for a great many years, in one case over 40 years, and who had to go on a starving diet or suffer the consequences after an inroad of a meat diet, began to feel well very shortly. Pain and distress begin to disappear almost at once; but absolute recovery, *i.e.* the return of the contractility of the pylorus, takes several months. The younger the person the sooner the recovery.

Treatment.—I believe that a little of the history of my treatment will be appreciated. When one examines the stomach contents, if there be any left, and finds the absence of free HCl., one is at once tempted to supply that deficiency. Such also is the teaching of achylia which I had faithfully followed. Somehow or another I found that patients did not care to recover under such treatment. Finding myself baffled and the patients gone to seek other advice I resolved to try a novel trick. I argued that, if the stomachs are so refractious and do not care for my ministrations, I shall disregard them altogether and see what I can accomplish by catering to the bowels. I had no distinct idea what might follow; my wish was to help my patient, indirectly if not directly. Lest I forget it I wish to state here that this reasoning took place before I evolved the presence of the condition of insufficiency. Of course, my treatment now had to change from acid to alkaline, agreeably to the dictates of physiology. Such is the history of the alakaline treatment of insufficiency of the pylorus which has given me most excellent results.

The treament for the insufficiency of the pylorus is alkaline. The most prominent of all alkalis is our

old standby, bicarbonate of sodium. Next is magnesia and, in conjunction with these, rhubarb and pancreatin. Ammonium chloride might be tried, so also asafetida. Bismuth and bicarbonate of sodium, of each ten grains, can be used occasionally. With the so-called intestinal antiseptics I have no experience; I get along excellently well without them. If we find that the insufficiency is not very far gone, if there is good digestion about half an hour after the test meal, we might find it work well to prescribe some bitters with HCl. before meals: Cinchona, condurango, gentian, nux vomica. But, if the insufficiency is far advanced, if even 15 minutes after the test meal no contents are found in the stomach, then the bitters, especially the nux vomica, should be given before meals without the HCl. It is absolutely necessary to be sure when to administer the alkalis and this can be ascertained only after repeated test meals. We certainly do not want to interfere with what stomach digestion is still present by giving the alkalis too soon and thus destroy the gastric acidity. But if the occasion warrants the alkalis should be given right or soon after meals. The same drugs, and the same doses act differently if administered at an improper time. I do not wish to give the doses of these drugs, as the dose will vary with the individual and with special condition under which the individual patient may live; every physician should find this out for himself. Different environments, different races, different physical conditions, different altitudes, different climates require different dosage, nay, and different drugs for the same pathological condition. There are two drugs which are not always fully understood and appreciated by the profession. These are atropine and strychnine; both should be pushed to their physiological limits. The usefulness of each drug is well defined. Atropine, in gas distension, and strychnine in insufficiency without gas distension. A less reliable guide is to use atropine when HCl is present and strychnine when HCl is absent. In the chronic diarrheas which I have mentioned before, strychnine acts as a specific. I seldom begin with less than a twentieth of a grain of strychnine and increase up to the point of tolerance. In the chronic diarrheas I try to reach a very large dose as soon as possible, and I have given in such case one-sixth of a grain three times daily; I try to reach that dose at about the end of the second week. I have always cured the chronic diarrheas, of years' standing, in less than four weeks. I proceed at once with the following old mixture: Fluid extract of hematoxyl, eight drams; aromatic sulphuric acid, two drams; paregoric, an ounce and a third, and syrup of ginger, up to six ounces. Of this a tablespoonful is to be given every two or three hours until the diarrhea has stopped, which usually happens after a few doses.

The question of diet is of great importance and whilst the diet which is permitted is quite liberal, certain restrictions are absolutely essential. The principle underlying the diet is to avoid ingestion of irritating food or of food which easily becomes irritating when within the alimentary canal and also to avoid such food and drink which contain or form gases. Therefore the prohibited list should contain all spices and seasoning, sour pickles, sourkraut, dishes which are prepared sour, all sorts of salad, tea, coffee, chocolate, cocoa, too much salt, meats fried in animal fat, bread baked with the bran, as Graham bread, whole grain bread, beans, peas, cabbages, barley, oatmeal, hominy, all fruits in whatever style they may be prepared and served. I must also warn against the use of much milk. My objection, verified clinically, to whole grain bread, cabbages, and other cereals which are eaten with the cellulose, is that the cellulose ferments and forms irritating gases. Milk also forms gases. Fermented liquors as beers and wines must be forbidden. Distilled liquors do not ferment and therefore do not form gases; they can be taken well diluted. I do not mean to advise it, but occasionally, when the patient does crave it it may be allowed. Where the patient has defective teeth, this must be remedied artificially. If the patient is too poor then he should have his cereals and vegetables cooked, well done, in the form of puree and the meat should be chopped very fine either with an ordinary knife or with the food chopper. I usually have the patient prepare the meat the way he likes it, then have it chopped fine and then mix it with the gravy. Objection is met with when stewed fruits are forbidden, because of the fact that we have grown up in the belief that such fruits are good for the bowels. This comes from the fact that we had not stopped to inquire into the modus operandi. The fruits do act on the bowels, because of the acids which they contain and form. It is these acids which whip the already overworked bowels into forced activity.

After eating the patient should lie down either flat on his back or somewhat inclined on his left side; not on his right side. The object of this is to keep the food away, by gravity, from the pylorus. On lying down the food gravitates toward the fundus, especially so if the patient lie on his left side. Neither in this nor in the ordinary condition should the person, if he can help it, walk after a meal; everyone should, if he can, lie down and rest after a meal; the animal does it instinctively.

Extragastric faradization and cautious massage may prove of benefit in many cases. Where there is much mucus, lavage should be practiced until the stomach is clean.

If one follows the instructions here given as to diagnosis and treatment, which are based upon a scrutinizing experience of some ten years and upon hundreds of successful cases, one will soon find an ever more restricting number of neurasthenics, hysterics, and nervous dyspepsias.

616 Madison Avenue.

SOME PECULIAR RESULTS OF EYE-STRAIN.

By WILLIAM MARTIN RICHARDS, M.D.,

NEW YORK.

The first time a fellow practitioner suggested to me the possible ocular origin of some constitutional disturbances I told him he was crazy, but have since come to the unflattering conclusion that I was speaking of the wrong man, as the results in the following cases are unquestionable and the names and addresses of the patients at the disposal of any doubting Thomas who may still hold opinions similar to those I once held.

Disorders of Sleep.—Whenever my patients complain of sleepiness or sleeplessness I make it a rule to examine their eyes, and the correction of any refractive errors almost invariably relieves such symptoms.

Case I.—My own. My entire family will sleep

ten hours if allowed. Several months before my term of service expired at Bellevue Hospital I had to leave the staff, as I had become so run down as to contract typhoid fever. Up to the time I put on glasses unless I went to bed at 10 P. M. I could do no intellectual work the following day, and on attempting to read or study anything at all difficult would become mentally confused, feel tired, and have to cease work. I do not remember having any headaches or pain in the eyes, and considered my eyes extremely good for I could see every bullet hole on a target at sixty-five yards. At my request the assistant professor of eye diseases in the medical college which I attended examined my eyes by means of test letters without a mydriatic and informed me that I might be a little far-sighted, but that he would not advise glasses. All through the medical school I would occasionally get to a point where I could not work any longer, and, unable to sleep, would finally cure myself by spending a day in the open air riding a bicycle. On leaving the medical school I entirely ceased all studying, and practically never resumed it until I put on glasses. I slept nine hours every night if possible, and unless at work, would take an hour's nap in the afternoon. These periods of sleepiness were frequently replaced by fits of insomnia, particularly if doing much work, so that on retiring there was always the haunting apprehension that I might lie awake the greater part of the night. Often I woke up at one o'clock in the night and was unable to sleep again, although I was apparently in the best of health. After beginning the use of a mydriatic the results were so surprisingly different and better than without it that, in spite of the fact that I had 20/10 vision with either eye without glasses, it seemed best to take a dose of my own medicine, and on testing my eyes with a mydriatic, which had never been done before, I was surprised to find that, under the mydriatic my best vision was O.D. + .75 + .37 cyl. axis 75, O.S. + .75 + .25 cyl. axis 90. On wearing the cylinders I not only could study all day, but actually wanted to study all day, and now I sleep on an average seven hours and a half out of the twenty-four, with no inclination to sleep during the day.

Case II.—Man. Age thirty-four. Bookkeeper. He telephoned me on September 9 that he was drinking heavily and for the first time in his life was unable to stop. He also said he had been unable to sleep for two nights. I emptied the stomach with a hypodermic of apomorphine, and within the next thirty hours he took 960 grains of bromide of ammonia, 2½ drachms of antipyrin, and 1 pint of liq. ammon. acetat., during which time he was still unable to sleep. As he wished me to fit him with glasses, and I intended doing so the following day, I determined to try the effect of paralyzing his muscle of accommodation, and instructed the nurse to instil in his eyes every seven minutes for one hour one drop of the solution which I use for mydriatic tests. This was done from 8:45 P.M. till 9:45 P.M. At 11:15 he dropped asleep and slept till 9 A.M. the following day. His correct refraction was: O.D. —1.37 +1.87 cyl. 100, O.S. —.87 +1.50 cyl. 87½. A letter from him a few days ago says that he has had no trouble since.

Case III.—Man, twenty-five years old. University instructor. All his life a long sleeper. He consulted me in November, 1908, for a small posterior polar cataract, slightly on one side of the center and not interfering with his vision at all. He was wearing: O.D. —5.0 —.50 cyl. 180, O.S. —.50 —.50 cyl. 180; on being fitted with: O.D. —6.0 — 6.2 cyl. 180, O.S. —.75 cyl. 175, he has ever since slept but eight hours each night instead of nine and a half or ten hours as formerly.

Many other cases could be mentioned, but the above seemed to me to indicate the possibility that one of the principal functions of sleep may be the resting of the muscle of accommodation of the eye.

Posterior Nasal Catarrh. For several years after graduation I saw so many unsuccessful results in the treatment of catarrh that I came to the conclusion that it was incurable, until I sent several cases to a specialist who cured them with a double inferior turbinectomy. Four years ago I began to do this operation myself. Most cases of posterior and anterior catarrh recovered, but occasionally a case would be quite relieved in every way, but would still have considerable discharge in the posterior nares, and accumulation of mucus in the nasopharynx in the morning, which no treatment seemed to relieve. In all cases of this kind in which I have tried it, correction of existing ametropia entirely relieved these symptoms. Following are the histories of three cases:

Case I.—Man, age thirty-two. Foreman in phonograph factory. Was brought to me by his dentist to remove his nasal stoppage, in order to relieve the lateral crowding of the teeth, caused by mouth breathing, as free nasal breathing was necessary to ensure the permanency of the dental work. Two months afterwards the dentist telephoned me that the nasal stoppage was entirely relieved, but that the patient had considerable postnasal catarrh. I examined his eyes and prescribed: O.D. +.12 +.37 cyl. 70, O.S. —.12 +.50 cyl. 78. In one week the postnasal catarrh disappeared. It invariably returns if he breaks a lens and lasts until the lens is replaced.

Case II.—Woman, age thirty-seven. Came to me for catarrhal deafness. I performed a double inferior turbinectomy, and fitted her with glasses. She recovered her hearing entirely, but she had 6° esophoria. I put 3° prisms, base out, in each eye. This gave her an immense amount of postnasal catarrh, which returned to normal on removing the prisms.

Case III.—Woman, age thirty-one. I performed double inferior turbinectomy on her in February, 1907. For the past year she has been wearing glasses for compound myopic astigmatism. She says she always knows when her glasses need changing because she then has postnasal catarrh, which disappears as soon as the correct change is made in her glasses.

Hoarseness.—Case I.—A girl of thirteen consulted me on July 29, 1908, with the following history: She had been quite well up to five years before when, while reading, she suddenly felt short of breath. She always had to sit in the front row at school to see the blackboard. These symptoms continued until the previous April, when she became very hoarse, and this condition remained unchanged in spite of all attempts to relieve it. With test letters she could see 20/100 with the right eye and 20/200 with the left eye. As well as I could ascertain on account of her amblyopia her refraction with a mydriatic was: O.D. —1.75 —.50 cyl. 170, O.S. —2.50 cyl. I ordered this correction. She objected to glasses unless they had gold frames, which she was then unable to buy. On the 11th of August, as she had

considerable nasal catarrh, I advised that double inferior turbinectomy should be performed, feeling sure that the reestablishment of nasal breathing would correct the congestion which I found in the vocal cords. I was greatly surprised that the voice did not improve, as she had perfect health and no signs of tuberculosis of the lungs. In the following October her hoarseness was as bad as ever, and she finally bought glasses. Shortly afterwards her sister informed me that the girl's voice became as clear as ever within a week after wearing the glasses. Her voice remained clear and was still so to date of writing (January, 1910), in spite of the fact that her refraction had changed slightly.

Case II.—Woman, age twenty-two. Vaudeville actress. Came to me in June, 1909. Her family for four generations gives a history of migraine. The mother at sixty-one years of age began to lose her vision from cataract, and at the same time her voice, previously very good, became so husky that she was unable to sing at all. The patient's voice, a soprano, had been perfect up to six months before coming to me when she noticed that it was not as good as usual, and three months later on singing a high note, previously very easy to her, she felt she did so with difficulty. Two or three days after that her voice became husky and it remained so up to June 10, when she consulted me. On account of this she and her husband had been obliged to cancel their engagements. I found that she had very large inferior turbinates, the left one entirely occluding the nostril. I performed double inferior turbinectomy, and because of my experience with Case 1, told her she must wear glasses when not on the stage, although her visual acuity was 20/15 in either eye. The day following the operation she was able to sing as well as ever. I then made a mydriatic examination of her eyes and informed her that unless she wore glasses she would soon lose her voice again. She came back for the postmydriatic test June 14, when I gave her the following prescription for spectacles: O.D. —.37 cyl. 10, O.S. —.37 —.25 cyl. 180, which, however, she did not have filled. The following Monday she and her husband took another vaudeville engagement, and her voice was as good as ever for the first two days. Soon, however, it began to grow husky again, and by the third day she was unable to sing at all. The next day she bought the spectacles and at the end of the week her voice was again as good as ever. She wears her glasses constantly when off the stage and has never again lost her voice. This year the vaudeville manager who sent her to me informed me that she and her husband were now earning $700 a week, instead of $450, which they received the year before.

Case III.—Woman, age forty-six. Singer and vaudeville performer. Soprano. She consulted me on the 25th of June, 1909, complaining of headaches and catarrh. The headaches she had had ever since she was a child, and at one time, when teaching school, she had had every Thursday an attack of bronchitis. Five years before she had been fitted with O.D. + 1.0, O.S. + 1.12 for reading, and was wearing them when she came to me. I performed double inferior turbinectomy and gave her the following prescription for glasses: O.D. —1.0 —.25 cyl. 20, O.S. —.37 —.12 cyl. 165, B.E. —1.87 added for reading. Her health, which had been very poor, improved and she has had no trouble since in getting engagements; but whenever she stops wearing her glasses for any length of time her upper notes begin to break and catarrh returns. These symptoms immediately disappear when her spectacles are straightened and she wears them always except when on the stage.

Asthma. Case I.—Woman, age twenty-two. Dressmaker. Consulted me on March 19, 1909. She never remembers injuring her nose. Ever since she can remember she has had what she calls a cold and difficulty in breathing, which has kept her awake most of the night for the greater part of the last seven years. Seven months before she had a spur removed from the septum on the right side and since then she has breathed a little more easily through that side. I removed two-thirds of the inferior turbinates, and the portions removed were the largest I have ever seen, that on the left side being as large as two-thirds of my ring finger, with enormous cauliflower excresences on the posterior end. She returned to me on the 28th, up to which time there was no improvement in the asthma, and her breath was exceedingly foul. At this visit she informed me of continual headaches, which she had had for years. This I got through her interpreter as she does not speak English well. I told her to come back and let me examine her eyes under a mydriatic, which I did the following day, and on April 10 I prescribed: O.D. + .37 + .37 cyl., axis 100, O.S. +.87 +.12 cyl., axis 105. The same day she bought her glasses and returned to me for their examination. At this time her asthma and breath were as bad as ever. She came again on April 18, at which time the breath was normal, and the asthma had entirely ceased. She sent me another patient on September 12, who informed me that she has had no asthma since wearing the glasses. On June 7, 1910, she returned with the old symptoms. On examining the glasses I found that the frame of her glasses was bent in such a way as to entirely change the axis. I straightened the glasses and up to date she is perfectly well again, and her symptoms only appear when the axis is wrong. She informed me to-day that she only wears the glasses when she is at work or is reading.

Case II.—Woman, age thirty-three. Height, 5 feet 6 inches; weight, 130. Miniature painter. Father suffered from asthma from the time he was seven years old until his death at fifty-two from kidney trouble. All of the family have had more or less trouble with their eyes. Patient's asthma came on after an attack of chicken-pox at seven and has continued ever since. Up to a few years ago she had it both day and night. Since that time she has had it only at night. Has tried various climates and had been treated by more than fifty doctors without relief. Has tried every variety of "cure" from starvation to Christian Science. For twenty-six years has had an attack of asthma immediately on retiring which would last until she used an inhalation. Three or four hours afterwards she has another attack, for which she has to use a second inhalation, and still another at daylight when she must either use the inhalation again or get up for the day. Consulted me not for asthma, but for red eyes, from which she suffers after any prolonged near work. Her mydriatic examination the 4th of December, 1909, was: O.D. +1.75 +.62 cyl. 95, O.S. +1.87 +.62 cyl. 85. That night she had no asthma for the first time in months. At the postmydriatic test she could accept nothing stronger than a cylinder in the right eye and a +.12 and cylinder in the left eye. During the succeeding week she accepted O.D. +1.0 +.62 cyl. 95, O.S. +1.12 +.62 cyl. 85. Since that time she has had

only a few mild attacks of asthma, once when her refraction changed and several times when the frame of her spectacles became crooked; thus changing the axis of her astigmatic lenses. In the first instance the asthma disappeared with the proper change of glasses and on the other occasions merely straightening the frame brought complete relief. Incidentally this result was as great a surprise to me as it was to the patient.

Case III.—Man, age thirty-four. Court clerk. Has had attacks of asthma ever since he was ten years old. While on a visit to New York City he noticed that during his stay he was entirely free from this disease. His father, who had had asthma for forty years, had been relieved by my performing a double inferior turbinectomy on him, and without correction of the errors of refraction. The patient, however, was unwilling to be operated on. He was offered a good position in a hotel near his former home, but as he invariably has asthma on returning there, he was compelled to refuse it. He brought a friend to me to be fitted with glasses and remarked that with the glasses he himself was wearing he could see only very few of the test letters at twenty feet. I found that the glasses were: B.E. +.50 cyl. 90. with which he had vision R. 20/200 L. 20/100. Under a mydriatic I prescribed O.D. —.37 —3.25 cyl. 180, O.S. —.50 —2.12 cyl. 5, and since that time he has spent four months at his former home, and the rest of the time in the West, without suffering from asthma. This I learned from a letter written from Montana, January 16, 1910.

Indigestion. My experience the last few months has convinced me that many digestive troubles, especially in children, are due to ametropia.

Case I.—Male, age eight. From the time he was born he has always suffered from sour stomach and abdominal cramps, which sometimes became so severe that his family often thought they would eventuate in his death, and which were entirely uninfluenced by the efforts of the family practitioners who attended him. On correcting his compound far-sighted astigmatism with: O.D. +.25 +.37 cyl. 90, O.S. +1.0, his indigestion entirely disappeared and his breath became normal in odor.

Case II.—Female, age twenty. Bookkeeper. At the time she was a schoolgirl of thirteen she began to have pain in the eyes and indigestion. She was fitted with glasses without a mydriatic, which did not benefit her at all. At fifteen she began to have attacks of what was apparently gastritis, with nausea and vomiting, and these attacks she has had at frequent intervals ever since. She was wearing far-sighted glasses when she came to me and on correcting her compound near-sighted astigmatism with: O.D. —.50 —.12 cyl. 150, O.S. —.12 —.25 cyl. 30, every disagreeable symptom disappeared.

Case III.—Female, age seventy. Housewife. Consulted me in February, 1909, for headaches and frequent attacks of acute indigestion, in several of which she and her family expected her to die. On fitting her with bifocal spectacles containing O.D. +1.25 +.25 cyl. 102, O.S. +1.37 +.62 cyl. 60, B.E. +2.87 for reading, all her symptoms disappeared except the indigestion, which recurred about every three weeks. I persuaded her to return to me in July and found that her spectacle frame was bent in such a way as to entirely change the axis of the cylinders. On straightening this she has since had no indigestion up to this date (June, 1910).

Conclusion. We have all had cases that seemed to be somewhat relieved for the time being by whatever therapeutics we employed, but that never were really cured by any treatment. As I look back on my years of general practice, before becoming a specialist, I realize how many patients I might have permanently cured had I then known as much of the constitutional effects of eyestrain as I do now—patients the cause of whose trouble I could never find. Where every other treatment has failed in such cases, would it not be well to try the effect of correcting any existing errors of refraction under cycloplegia? The cases above quoted seem to me very suggestive and I submit them in the hope that perhaps they may help some fellow practitioner to find the cause of, and cure for, such chronic and obscure maladies as we have all met in our practices.

Broadway and Ninety-seventh Street.

TECHNIQUE OF EXAMINATION OF THE DUODENAL CONTENTS.*

By MAURICE GROSS, M.D.,
F. VON OEFELE, M.D.,
AND
MAX ROSENBERG, B.S., M.D.,
NEW YORK.

The examinations were made with the duodenal tube devised by Gross, published in the *Journal of the American Medical Association* for April 23, 1910. All the chemical examinations were made in the laboratory of Dr. v. Oefele.

Preliminaries.—(1) Record name, anamnesis, or clinical diagnosis, and journal number of the test sample. (2) For all examinations, note day and hour when the intestinal juice is taken, recording the time of the beginning and of the completion of the aspiration as well. (3) Record the distance, in centimeters, at which the intestinal juice is taken—as indicated by the length of the duodenal tube measured from the line of the teeth. (4) Note the time of the ingestion of the last meal and the nature of the meal.

Physical Examination.—(5) The total quantity is measured in a graduated tube of 100 c.c. capacity. (6) When pouring out the fluid, attention should be paid to the consistency of the juice; whether it be fluid, slightly or markedly viscous or ropy. (7) Also note whether a special kind of smell can be detected. (8) The degree of permeability to light should be noted, as to whether the juice is transparent, cloudy, diaphanous or impenetrable. (9) The color of the diluted juice should be stated. (10) In view of the fact that bile pigment has the peculiarity of staining very intensely, even when strongly diluted, it is important to note the color of a fourfold dilution with water.

(11) The specific gravity should be determined. This is of great importance and more difficult than with other substances. The specific gravity varies only in narrow limits, between about 1000 and a little over 1010. The quantities obtained are often only small, so that it may be necessary to work with about 15 c.c. or slightly more. Furthermore, the fluid being generally very viscous, the instrument registers slowly. We were unable to find a suitable areometer in the market and, therefore, had to have special instruments made; these will be described in a later communication. We wish, however, to state particularly that Saxe's areopicnometer is not suited for examining intestinal juice.

(12) The next point calls for the recording of the quantity and appearance of the centrifugalized sediment. Intestinal juice which is no longer

*From the Laboratory of the Har Moriah Hospital.

quite fresh furnishes considerable sediment. If the intestinal juice has been kept in a room at ordinary temperature, the sediment results from processes of decomposition; in addition the normally appearing ferments are rapidly destroyed. If the intestinal juice is kept on ice, the solubility of many of its components is diminished, a sediment resulting that brings down part of the ferments in their *active* state.

Qualitative Chemical Analysis.—(13) Reaction.—The reaction may be tested with litmus paper, aqueous litmus solution or phenolphthalein. At this time it is impossible to state the reasons why, frequently, a given intestinal juice may react alkaline to litmus paper, neutral to litmus solution, and acid to phenolphthalein. This fact explains why it is necessary to state the method employed in the test.

(14) Bile Pigment.—In a test tube containing about 1 c.c. of fuming nitric acid and 1 c.c. of intestinal juice, Gmelin's reaction is carried out. If there is a sufficient quantity of bile, the intestinal juice sometimes turns green, which color may last for some time; sometimes, however, the green color may rapidly turn to dirty violet. In the first case one may speak of biliverdin production, in the second case, of bilicyanine production.

(15) Carbohydrate Test. (*a*) Since amylopsin has always been found to be active, it is generally unnecessary to institute an iodine test for unchanged starch, but for exceptional cases this should nevertheless be kept in view. (*b*) Tests for amylodextrin, erythrodextrin, and arthrodextrin may likewise be made with corresponding iodine solutions. (*c*) Tests for sugar are made with Fehling's method. They are called positive only when red copper hemioxide is formed. (*d*) Other reducing substances may produce a green sediment with Fehling's test.

(16) Fat Tests.—Fat tests cannot here be briefly described. Furthermore, as the result of the experience thus far gained, they appear to be of secondary importance.

(17) Qualitative Test for Albumin.—This test is of the highest importance for obtaining a correct picture of the intestinal juice, and should, therefore, never be omitted. The best method is the well known biuret test. With a little experience, it is possible to clearly distinguish, and to estimate the density of the various color rings formed. This enables us to obtain indications as to the presence of (*a*) nuclecalbumin, (*b*) seralalbumin, (*c*) albumoses and (*d*) peptones.

Quantitative Chemical Analysis.—(18) Mucin.—The consistency of the intestinal juice, judged from the viewpoint of viscosity, gives no indication as to the mucin contents, inasmuch as dextrins, pentose derivatives, and some albumoses are just as glutinous as true mucin and may be present in the intestinal juice in the shape of products of digestion. To prove the presence of mucin, 2 c.c. of nonsedimented intestinal juice, 8 c.c. of distilled water, and 1 c.c. of glacial acetic acid are mixed in a Purdy's centrifugal tube. After centrifugalizing, the volume percentage of the precipitated mucus can be read off. It is also useful to note the color of this sediment.

(19) Albumins.—The supernatant fluid used for the determination of mucin is then mixed with 3 c.c. of a 10 per cent. solution of potassium ferrocyanide; subsequently the procedure is that employed to determine the mucin contents, subject to correction due to diminished amount.

(20) Further Determination of Albumin.—Two c.c. of previously sedimented intestinal juice are mixed with 8 c.c. of distilled water and 5 c.c. of Esbach solution, centrifugalized; the volume percentage is then read off. In view of the fact that the proteids precipitated by potassium ferrocyanide and by picrin do not agree, these two precipitates will nearly always differ widely. But it is just this difference which permits of further conclusions which, however, cannot be entered into on this occasion.

(21) Total Solids.—In a weighed porcelain dish we dry up 10 c.c. of intestinal juice at 100° C. and afterwards for a few hours, at a temperature of 55° C. The percentage of dry residue is established by weight.

(22) Ashes.—To the total solids about 2 grams of ammonium nitrate and a few drops of fuming sulphuric acid are added. These are to be nearly dried up at a temperature of 55° C., then burnt up and turned into almost white ash by the glowing process, after which the weight of the ash is determined. These ashes generally contain a large quantity of iron which can be demonstrated by the addition of hydrochloric acid solution.

(23) Iodine Discoloration.—For several of the above qualitative reactions the color of the intestinal juice is disturbing. To eliminate this disturbing factor, the juice is readily discolored with an aqueous iodine solution, containing equivalent parts of iodine, sodium iodide, potassium iodide, and ammonium iodide. Titration should be employed until discoloration results. The quantity of iodine solution used should be stated.

(24) Determination of Chloride.—The determination of chloride is established by titration with a solution of silver nitrate and a few drops of potassium chromate solution as indicator. The other organic acids are present in considerably smaller quantities and do not appear to be of much importance for the purposes of the analysis.

Examination for Active Ferments.—In the examinations thus far made, it was possible to employ methods for the most part well known, and to adapt the same to the special properties of the intestinal juice; for this reason there was no need of describing these methods in detail. For the duodenal examination, however, the most important ferments occupy the foreground of our attention. The chief point in the examination of the intestinal juice will probably be assigned to the determination of the ferments by the clinical investigation. The gall ferments are here of less importance, since the gall-pigment furnishes sufficient indications. The presence of these gall-pigments has already been noted. Methods for the determination of cholalic acid and its derivatives have been found too complicated for clinical purposes, although it is hoped that it will become possible at a future time to establish simple methods for the determination of sodium chloride and baryum. The three pancreas ferments are of the greatest importance and for these, we believe, we have worked out clinically satisfactory methods.

(25) Amylopsin.—A liberal quantity of a 1 per cent. aqueous solution of Kahlbaum's soluble starch is heated in the incubator to 55° C., also a number of empty test tubes. Five c.c. of this heated solution is put into the heated test tube, four drops of duodenal juice are added, the tube being shaken vigorously for a minute. Thereupon ½ c.c. of a 250th normal iodine solution is added as above de-

scribed. (*a*) If no amylopsin is present, the solution will become sky-blue, or green when gall is present; if traces are present, it will turn blue-violet; if large traces are present, it will turn red-violet; if the quantity is normal, it will turn pale pink, and if there is an excess, it will be colorless. (*b*) If, to this solution a sufficient quantity of Fehling's alkaline be added, it will always become colorless. Upon a further addition of Fehling's copper and subsequent boiling, it can be demonstrated whether the starch digestion has at least partly taken place up to the point of sugar formation.

(26) Steapsin.—Some fresh butter is melted and the clear, pure fat abstracted. This is mixed with a little 0.1 per cent. aqueous potassium carbonate solution and phenolphthalein, then shaken and titrated with liquor sodæ until there remains a distinct red coloration. This solution is likewise heated in the incubator to 55° C. and 5 c.c. of the same is shaken with 5 drops of intestinal juice in a heated test tube. If there are normal quantities of steapsin, the red color will disappear in from 2 to 5 minutes. According to the rapidity of this decoloration, the quantity of active steapsin can be estimated.

(27) Trypsin.—A solution of 0.07 per cent. copper sulphate and 0.1 per cent. sodium carbonate is mixed with a few drops of Fehling's alkaline and ½ per thousand of casein. This solution is heated in the incubator at 55° C. In a heated test tube again 5 c.c. are shaken up with 5 drops. At first the color is distinctly blue or, if there is gall present, it will turn green. Dependent upon the quantity of trypsin present, this color will become more or less red-violet or, after a few minutes, even pink.

For the practical purposes of clinical investigation it will be sufficient to examine duodenal juice by means of the methods above described, these being much more complete than the clinical routine examinations of the gastric juice.

A CASE OF DEATH UNDER GAS AND OXYGEN ANESTHESIA.

By G. FRANK LYDSTON, M.D.,

CHICAGO,

PROFESSOR OF GENITOURINARY SURGERY, ILLINOIS STATE UNIVERSITY MEDICAL DEPARTMENT.

ACCIDENTS in surgical practice, more particularly accidents from anesthetics, are unpleasant experiences. Still more unpleasant is the duty of recording them for the benefit of the profession at large. The experience of surgeons in general has shown that, up to date, a perfectly safe anesthetic has not been discovered. It is my humble opinion that the mechanism of anesthesia, involving, as it does, experience, varying skill and caution on the part of the surgeon and his anesthetist, and varying conditions upon the part of the person anesthetized, to say nothing of varying quality of the anesthetic, has too many cogs for safety. Sooner or later something is bound to slip, with disastrous results.

Notwithstanding what would seem to be the hopelessness of the task, the profession goes on in the attempt to discover a perfectly safe anesthetic. From time to time one thing or another is advanced as the ideal anesthetic only to go the way of all other "safe" drugs for anesthesia. One of the latest aspirants for the crown of safety is the gas and oxygen combination. It is not my intention to attack this method, but merely to relate a disastrous experience which shows that death upon the operating table under gas and oxygen may occur under what seem to be conditions favorable to its use as compared with other anesthetics. It was my ill fortune to lose the only case in which I had ever used the gas and oxygen, and incidentally the only case I have ever lost under anesthesia. I make the latter statement with due respect to certain very "close calls" I have had and with some dread of what may happen at my next operation.

CASE.—X., aged sixty-five. Had always been a free liver and addicted to the excessive use of alcoholics. Consulted me for a tight, at first impermeable, bulbo-membranous stricture with several false passages and a severe chronic cystitis. The kidneys were apparently in excellent condition. I began treatment by dilatation, but after some weeks of careful study and treatment of the case, found that the stricture was so irritable and resilient that further dilatations seemed worse than useless. I therefore suggested perineal urethrotomy and bladder drainage. The heart and kidneys being in excellent condition, I did not particularly fear anesthesia, although a slight asthma suggested the advisability of extra caution in its administration.

The patient being a relative of a prominent Chicago physician who had referred the case to me, I was exceptionally interested in avoiding unpleasant accidents. I therefore asked the doctor to be present at the operation and requested that a specialist in anesthesia be employed. The doctor and myself eventually agreed upon one of the most experienced and capable men of our acquaintance.

As is true of many cases of anesthesia, no matter what anesthetic is used, the blood escaping from the operation wound was at first dark, showing imperfect oxygenation. The color of the blood speedily turned to the usual color of arterial blood, and remained normal for perhaps five minutes, when, just as I had entered the deep urethra and divided the stricture, the blood suddenly again became of a venous hue. I immediately rose, glanced at the patient's face, and, simultaneously with the anesthetist, discovered that we were in trouble, the patient being deeply cyanosed and respiration having ceased. The heart was still beating, but laboredly, and continued to beat for some minutes. We worked manfully over the patient for more than an hour, using all the ordinary and some extraordinary methods of resuscitation, but to no purpose. No autopsy was permitted, but from the data at command the cause of death was apparently respiratory paralysis and consequent asphyxiation.

815 RELIANCE BUILDING.

Action of Homogeneous Products of Autolysis of Fetal Tissues in Malignant Tumors in Man.—G. Fichera, in the course of experiments on vaccines, has noted that spontaneous malignant tumors in young rats were extremely rare, that resistance was conferred upon rats with reference to neoplasms by inoculation with embryonal and fetal tissues, and that embryonal and fetal tissues treated by autolysis when injected under the skin caused involution of neoplastic grafts. He experimented on the injection of homogeneous products of fetal autolysis upon victims of malignant disease of the human race, the results of which he gives. Eighteen cases are included in his report; the tumors varied in nature and location; in eight there was no improvement; in ten there were beneficial results, and in five the tumors completely disappeared. Excision showed that substitution of sclerotic connective tissue for the neoplastic tissues had taken place. Hemorrhagic, necrobiotic, or necrotic zones were caused by general infections. The author thinks that persons afflicted with inoperable malignant diseases may undergo these injections without any danger of absorption of poisonous substances, especially of neoplastic origin. This treatment is contraindicated in cachectic cases. The author made use of tissues of fetuses from two to six months of intrauterine life.—*Il Policlinico*

MEDICAL RECORD.

New York, November 12, 1910.

HEALTH PROBLEMS OF THE PHILIPPINE ISLANDS.

It goes without saying that there are many health problems of the Philippine Islands and it is equally obvious that most of these are unsolved. When the white man takes up his burden in tropical countries he invariably finds it a burden indeed. He has not only to contend with obstacles of climate and of a physical nature, but he has to overcome the ignorance, prejudices, and superstitions of the natives. These are the most difficult to combat successfully. The Asian peoples, generally speaking, at any rate those of a lower grade, are fatalists and do not wish to be assisted to lead a more healthy life. In many cases, as in India, their religion stands in the way of sanitation and hygiene. However, American medical men have entered upon their self-imposed task of rescuing the sons of the tropical soil from the degradation of unsanitation and ill health with enthusiasm, and have been greatly stimulated to fresh efforts by their success in Cuba and more recently in Panama.

Victor G. Heiser, of the Public Health and Marine Hospital Service, Director of Health for the Philippine Islands, read a paper entitled "Unsolved Health Problems Peculiar to the Philippines" at the first meeting of the Far Eastern Association of Tropical Medicine held at Baguio, P. I., March 14, 1910, and published in the *Philippine Journal of Science* July, 1910. Heiser states that in the first instance the work of sanitation in the Philippines has been considerably handicaped by the meager funds at the disposal of the health department, so that discrimination must be used as to the employment of their resources. Up to the present time the policy has been to do a little toward solving each problem and not to concentrate on any one. Naturally malaria is one of the most important questions. The difficulties in the way of eradicating mosquitos from Manila alone are well-nigh insuperable. It would cost an immense sum to drain Manila and neighborhood, and Heiser is of the opinion that it would be unwise to recommend such an undertaking. The water supply is another question of prime importance in the Philippines, as all surface waters, except the thermal waters, or those heavily charged with certain minerals, are infected with amebæ. Artesian wells, however, are being drilled as quickly as possible. The health department has won a great triumph over smallpox in the Philippines. The disease was formerly a terrible scourge but owing to the energy of the members of the Bureau of Health over 6,000,000 have been vaccinated within the past five years and now smallpox is a negligible quantity. The results of vaccination in eradicating smallpox in the Philippines may be recommended to the earnest consideration of antivaccinationists in the United States or elsewhere.

Tuberculosis is prevalent and the superstitions and habits of the people, especially the habit of betel nut chewing, render the task of fighting the disease peculiarly difficult. Cholera, again, is a disease with which it is not easy to cope, and it is constantly appearing in sporadic form in widely separated sections of the islands. Some years ago Heiser drew attention to the fact that logical deduction indicated that there was a morphological change in the cholera organism, which made it difficult to recognize at certain stages. Research work seems to have strengthened this view. Possibly, also, cholera carriers may be responsible for some outbreaks. At the present time plague is nonexistent in the islands, but rigid inspection of incoming vessels and destruction of rats are being continually carried on. Typhoid fever exists the greater part of the year in some of the islands in the archipelago, but is by no means prevalent.

Of course, infant mortality is very large; about one-half the total number of deaths occurs in children under one year of age. Improper nourishment plays the leading part in this deplorable state of affairs. Cow's milk either fresh or canned is beyond the means of the native mothers. The raising of goats for the sake of their milk is suggested and already experiments in breeding a hardy variety of milk goats have been initiated. A very conspicuous cause of ill health in the tropics is the rapid putrefactive changes which take place in nitrogenous foods. As Heiser very wisely remarks, "the problem is either to provide ways properly to preserve such foods or to find suitable substitutes which will enable us to eliminate them from our tropical dietary."

So far as the natives are concerned the habit of eating from their fingers is a fruitful cause of disease. It is known to be the most prominent factor in the transmission of cholera and intestinal diseases. The custom is deeply rooted and consequently hard to break. Education is the sole mode by which customs and habits the products of ages can be successfully dislodged and this again is a matter which time must bring about. The impossibility of procuring accurate statistics is another spoke in the wheel of progressive sanitation and health laws in the Philippines. The medical profession of the United States is comparatively new to tropical health problems. Nevertheless, the work already done by its members in this direction is a happy augury for the future. In the case of the Philippine Islands slow but sure must be the motto of the Bureau of Health, for it is not possible to move rapidly or cover at once a large extent of territory with a more or less depleted treasury.

SUDDEN CHANGE OF CONSTITUTION.

This subject, although continually in evidence in the isolated example, has been much neglected by scientific writers, largely, of course, because "constitution" is an empirical expression. Much information under this head appears in the form of the change in the bactericidal power of the blood, in the variations in the opsonic index, and in several other fashions. The late Dr. Heitzmann believed that he could recognize the degree of vitality of the organism, including its resistance to disease, by the amount of protoplasm in the leucocytes and tissue cells, this amount being readily determinable by the refractive index of the cells in question—always provided that the refraction was natural, or, in other words, not due to fatty or amyloid change. He believed that this condition of the cell varied greatly in the individual at different times. In fact, he built up an entire superstructure of "constitution" in man and animals upon this seemingly slender foundation.

According to Heim (*Berliner klinische Wochenschrift,* Sept. 26), the late Dr. Rosenbach, who was not only a medical man of commonly good repute, but also a medical individualist, traded extensively upon a theory of the instability of constitution. It appears to be well founded that our ancestors could withstand more bleeding, purging, salivation, and the like than the present generation. Some mineral drugs were administered several centuries ago in doses that would now be termed toxic. The present generation cannot profit by routine bleeding. The history of syphilis and tuberculosis shows that at certain periods and localities resistance to infection must have been either lessened or heightened. Heim cites the common example of a foundling suckled by a series of wet nurses. At first all disagree. Finally one is found who suckles the child successfully. This is not due to any quality of the nurse, but to the fact that the infant's constitution undergoes some slight change which makes it take naturally to breast milk. Another familiar example is that of the scarlet fever nurse, who is exposed year in and out, but who finally contracts the disease. Lues and gonorrhea appear to be contracted at times after indefinite exposure with negative results.

Heim, although a Budapest practitioner, seems inclined to let go scientific dogmata of any sort and to put faith in the old French diathetic theory. He bears witness to an exudative diathesis and an exudative constitution. Children of such constitution are believed to correspond to certain factors in the newly born. The original purport of Heim's article was to show that certain children who succumbed to scarlatina had already been subjected to the exudative diathesis and neuropathic constitution. According to the author certain children foredoomed to this death exhibit premonitory signs, which comprise meteorism, restlessness, insomnia, etc. The main value is placed upon the animal vigor of these infants under particular circumstances. Aside from this general connection the subject of constitutional changes has not been completely elaborated.

The Phosphorus Metabolism in Rachitis.

Among the diseases of metabolism rickets is one whose pathogenesis has for a long time baffled clinical observation and laboratory investigation. Apart from a realization that all the vague nutritional errors associated with a poor environment are to a certain extent responsible for this condition, no tangible factors have yet been gleaned to which one could point as the main causes in its evolution. In a most exhaustive series of investigations undertaken with a view of determining the significance of calcium in the pathogenesis of rickets, J. A. Schabad, in his sixth contribution on this subject in the *Archiv für Kinderheilkunde,* Vol. 54, Nos. 1 to 3, has come to the conclusion that the pivotal point in the morbid mechanism of this disease is the metabolism of phosphorus and not calcium. In the evolution of rachitis there is an increased elimination of both of these substances. The increased excretion of phosphorus is greater than can be accounted for by the amount of this substance and the equivalent amount of calcium contained in the bones, so that it is probable that the nervous tissues share in the pathological process. The increased phosphorus elimination is in the feces, while that in the urine is really less than the normal (hypophosphaturia). The ratio between the phosphorus content of the urine and that of the feces is changed. The normal ratio in nursing infants, 80:20, becomes in rickets 65:35, while in artificially fed infants and in older children the normal ratio of 60:40 is practically reversed to 40:60. In the convalescent period this disturbed ratio of phosphorus elimination is gradually restored to normal, while the total excretion of phosphorus reaches the subnormal. At the same time there is a relatively great increase in the urinary phosphorus, the ratio becoming 75:25. There is a close relationship between the calcium and phosphorus content of the feces; increase in the intestinal elimination of calcium goes hand in hand with a phosphorus retention and vice versa. The interpretation of these results brings out the important fact that, inasmuch as in rickets there is excreted more phosphorus in proportion to calcium, the possibility is excluded that the augmented phosphorus elimination is to be attributed to the increased excretion of calcium. The conclusion is obvious that the primary factor in the metabolic disturbances underlying rickets is to be sought in the increased elimination of phosphorus. These experimental results apparently explain the good effects that have for a long time been observed from the empirical administration of phosphorus in this disease.

Criticism of a Hospital.

The Flower Hospital of this city was recently very severely criticised in the *New York Times* because of its treatment of a man who had been murderously stabbed by the striking expressmen. The man was taken to the Flower Hospital, which institution has received most of the victims of the strikers, and there died of pulmonary hemorrhage, the result of one of his stab wounds. A friend and employee of the murdered man was dissatisfied with the treatment the patient had received and brought charges against the hospital in the columns of the newspaper. Those charges, as printed in the *Times,* sound very bad, as bad as did the accusation of cruelty to animals which the *Herald* brought some time ago against Carrel and other workers in the

Rockefeller Institute—and to a medical man they have just as little foundation. One of the complaints of neglect, for instance, was based on the fact that the man's wounds were dressed only twice between Monday, the day he was received in the hospital, and Thursday, the day he died. To the layman, of course, who thinks a wound should be dressed as a fastidious man washes his hands, this sounds like neglect of the most criminal sort; to the physician who knows that the less done to an aseptic wound, the better the chance of healing, the only thought is that it might have been dressed once more than was really necessary. An analysis of the other charges shows clearly enough their origin: A well-meaning layman, unused to hospital sights and to the necessary institutional discipline, distracted with anxiety and grief, seizes on what appears to him to be abuses, and in his anger and distress brings them to the notice of a reporter, who makes a good "story" and gets it displayed on the front page of his journal, thereby injuring, in the minds of many, the good name of a hosital of standing, one whose ambulance service covers a large district, and one which does an immense amount of good in the community. The good name of a hospital, the support of which is largely from contributions by the charitably disposed, is its most valuable asset, and it is a pity that a large and influential journal of the "read," not yellow, sort, one too which is usually so eminently fair and intelligent in its discussion of medical matters, should have accepted such charges, brought in evident ignorance of the true conditions, and given them to the world with its authority as being "news fit to print."

The Practical Applications of Blood-Vessel Surgery at the Present Time.

In the Quarterly Bulletin of Northwestern University Medical School, September, 1910, V. D. Lespinasse points out the indications for blood-vessel surgery in the operation of transfusion, in cases of shock, acute hemorrhage, hemophilia, purpura hæmorrhagica, melena neonatorum, carbon monoxide poisoning. Especially, according to the writer, are the effects of transfusion in melena neonatorum marvelous, but technically, the transfusion is very difficult, as the veins of a newborn babe are quite small. Transfusion should be done in all cases of this condition and as early as possible. Lespinasse recommends that transfusion should be done in the treatment of pellagra, typhoid fever, and smallpox with the blood of patients recently recovered from these diseases. Permanent anastomoses should be performed in wounds of all the large vessels, brachial, femoral, aorta, renal, etc., in aneurysms of all types, in cirrhosis of the liver to replace omentopexy and relieve ascites, in order to save crushed extremities by repair of the crushed vessels, and for the removal of emboli from their point of lodgment. It may be noted that, although surgery has advanced with rapid strides during the past two or three decades, surgery of the blood-vessels up to a recent date has been at a standstill. J. B. Murphy was among the first to inaugurate a movement in the direction of blood-vessel surgery, and since his early experiments in suture of the arteries numerous other surgeons have successfully made experiments in the same field. The operations of Matas for the cure of aneurysm are especially noteworthy.

News of the Week.

Accidents in New York.—During the month of October seventeen persons were killed and 151 injured on the streets of New York, according to the figures compiled by the National Highways Protective Association. Seven of those killed were children. Automobiles were responsible for the death of eight persons, trolley cars for the death of six. The total number of persons killed on the streets of New York during the ten months ending October 31 was 138, and the total number of injured 811.

Births Increase in France.—It is officially announced that during the first half of the year 1910 the births throughout France exceeded the deaths by 21,189. During the year 1909 the deaths were said to have exceeded the births by 28,205.

Hospital Dedicated.—The new Holy Family Hospital on Dean street, Brooklyn, formerly known as St. Mary's Female Hospital, was dedicated on October 2 by Bishop McDonnell. The building has been equipped with all the appliances of a general hospital.

Water Contaminated.—The Board of Health of Milburn, N. J., has notified all the residents of the town that the drinking water has been found to be infected and must be boiled before using. The water is obtained from driven wells and an investigation will be made to find out how the contamination occurred.

Red Cross Endowment Fund.—Efforts to raise an endowment fund for the National Red Cross will be begun shortly by a committee of prominent men appointed by President Taft. Among the members of the committee are Robert Bacon, Lloyd C. Griscom, Charles H. Keep, Felix Warburg, H. P. Davison, Charles P. Taft, John Hays Hammond and former Vice-President Charles W. Fairbanks.

Tuberculosis Sanatorium.—The Metropolitan Life Insurance Company of New York has changed the proposed location of the tuberculosis pavilion, which it plans to build for its employees, from Sullivan to Saratoga County. The company has filed an application with State Health Commissioner Porter for permission to erect a sanatorium near Mt. McGregor.

A Year's Accidents.—The Interstate Commerce Commission has recently issued a bulletin which completes the publication of accident records for the past nine years. During the year ending June 30, 1910, 3,804 persons were killed and 82,374 were injured in train accidents, an increase over the figures for the previous year of 1,013 and 18,454 respectively. Collisions caused the death of 433 persons, an increase of 91; the total number of collisions being 1,450 more than the previous year. The total number of derailments was 5,910, with an increase of 79 deaths and 676 injured from this cause.

Birth Statistics.—The new Statistical Advisory Board of the Department of Health of New York City, of which mention was made last week, has suggested means to secure complete returns and registration of all births in the city. Upon the thorough registration of births depends, as the Health Commissioner points out, the accuracy of estimates of population and the value of comparative statistics in relation to disease and other social problems, insofar as they refer to the total population. Hereafter the law providing a penalty for failure to record a

birth will be strictly enforced, and the Board urges that on the death of any infant under one year of age the registration of its birth be verified in order to detect omissions.

Red Cross Seals.—A million dollars from the sale of the Red Cross seals for the stamping out of tuberculosis is the object of the campaign for this Christmas. Forty million of the seals have already been printed and distributed, the Red Cross and the National Association for the Study and Prevention of Tuberculosis cooperating in handling them.

Special Milk Order.—The Secretary of Agriculture has recently issued a special order to the chiefs of bureaus, offices and independent divisions of the Department of Agriculture in Washington, prohibiting the sale in any building occupied by the Department of Milk which is not equal to the classification as defined in the Bureau of Animal Industry Circular 114. The determinations as to the standards of milk are to be made by the Dairy Division of the Bureau. In this way the sale of milk containing extraneous matter, raw milk from cows not known to be free of tuberculosis, and milk of unknown origin will be prevented in the buildings under the control of the department, and such a step will probably have a great influence on the improvement of conditions throughout the city.

Cholera in Italy.—Following the optimistic statements of October 31 that the epidemic of cholera in Italy might be considered at an end, came the announcement of the occurrence of six new cases on November 1, with two deaths, both in the asylum for the insane at Aversa, and of ten new cases on November 2, with two deaths. Naples has, however, been officially declared free of cholera, and the trans-Atlantic steamship lines have been notified that clean bills of health will be granted. As a result of the report of the Italian Board of Health, which says that the epidemic in the Apulia region may have been caused by the poor water supply, the Government will ask an extraordinary credit amounting to $60,000,000 for the construction of dams, aqueducts and artesian wells to provide the cities and villages of Apulia with a properly protected watershed.

Ambulance in Collision.—An electric ambulance belonging to the New York Hospital while going north along Madison Square in answer to a call on October 30, collided with an automobile. Although both vehicles were badly damaged none of the passengers was hurt.

Prize to Insane Patient.—An insane woman, a patient in the State Hospital for the Insane at Anoka, Minn., recently was awarded a prize for the best literary contribution submitted to a certain magazine. Under the circumstances the award, a trip to Europe, was of but little value to the winner, who was, therefore, given a cash prize.

Measles on Steamship.—Fifty passengers on board the steamship *Ultonia*, which reached New York on November 3 from various Mediterranean ports, were found to be suffering from measles when the vessel was inspected at Quarantine, and were removed to Hoffman Island.

Mt. Vernon Water Supply.—The Board of Health of Mt. Vernon, N. Y., has sent out photographers and engineers to inspect and obtain evidence of the condition of the watershed of the company furnishing the water supply of that city. It is possible that a bill may be introduced into the next Legislature providing for the purchase of the company's plant by the municipality.

Fall River Death Rate.—In spite of protests on the part of its citizens, the town of Fall River, Mass., is still rated by the Census Bureau as having a death rate of 19.1 per 1,000 of population, the highest rate recorded among American cities. Census Director Durand attributes the high total rate to the unusual proportion of deaths among children.

Typhoid Fever Investigation.—Because of the prevalence of cases of typhoid fever in certain sections of New York City, Commissioner Lederle recently appointed a committee to investigate and report. The results were announced on November 4. In the Nineteenth Ward a six weeks' investigation was begun on September 3. Fifty-six cases were found, of which 17 were considered to be due to out-of-town infection, 4 to impure water, 19 to artificial ice, 14 to natural ice, and 2 to infection from a typhoid patient. In the Ninth Ward the investigation also covered six weeks, beginning on July 26. In that time 88 cases were reported, 4 of which were due to out-of-town infection, and 4 to direct exposure, other members of the family being sufferers from the disease.

Academy of Medicine.—The Finance Committee of the New York Academy of Medicine announces that for the fund to be applied in payment for the properties recently purchased subscriptions have already been received of $1,000 each from thirty Fellows of the Academy, to be paid in five annual installments of $200.

Dr. C. D. Spivak, editor and publisher of *Medical Libraries*, a bimonthly magazine which appeared first in 1898 and was discontinued in 1902, announces that he will furnish, as long as the supply lasts, complete sets of volumes II, III, and IV, and incomplete sets of volumes I to V, free of charge, to any medical librarian making a request for them. Dr. Spivak's address is the Metropolitan Building, 1421 Court place, Denver, Col.

Dr. Charles Hitchcock of New York announces his removal to 61 East 65th street.

Dr. James Morrison Bodine, Dean and President of the University of Louisville Medical Department, will be given a testimonial dinner at the Seelbach Hotel in Louisville on December 16, 1910. Those friends whom the committee has not been able to reach by personal note are cordially asked to signify their intention to attend.

Dr. John W. Goodsell of New Kensington, Pa., who accompanied Commander Peary on his successful expedition to the North Pole, has received, rather tardily it would seem, a letter from the Peary Arctic Club commending the physician for his work. The party numbered twenty-five, in addition to fifty Eskimos who joined the expedition at Etah, and all returned in good health.

An Historical Portrait.—The New York Historical Society has recently received as a gift a copy of a portrait of David Hosack, M.D., who was president of the society from 1820 to 1827. The original portrait was painted by Thomas Sully. Dr. Hosack was a well-known New York physician and a member of the staff of the New York Hospital.

The American Cancer Research Society.—The semiannual meeting of this society was held in Chicago on October 26. The following officers were elected: *President*, Dr. L. D. Rogers of Chicago; *Secretary*, Dr. William A. Guild, Des Moines, Ia.;

Treasurer, Dr. E. Mather, Detroit, Mich. The annual meeting of the society will be held in Chicago on June 6 and 7, 1911, and every physician is invited to take part by attending or by sending reports of cases. The society has authorized the establishment of a cancer clinic and research laboratory at the Cancer Hospital, Chicago, and the publication of a bulletin giving the latest information concerning the disease.

Sanitary Officers.—The tenth annual conference of the sanitary officers of the State of New York will be held in the Y. M. C. A. auditorium at Buffalo,, N. Y., on November 16, 17, and 18, 1910. The program for the first day includes a number of papers on the relations of public health to the school, to the dental profession, to the medical profession, to the press, to the municipal authorities, and to the conservation movement. On the same evening a public meeting will be held, the subjects being "The Health Department: Its Supreme Value to the People" and "Public Health and the Public Purse." On the second day subjects of interest to city health officers will be considered, and on the third there will be a symposium on communicable diseases. Arrangements for securing reduced railroad fares for those attending the conference have been made.

The New York and New England Association of Railway Surgeons at its twentieth annual meeting held at the Hotel Astor, New York, on November 3 and 4 elected the following officers for the ensuing year: *President*, Dr. F. A. Goodwin of Binghamton, N. Y.; *First Vice-President*, Dr. Walter Lathrop of Hazelton, Pa.; *Second Vice-President*, Dr. J. W. Le Seur of Batavia, N. Y.; *Corresponding Secretary*, Dr. George Chaffee of Brooklyn; *Recording Secretary*, Dr. C. A. Pease of Burlington, Vt.; *Treasurer*, Dr. J. K. Stockwell of Oswego, N. Y.

The Miami Valley Homeopathic Medical Society held its one hundredth semi-annual convention at Dayton, O., on October 28. The following officers were elected: *President*, Dr. Webster Ensey of Dayton; *Vice-President*, Dr. J. E. Studebaker of Springfield; *Secretary*, Dr. R. M. Webster of Dayton; *Treasurer*, Dr. W. H. Dickinson of Dayton.

The Texas State Homeopathic Medical Association held its annual convention at Dallas on October 25 and 26. Officers were elected as follows: *President*, Dr. T. J. Crowe of Dallas; *First Vice-President*, Dr. F. L. Davis of Dallas; *Second Vice-President*, Dr. Bowes of Greenville; *Secretary*, Dr. J. H. Bass of Austin; *Treasurer*, Dr. F. L. Griffith of Austin. The society adopted resolutions opposing the Owen bill.

The Western Illinois Medical Society held its annual meeting at Alton on October 28. The following officers were elected: *President*, Dr. G. Taphorn of Alton; *Vice-Presidents*, Drs. L. H. A. Nickerson of Quincy, and E. L. Grouch of Jacksonville; *Secretary and Treasurer*, Dr. W. Duncan of Jacksonville.

Obituary Notes.—Dr. Michael B. Van Buskirk, formerly of Aurora, N. Y., a graduate of the Medical Department of the University of Pennsylvania in 1866, a member of the New York State and Cayuga County Medical societies, died at his home in New York on October 30, after a long illness, aged 96 years.

Dr. James Baynes Walker of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania in the class of 1872; visiting physician to the Philadelphia Hospital from 1876 to 1893; professor of the practice of medicine in the Woman's Medical College of Pennsylvania, and physician to the Woman's Hospital from 1879 to 1890, a member of the Pennsylvania State Board of Medical Examiners, a fellow of the College of Physicians of Philadelphia; a member of the Pennsylvania State and Philadelphia County Medical Societies, and formerly president of the latter; a member of the American Medical Association, the Northern Medical Association, the Philadelphia Medical Club, the American Climatological Association, and the American Academy of Medicine, died at his home, on October 19, aged 64 years.

Dr. N. Pendleton Dandridge of Cincinnati died on Monday of this week at the age of 64 years. He was born in Cincinnati in 1846 and received his arts degree from Kenyon College in 1866. He then entered the Medical College of Ohio, but after a year of study went to Vienna and Paris, and finally obtained his medical degree from the College of Physicians and Surgeon, New York, in 1870. He early turned his attention to surgery and was for many years one of the leading surgeons of the Middle West. He was for several years professor of surgery in the Miami Medical College, and was surgeon to two of the Cincinnati hospitals. He was a prominent member of the American Surgical Association, and was also a member of his State Society and of the national associations.

Dr. Edward Holman Hamill of Chatham, N. J., a graduate of the Medical Department of New York University in 1868; consulting medical director of the Prudential Insurance Company, formerly president of the Association of Life Insurance Directors of America, and a member of the American Medical Association, the New Jersey State and Morris County Medical Societies, and the Practitioners' Society of Jersey City, died at his home, after a long illness, on October 29, aged 67 years.

Dr. Charles H. Shepard of Brooklyn, N. Y., a graduate of the New York Medical College in 1859, and a member of the American Medical Association, and of the New York State and Kings County Medical Societies, died at his home, on October 29, aged 85 years.

Dr. John H. Nesbitt of New York, a graduate of the College of Physicians and Surgeons, New York, in 1875, a member of the New York State and County Medical Societies, of the Greater New York Medical Association, and of the Physicians' Mutual Aid Association, the senior surgeon in point of service in the New York Police Department, with which he had been connected since March 11, 1884, died on the steamer *Arabic*, bound from New York to Queenstown on October 29, it is feared from self-inflicted wounds. Dr. Nesbitt, who was 55 years of age, had been in ill health for some time and was taking an ocean voyage in the hope of improving his condition.

Dr. W. S. Searle of Brooklyn, N. Y., a graduate of the Department of Medicine of the University of Pennsylvania in 1859, a member of the Homeopathic Society of the State of New York, for many years vice-president of the State Board of Medical Examiners, and consulting physician to the Cumberland Street Hospital, of which he was one of the founders, died at his home on October 30, aged 76 years.

Dr. George Austin Bowen of Woodstock, Conn., a graduate of the Medical Department of the University of New York in 1863, formerly surgeon-general on the staff of Governor Coffin of Connecticut and a member of the Connecticut State Legislature, died at his home on October 30, aged 68 years.

Dr. Norman McLeod Carter of New York, a graduate of Princeton University in 1899, and of the College of Physicians and Surgeons, New York, in 1902, died at Saranac Lake, N. Y., on October 2, aged 32 years.

Dr. Lewis William Krieger of Peoria, Ill., a graduate of the Jefferson Medical College, Philadelphia, in 1892, died in St. Francis Hospital, Peoria, on October 23, aged 51 years.

Dr. Paul Thomas Kimball of Lakewood, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1887, a member of the New Jersey State and Ocean County Medical Societies, died at his home on November 3, aged 48 years.

Dr. William F. Scott of Somerset, Ky., a graduate of the Kentucky School of Medicine, Louisville, in 1850, at one time superintendent of the Eastern Asylum for the Insane at Lexington, died at his home after a brief illness on October 26.

Correspondence.

LODGE PRACTICE.

To the Editor of the Medical Record:

Sir: In a recent issue of the Medical Record Dr. Wolf has criticized my attitude on "The Lodge Practice Evil of the Lower East Side" which I described in the October 22 issue. I am taken to task for merely setting forth an existing evil without outlining an adequate remedy for the condition. In justice to myself I might say that the diagnosis of a disease is often of vast importance even though specific treatment cannot be immediately instituted against that disease. Although I cannot claim total originality in my diagnosis of the Lodge Practice Evil, yet my article again calls attention to a condition of affairs among the East Side medical fraternity that has become wellnigh intolerable socially, financially, and ethically.

Dr. Wolf forgets that it would have been almost a presumption on my part had I attempted to suggest a suitable remedy for this existing evil. To do that requires more than the work of one man. Indeed it can be accomplished only by the East Side physicians zealously and earnestly uniting to discuss ways and means for the abolishment, or, if that is not immediately feasible, for the amelioration of the lodge practice degradation.

I might further add that not long ago the Eastern Medical Society on several occasions undertook to thresh out the lodge question from every standpoint. Papers were read upon the subject, statistics were cited, and considerable eloquence was wasted, but naught was accomplished.

To-day I believe it is no exaggeration to say that at least 85 per cent. of all the East Side practitioners have one or more lodges. Parenthetically I might say that this evil is gradually spreading out its tentacles toward other sections of Greater New York.

A practical and complete discussion of the subject with a spirit of sincerity by all the physicians concerned should be the first step in the betterment of the Lodge Practice Evil.

Morris Joseph Clurman, M.D.
142 Rivington Street.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HARVEIAN ORATION ON HEREDITY AND MIND—HEALTH ASSOCIATIONS, THEIR WORK, AMALGAMATION OF TWO—CHRONIC ABSCESSES OF BONE—RADIUM SEPARATED IN ENGLAND—CALENDAR OF R. C. S.—OBITUARY.

London, October 21, 1910.

The Harveian Oration at the Royal College of Physicians was delivered on Tuesday by Dr. H. B. Donkin. As he is one of H. M. Commissioners of Prisons he has been much concerned with questions relating to crime and heredity. It was therefore natural for him to take as his subject "Some Aspects of Heredity in Relation to Mind." There was no evidence, he said, that mental capacity had increased in historical times and natural selection was the best explanation of the development and inheritance of cerebromental functions. Criminology, mental defect, and eugenics might illustrate the influence of acquired conceptions, but there were no special qualities, mental or physical, common to all criminals. The only important link between crime and heredity was that a larger proportion of mental defectives were found among criminals than in the total population. Those defectives were found among criminals of all classes. Unable to acquire the complex characters necessary for the average civilized man they followed the path of least resistance, which was often the path of unsocial or criminal action. This he believed would be confirmed by a report of a nearly completed inquiry by the managers of our convict prisons. Referring to the loose talk about degeneracy by speakers, novelists and other writers, Dr. Donkin said that no really rational hypothesis of hereditary criminality had been even formulated.

The object of eugenics was to discover the change in racial qualities which might be anticipated and what would improve them. That depended on the assumption that the qualities are really innate and transmissible; but were they? Is ability or probity acquired? Defined in one way the reply as to ability might be that it is germinal; in another that it is acquired. As to probity it is certainly acquired.

Some characters were handed down by teaching and example from one generation to another and so might appear to be inherited. Negative eugenics might make some progress, but not positive. As to the human mind, whether nurture or nature had most influence on its development was a meaningless question. For its development the brain required its appropriate stimulus. The mental and physical maturity of a normal human being largely depended on acquirements. Some biologists seemed to think most moral and intellectual characters inherited instincts which could be improved by selective breeding. Others hold that the innate characters were few in comparison with those acquired and demonstrably non-transmissible. The orator concluded that the human mind was both born and made and so the object of education was to fit for social life and make good citizens and afford any one with gifts above the average the opportunity of developing them. Education emphasized and largely made the individual, but not the race. The progress and efficiency of man were not mere questions of breeding.

The Countess of Aberdeen, presiding at the last meeting of the Irish Women's Health Association, described the good work already accomplished, re-

ferring especially to the opening of the hospital named after Mr. Allan Ryan of New York, who is giving $1,000 a year for five years to establish it. It is intended for consumptives in the middle stages in whom arrest may be hoped for and is the most necessary, as the society has already "preventoriums" for those in the incipient or threatening stages. The Countess instanced the Sutton preventorium, formerly a coast guard station, at the first annual meeting of which they had been able to report improvement in all the 124 residents. Those admitted had to be certified as run down in health and in danger of becoming victims, but not actually suffering from any form of tuberculosis, and such homes she believed could stop an immense amount of illness. They had also in process of erection the P. F. Collier dispensary, for which they were indebted to Messrs. Collier of New York, as a memorial to their father, a great friend of Ireland. Their Pasteurized milk depot was doing good work, and their caravan had carried on its useful educational tour in Limerick and Kerry. It was encouraging that England had appealed to them for help, and the Imperial Health Association had started two caravans on the Irish plan. They had been invited to assist in the tuberculosis exhibition and had received another invitation for next year from Allahabad. They proposed to give lectures to women in the prisons; in fact, they had made a beginning in Mountjoy Prison.

Two societies concerned with sanitation, viz., the Mansion House Council on the dwellings of the poor and the London Council of Health Societies, have come to the conclusion that their amalgamation is desirable, as it would economize the co-ordination of many voluntary workers and assist them in a determined effort to improve the health conditions of the metropolis. So fusion has been effected. The Mansion House Council is the older body, dating from 1883, an outcome of conferences held in connection with the "Healtheries" exhibition. This council carried out unofficial inspection of poor houses to the number of 200,000, took an active share in promoting sanitary legislation and in numerous congresses and conferences, local, national and international. They also formed sanitary aid committees which led to many societies growing up during the last ten years, which concerned themselves with personal hygiene as well as the sanitary environment.

In 1905 there was a conference which eventuated three years later in the London Council, with representatives of more than twenty societies engaged in health work. It has done in these two years some useful work in the way of discussion of methods and bringing together active workers in the promotion of personal health. The fusion of these two bodies is a step further in co-ordination. The amalgamated societies take the name of the "Mansion House Council on Health and Housing."

The annual meeting of the Society of Medical Officers of Health was held on the 14th inst., when Dr. Willoughby, M. O. H. for Eastbourne, was elected president and spoke of the recent legislation adding to their duties, especially the new Housing Act, which he approved, for unsanitary housing was a constant accompaniment of ill health. He could not agree with a statement in the Minority Report on the Poor Law, to the effect that four-fifths of their work was wrapped up in the casual laborer and his home. In his own district he found many other causes of the trouble and often several were so combined that it was difficult to disentangle them or to say which was cause and which effect. One interesting observation he had made was that mentally defective children were found in undue proportion in unsanitary houses. Here the cause was obscure. Often such children had similar defective parents, and the neglect of home and children was sometimes due to weak-mindedness rather than viciousness or neglect. Experience had shown him that in bad home conditions feeble-mindedness produced some of the worst results from a public health point of view. Feeble-minded parents produced offspring and were oftener than imagined the cause of a disgraceful house. They must do their best for such children, though it sometimes seemed hopeless. Unfortunately this sometimes only carried the imperfect into the marriage market with disastrous results for the next generation. The care of the feeble-minded was too great a responsibility for a local official, but the sooner the State took charge of them and directed their career the better it would be for the country.

Hospital surgeons are interested in the treatment of chronic abscesses in bone by metal drains as described by Mr. Symonds in his address at the Medical Society of London and mentioned in my last letter. He did not treat of the acute or chronic osteitis by operative measures, but of the after treatment—the effect of the central osteitis about which medical literature is scanty. A metal drain did not irritate like rubber or gauze. It could be retained during the long period of absorption and reconstruction and the patient could attend to the cleaning and management of the tube. Most of the cases referred to seemed due to a late mild infection which might have been dormant for years. Some were likely to be mistaken for tuberculosis. Probably during acute osteitis foci of infection were deposited. They were quiescent as to symptoms, but a painless osteitis was going on all the time, and some day when the surface was reached there would be pain. The protective layer of dense bone forming the wall of those old abscesses proved the chronicity.

Sir Watson Cheyne said the main thing and a difficult one was to render the cavities aseptic. He was impressed with the plan of metal tubes, for rubber tubes did not answer. If he could not cut away and level down the bone he would certainly try Mr. Symonds's plan.

Mr. Barker advocated bismuth paste, which could reach the farthest ramifications of the cavity and acted as a germicide and a framework for the granulations.

Mr. A. Pearce Gould held the ideal plan to be by an extremely patient operation to eradicate the whole affected area and if possible flatten the dense wall of the abscess and so get sound healing from the bottom. If prolonged drainage was needed the metal tubes used by Mr. Symonds would certainly be best. But it was to be hoped that none would suppose drainage by metal tubes for a long time was sufficient, for the one thing needed was to get rid of the disease by a thorough primary operation.

The calendar of the R. C. S. for 1910-11 has been issued. The fellows number 1,487, the members, 17,030; dental licentiates, 2,263; the diplomates in public health, 674. The figures given point to the discontent that only the few fellows have a vote.

Prof. A. Keith begins a series of demonstrations on specimens in the museum this afternoon.

Sir William Ramsay announced on Wednesday that radium had been produced for the first time in

Great Britain from British ore by a new method which extracts it in a couple of months instead of the other processes which require a year. The supply of radium is now assured, for there is plenty of pitchblende in Cornwall. Today the St. Ives Consolidated Mines, Limited, announce that they have a quantity of bromide of radium in an advanced state of manufacture for sale.

The death is announced of Dr. Sydney Ringer, F. R. S. His "Handbook of Therapeutics" will be well known to you, for it was one of the most successful manuals and has passed through a dozen or more editions. He was professor of the subject at University College (his old school) for a number of years and later became Holme professor of clinical medicine, being all the time physician to the University College Hospital.

William P. J. Fagan, F. R. C. S. I., surgeon to St. Vincent's Hospital, Dublin, and a professor in the Catholic University there, died suddenly on October 10 of angina pectoris. He was only 46 years of age, but his talents and skill had established him in an excellent position in Dublin.

Dr. Surg.-Gen. John Martin Hyde has died in his eighty-first year. He qualified in 1854 and joined the Army Medical Service that year. The next year he was in the Crimea and present at Sebastopol. He was awarded the medal with clasp and also the Turkish medal. He retired in 1879.

The death is announced of Surgeon Lieut.-Col. Henry Hyde, late I. M. S., at the age of 77. He was a King's College student, qualified M. R. C. S. 1865, and L. R. C. P. I. the next year, when he entered the Madras Army Service. He was appointed district surgeon at Tinnevelly in 1878 and afterward transferred to Trichinopoly.

The death has also occurred in London of Dr. Alfred Earnshaw Hewer, surgeon to Blackall Hospital, Queenstown, and Government medical officer there. He was only 45 years old. He graduated at Cambridge in 1889 and took the two Royal College diplomas the previous year.

Cholelithiasis. R. F. Chase.
Further Observations on the Wassermann Reaction for Syphilis. W. P. Boardman.
The Technique of Arthrotomy. A Report Upon and Discussion of One Hundred and Ninety-eight Cases. C. F. Painter and A. P. Cornwall.
The Extreme Blood Picture in a Case of Pernicious Anemia. W. C. Speidel.

Cholelithiasis.—R. F. Chase has come to the conclusion that this condition is more often mistaken for primary digestive diseases by the general physician than is the case with any other organic disease. As in peptic ulcer it is usually hemorrhage that is wanting, so in gallstone disease it is usually jaundice. This has been observed in less than 5 per cent. of the cases. Gallstones are found in 7 per cent. of all autopsies, while in autopsies of persons over sixty years of age they are encountered in 25 per cent. The symptoms of cholelithiasis are mainly those of indigestion. Colic is the most prominent symptom. Pain frequently and tenderness of the liver almost always follow the colic. There is a tender area on the right side behind, on a level with the twelfth dorsal vertebra, and extending at times to the posterior axillary line. This is a sign of great value. Jaundice when present usually occurs only after one to several days from the beginning of the colic. Immediately following an attack of biliary colic there is impairment of both the secretory and motor functions of the stomach, as evidenced by a diminution or absence of HCl. Lavage of the stomach is one of the best methods by which to overcome recurrent vomiting. In the treatment the foremost fact to be impressed is that stones in the gall-bladder probably cannot be dissolved by the administration of medicine. Confinement to bed after an attack of colic until inflammatory conditions have subsided should be insisted upon. As medicinal agents for the gall-bladder conditions and the usual digestive disturbances, the following combination has been recommended by Billings: Sodii salicylatis, 1.0; sodii phosphatis, 2.0; sodii sulphatis exsic.; 6.0; of this from one-half to one dram is to be taken in a glass of hot water thirty minutes before meals. The general attitude of both physicians and surgeons regarding operative procedure in most cases is too well fixed to warrant much discussion. In some cases Richardson advises operation the moment the first symptom of impaction appears, unless this impaction should be of the briefest and most trivial character.

Further Observations on the Wassermann Reaction for Syphilis.—W. P. Boardman states that the theory upon which this reaction is based is still obscure. As regards the Noguchi modification enough has already been done with this to show that it, like the many other modifications, gives a higher percentage of positive results in syphilitics, but like the others (though not nearly as often) it gives occasional positive results in non-syphilitics. It is concluded from an analysis of 500 cases examined with the original Wassermann technique, except that an alcoholic extract of normal liver was used as antigen, that a positive reaction is obtained in a large number of syphilitic cases, and if one adheres to the original Wassermann technic a positive reaction in a suspected case means syphilis almost without exception. A negative reaction in a suspected secondary or tertiary or congenital case means that it is probably not syphilis, but the finding should be used with caution and only in conjunction with clinical evidence and not by itself alone. A negative reaction in a suspected primary case, except one of long duration, and in an early case of general paresis, has very little value. In treated cases it has very little value except some months after treatment has ceased. To sum up, one may say that in the Wassermann reaction we have a definite aid to diagnosis, but its value in treatment and prognosis has not yet been carefully worked out.

The Technique of Arthrotomy.—C. F. Painter and A. P. Cornwall continue their contribution on this subject, referring in particular to the second largest group of cases for which arthrotomies have been performed at their clinic for tuberculous disease, and they describe the technique of the two procedures by which this is ordinarily accomplished, namely, excision and erasion.

Extreme Blood Picture in a Case of Pernicious Anemia.—W. C. Speidel reports a case in which the erythrocyte count dropped to 100,000 per cubic millimeter two hours before death, being the lowest count yet reported. The hemoglobin was 9 per cent. (Sahli).

Shakespeare's Knowledge of Medicine. M. Kahn.

Shot Wound of Brain.—J. C. Da Costa states that the lead pistol bullet is septic. If the patient does not die

quickly of shock or hemorrhage, the bullet, if allowed to remain, will usually soon induce septic leptomeningitis, encephalitis, thrombosis, or abscess. It may be responsible for some such complication at a much later period. Even if the patient escapes septic complications and the bullet becomes encysted it will sooner or later, in almost all cases, cause irritation or destruction of brain matter, and be responsible for death after a prelude of epilepsy, paralysis, amnesia, deafness, blindness, cerebral softening, or insanity. Therefore, though a man may carry a bullet in his brain for a long period without apparent harm, such cases are very rare, and a lodged ball is practically always a deadly menace. A lodged ball will almost certainly some day, and probably very soon, cause grave disaster and eventually kill the victim; hence, if at all possible, it should be removed. The Röntgen rays enable one to be certain as to the situation of the bullet. The Mackenzie-Davidson localizer, an apparatus made entirely of metal, can be applied to the head during the operation, and used to indicate the depth of the ball from a chosen point on the surface without the necessity of mathematical calculations. The old conservative view of *laissez faire* is an error. In cases of lodged bullets radical surgery is usually the safest and the wisest. Having decided that a bullet is accessible one must study out how it may be reached most easily, most safely, and with the least injury to function. In some cases it is best reached by following the course of the ball from the entrance wound, in others from the opposite side, in some cases from the front, in others posteriorly. The author reports two cases of lodged revolver bullets. The first was that of a No. .22 bullet lodged in the brain for eight months, which had produced amnesia and convulsions. The bullet was successfully removed, the convulsions were arrested, but the amnesia was not improved. The second case was that of a .32 calibre bullet that had lodged in the brain for over four weeks, causing violent headaches; the bullet was successfully removed with complete recovery.

X-Ray Localization of Bullets.—S. Tousey describes a simplified method for localizing bullets in the thicker portions of the body, without the aid of elaborate apparatus.

Japanese Method of Restoring Life.—A. Abrams states that *kuatsu*, an integral part of *jiu jitsu*, is the method resorted to by the Japanese for the restoration of those who have been "knocked out." It was also found to be effective in instances of sunstroke, drowning, and injuries from other causes. The method is performed as follows: The subject is placed in the prone posture with arms extended sideways and the operator with his wrist lands severely upon the seventh cervical vertebra with the regularity of a carpenter striking with a hammer. As soon as the patient recovers consciousness, he is placed in a sitting posture, his arms are rotated, and he is aided in walking. The latter injunction is regarded as mandatory in the application of *kuatsu*, the object being to completely restore the functions of the circulation and respiration, otherwise, it is said, the patient relapses into unconsciousness. According to the author, the essential feature of this method is concussion of the seventh cervical spine. This is one of the means by which the heart reflex may be elicited. The most effective instrument for this purpose is a pneumatic hammer. The author states that he has had an opportunity of gauging the efficacy of vertebral concussion in many acute infectious diseases implicating the heart and he has noted the almost miraculous action of the method in question.

Circinate Syphilides.—J. Kingsbury describes seven cases that belong to this category.

Fulguration of Papillomata.—L. Buerger and A. L. Walbarst conclude that the de Keating-Hart method of fulguration of tissues when applied to bladder papillomata in the manner suggested by Beer offers an easy and reliable mode of treatment. Local anesthesia applied to the bladder is sufficient to eliminate pain. Three cases of bladder papilloma responded excellently to this method of treatment. Apparently a cure has followed in each case. Although the exact *modus operandi* of the high frequency current is not thoroughly understood in practice, one may regard this type of fulguration as a method of cauterization which easily surpasses the electrocautery in the facility with which it can be employed in the bladder.

Surgery of the Stomach.—W. D. Hamilton states that pain after food is a common symptom of chronic gastric or duodenal ulcer. When it occurs in from an hour and a half to two hours after meals, and if it persists, one may suspect that the ulcers may be at or near the pylorus. If the pain occurs four or five hours after food the duodenum may be the seat of the ulcer. The ingestion of food may relieve, at least for a short time, the pain of duodenal ulcer, while in the case of gastric ulcer it may enhance the patient's discomfort. Pain, nausea, vomiting, hematemesis, attacks of peritonitis, with or without crippling adhesions, or cicatricial distortion, emaciation, anemia, invalidism, phthisis, or even cancer and death, are a few of the incidents or results of chronic gastric ulcer without going more into the numerous pathological complications besetting ulcer of the stomach. That duodenal ulcer, too, is liable to mark its presence by many of those symptoms is undoubtedly true. The diagnosis of gastric or duodenal ulcer is presumptive until the abdomen has been opened. The precipitate opening of the abdomen for diagnostic purposes is to be deprecated. All kinds of evidence which may be pertinent to the case should be used and recorded before operation is done. Mr. Moynihan has called attention to the anamnesis, the patient's own written account of his disability up to the time of his admission. Test meals with their associated investigations, while of some value, should not be relied upon too implicitly. In a similar category are examinations of the feces for occult blood. While it is desirable beforehand to get all such contributory or negative evidence, and all such pertinent information in each case, each method derives its value very largely by association with other evidence.

The Variability of the Gastric Juice.—E. L. Eggleston, as the result of experimental studies, draws the following conclusions: With the same food materials there may be quite a marked variation in the percentage of composition of the gastric juice which may result from psychic influences. Iced foods or beverages have only a slight inhibitory action on gastric secretions. Foods containing free fats in any quantity when taken either at ordinary temperature or frozen have a decided inhibitory effect on gastric secretions. Fruit juices either frozen or at ordinary temperature quite markedly increase the secretion. Compound tincture of gentian seems to have but little effect as a gastric stimulant.

Shakespeare's Knowledge of Medicine.—M. Kahn states that the many references that the poet has in his works to the various medical sciences and arts would convince one that he had read books on medicine and that he had studied the writings of the ancient Greeks and Romans.

Cultivation of Sarcoma Outside of the Body.

Histopathology of Cancer.—F. B. Mallory defines cancer from a pathologist's point of view as an epithelial tumor which infiltrates and which may give rise to metastases. To understand the full significance of this definition it is necessary to study in groups by themselves all the tumors which arise from each variety of normal epithelial cells and which tend to differentiate like them. Each group has its own peculiarities. There is a tendency to group together for study all tumors built up from the multiplication of single type cells which tend to differentiate alike. As examples of type cells he mentions the fibroblast, the smooth muscle cell, and the neuroglia cell. Two or more varieties of the type cell often exist, however. The newer classification recognizes that every simple tumor is due to the proliferation of one of the type cells which give the name to the tumor.

Mechanical Ileus Complicating Pregnancy.—P. S. Doane reports a case of this condition in which there had been a history of some intestinal inflammation seven years previous to the formation of the ileus, the inflammation at that time having been severe enough to produce adhesions which undoubtedly existed for a number of years.

Colon Bacillus Infection of Operative Wound.—E. A. Babler reports a fatal case of this condition following an operation for subphrenic abscess. The true origin of the subphrenic abscess was not clearly determined. The fact that a large portion of the diaphragm was destroyed by the bacterial invasion is interesting. The main feature of the case centered in the action of the colon bacilli on the postoperative wound. The author has not been able to find a similar report in the available literature. In his opinion the patient's lowered vitality, combined with the extensive distribution of the organisms, permitted but feeble opposition to the invasion into the skin and subcutaneous tissue.

The Tuberculous Tonsil.—R. Levy concludes that tuberculosis of the tonsils occurs more frequently than previously recognized, owing to newer methods of investigation. Clinically, tuberculosis of the pharynx, with or without tonsillar involvement, must still be looked on as among the rarer manifestations of tuberculosis. Clinical tuberculosis of the tonsils and that determined by histologic examination present marked differences. They are differentiated by the absence of symptoms in the latter and definite subjective and objective manifestations in the former. Many of the histologic findings attributed to tuberculous changes occur in other pathologic conditions. The diagnosis of true tuberculosis of the tonsils is more satisfactory when based on definite physical signs corroborated by typical histologic findings. The clinical form must be looked on as very grave, its curability being extremely doubtful. Extirpation of the tonsils is rarely indicated in clinical tonsillar tuberculosis. In the presence of cervical adenitis, lowered resistance, and evidences of malnutrition the best interests of the patient will be subserved by radical tonsillectomy even though other well-recognized indications for the operation be absent.

Tonsillar Enucleation.—J. C. Beck calls attention especially to the influence of the removal of the tonsils on enlarged glands of the neck and the cardiac complications of the rheumatic affections. Acute infectious diseases have been prevented or rendered mild by the operation, and in the diphtheria hospital in Chicago enucleation is performed on patients as soon as their cultures are negative. He has observed distinct improvement in several cases of tubal catarrh and ear disease. Apical tuberculosis of the lung was markedly improved in some patients by tonsillar removal, and he says that chronic bronchitis in children, not yielding to ordinary treatment, invariably yields to enucleation of tonsils and adenoids. A number of rheumatic conditions enumerated greatly improved under the operation, and he especially mentions 20 cases of rheumatism and cardiac complications giving a history of repeated attacks of tonsillitis, the cardiac disorder, as a rule, consisting of loss of compensation following such attacks, which had remained in good health since the operation. Other cases which yield to this treatment are mentioned, such as chronic septicemia with secondary anemia, certain gastrointestinal disturbances, nephritis, hepatitis, and pancreatitis resistant to other methods; also, certain eye troubles which have been permanently cured. In closing he presents a theory as to the raising of the opsonic index of the blood in all infections when the tonsils are enucleated.

Tonsillectomy.—B. R. Shurley states that the normal tonsil should not be disturbed, particularly in early infancy. Simple hypertrophied tonsils may be removed satisfactorily with the tonsillotome. Pathologic tonsils, especially those of the submerged type that produce well-defined local or general symptoms, should be completely removed within the capsule. In children tonsillectomy requires a general anesthetic, preferably ether. This should be a hospital operation when possible. Tonsillectomy is an operation that should be restricted to those who are specially qualified. The removal of the velar lobe and the complete separation of the pillars are the most important parts of the tonsil operation. Tonsillectomy is not indicated in all cases of so-called rheumatism. Complete enucleation is usually attended by more pain, a longer period of convalescence and greater danger of infection than tonsillotomy. When tonsillectomy is skillfully performed the hemorrhage is less than when the average tonsillotomy is done. Tonsils which have been involved in recent acute inflammation should not be operated on until all evidence of the acute condition has subsided. Many tonsils seen by the general practitioner, with every appearance of serious pathological condition, never develop local or systemic symptoms.

Progress in Cancer Research.—L. Loeb enumerates the important facts that have been elicited by cancer research in the past ten years as follows: Tumor cells in many cases can be propagated in other individuals of the same species and on the whole preserve their specific character as cancer cells. This proves definitely that tumor cells are not merely regenerating tissue cells and their activities cannot be merely due to the peculiarities present in the individual organism in which the tumor originated. In accordance with this fact is the other that the ferments of tumor cells differ quantitatively and probably also qualitatively from those of ordinary cells. The propagation of tumor cells is amenable to variations that can be experimentally produced, and the experimentally produced changes may be transmitted to a succession of generations of cancer cells. New and unsuspected properties of cancer cells have been discovered, among these their great capacity for recovering from external injurious influences. By selecting very well-growing tumor cells, it is possible to produce more rapidly growing tumors. Some important facts have been learned which may appeal to the physician. The transplantability of the tumor depends first on the character of this particular tumor, and second, on the character of the host. The majority of tumors, so far as one can at present say, can be transplanted in the same individual in which the tumor originated; others can be transplanted into individuals nearly related, while a certain number grow on a large number of individuals of the

same species, and a few grow even in different though in nearly related species. Some individuals of the same species are found immune and others can be rendered artificially immune. A very potent immunity can be produced by inoculating living tumor material, the vitality of which has been lowered by previous heating, and an active immunity has been produced in animals by the use of material from retrogressed tumors. The first positive results have been obtained in experimental immunization against tumor growth, a fact of great theoretical and practical significance. Experimental cancer research has also stimulated the experimental study of general tissue growth, and *vice versa*. It has also exerted a stimulating effect on some other apparently unrelated fields of science.

Biochemistry of Tumors.—R. Weil states that two agents have been identified in tumors which might be accused of a toxic influence on the somatic cell, namely, a hemolytic substance and a proteolytic ferment. The simple hemolysins are chiefly present in necrotic, and the complex hemolysins in the non-necrotic tumors. There is ample evidence that they pass into the circulation and may be regarded as active agents in tissue destruction. It has been shown to be a fact that anemia of marked grade with normoblasts in circulation and the development of a race of resistent erythrocytes, can be induced experimentally only by the repeated injection of hemolytic substances. The fact that a hemolysin can be extracted from cancerous material and that in a considerable proportion of cancer cases a hemolysin is found in the circulating blood strengthens the evidence that the anemia of the disease is caused by this hemolysin; but it cannot be considered of diagnostic importance; a positive reaction does occur in cancer cases with greater frequency than in non-cancer cases and it may therefore be cautiously considered in connection with other symptoms as an auxiliary to the diagnosis. The antitryptic reaction is also recognized as a striking symptom of cancer; it occurs also in other conditions, but the general consensus of opinion in England and Germany seems to be that it furnishes a very valuable aid in the diagnosis of cancer, especially if certain complicating factors such as tuberculosis can be excluded. It cannot be considered specific but that does not destroy its value as a clinical adjunct. The other so-called diagnostic reactions for cancer which have developed on the analogy of the well-known specific reaction, from immunology, such as the precipitin reaction, the complement deflection test and the anaphylactic method, have not proved to be of value. While the early reports of Ascoli's meiostagmin reaction, based on the diminution of surface tension when antigen and antiserum are brought together, are encouraging, it is too soon to decide as to its merits.

Heredity of Cancer.—E. E. Tyzzer concludes that heredity plays a rôle in the general incidence of cancer with regard to species, as is indicated by the frequency of mammary tumors in mice, while they are rare in cattle, which, however, develop primary tumors of the liver and adrenal. Although much of the evidence collected tends to indicate that heredity is not an important factor in the development of cancer, it would appear that this question cannot be definitely settled without the use of more accurate methods than have heretofore been employed. For this work the importance of the experimental breeding of animals cannot be overestimated, for here it is possible not only to obtain accurate data, but to shape the course of the experiment.

Surgery of Malignant Growths.—J. C. Bloodgood believes that one has come to a better conception of the pathologic varieties and also of their local growth and tendency to metastasis. Surgeons are learning better which kinds of tumors need extensive operation and which can be treated with less mutilation. Benign forms of tumors may become malignant and scars may give rise to sarcoma. The physician should constantly bear in mind the late effects of trauma. One of the important things in recent progress is the better knowledge and opportunities to anticipate malignant growths before they become really malignant. Bloodgood emphasizes the importance of diagnosis and states that one should try to become skilled in the clinical diagnosis. Surgeons with the largest experience find themselves frequently unable to decide whether a restricted or extensive operation is needed unless by pathologic as well as clinical examination. The experience to-day, he says, reverses the old rule of amputation for sarcoma of bone unless the resection of malignant disease would leave a limb without function. If spindle-celled or round-celled sarcoma of bone has grown to such a size as to require amputation metastasis has already taken place and the patient should not be subjected to the mutilation of an amputation for the few months they have to live, unless the tumor is giving so much pain or discomfort as to call for it. On the other hand, if the tumor belongs to the less malignant type, amputation should be performed, since in the majority of cases it will accomplish a cure. He concludes that until one has found some other method of treating malignant growths future progress must proceed along the lines followed at present.

Cardiospasm.—J. S. Myer states that an experience in ten cases leads him to the belief that there is a congenital basis for the development of the sacculation and that is the same that is the basis of the enteroptotic condition, a sort of general asthenic condition, the type of individuals being similar. While it is generally believed that cardiospasm is of nervous origin, how or why it develops in certain individuals has never been satisfactorily explained. He is inclined to attribute it to the neuropathic predisposition which accompanies the general neurasthenic predisposition. He doubts whether any complete relief can be obtained after sacculation exists, and the earlier a case can be recognized the more complete will be the cure.

Strangulated Congenital Umbilical Hernia.—I. R. Maercklein reports a case of this condition successfully operated upon, in an infant twelve hours old.

Uvula Forceps and Tonsil Separator.—H. R. Boettcher describes a new uvula forceps and a combined tonsil separator and scissors.

Treatment of Typhoid.—L. M. Warfield states that a life-saving procedure in the treatment of typhoid fever is the elevation of the foot of the bed.

Medicine Dropper Clip.—P. R. Wood describes a blued steel clip, which springs securely over the sides of the bottle and at the same time holds firmly a common rubber pipette, which, after using, is readily returned, to be at hand when wanted, and, which being cheap, is easily replaced.

Cultivation of Sarcoma Outside of the Body.—A. Carrel and M. T. Burrows state that their results show that sarcomatous tissue grows luxuriantly outside of the organism, that a second generation can be produced by the cells grown in a first culture and that the whole process can be observed with ease at every instant of its evolution. It is probable that the malignant tumors of the human organism can, in a similar manner, be caused to grow outside of the body. The method, therefore, will be a valuable addition to one's means of studying the problem of cancer.

The Action of Chlorine upon Water Contaning the Cholera Vibrio. H. W. Harding.

Heredity in Relation to Mind.—H. B. Donkin states that the only important link between the study of crime and that of heredity is the fact that a considerably larger minority of persons with clearly appreciable mental defect, apparently of congenital nature, is found among convicted criminals than among the population at large. But no really rational hypothesis of hereditary criminality has been formulated. As to the physical character of the brain of imbeciles, no absolutely positive statement can yet be made from the anatomical point of view as to how far true retrogression or how far arrest of fetal development can be said to contribute toward the solution of this problem. Touching the mental and moral characters of man, there is massive evidence which shows that many even of the most importantly adaptive among them are the result of modifications developed in each individual under the stimulus of actual use and training alone. Such characters are mainly and clearly traditional; they are handed down by each generation to the next through teaching and example, not through real inheritance; but their constant acquirement by every generation gives them the appearance of naturally inherited qualities. The doctrine of the leading biologists of the present day who recognize the truth of the principles of evolution as established by Darwin and who hold, in substitution of Darwin's supposition of the transmissibility of some acquired characters, that it is "educability" or the organic capacity of making such acquirements, not the acquirements themselves, which is innate and transmitted, seems to form the only synthesis which covers the known facts of heredity, is contradicted by none, and tends in consequence to be of further interpretative value. "The mind of the adult is mainly a social product, and can be understood only in relation to the special environment in which it develops and with which it is in perpetual interaction."

The Royal Navy Medical Service.—Admiral Sir John Durnford states that though there are some difficulties in a naval career there is much to recommend it. One cannot fail to appreciate the associations, the work, and the opportunities and advantages incidental to a life of travel. One may not obtain the reward a Harley street reputation sometimes carries with it, but perseverance will obtain the most satisfactory recognition a naval officer can aspire to, the good opinion of the great silent sea service which, when merit is deserved, communicates its appreciation in no uncertain voice. This and the gratitude of the officers and men served, and sailors are not ungrateful, will stimulate zeal in what one will find a satisfactory career.

Further Experiences with 606.—J. E. R. McDonagh states that in the treatment of syphilis with 606 a much bigger dose is required to heal an early chancre than to cure completely a case of extensive gummatous ulceration, for instance, in a congenital syphilitic; therefore one is justified in assuming that the cure is largely due to the amount of antitoxin formed. He concludes that much has yet to be learned before the final word on this wonderful remedy is given; one can say that the dangers have been extremely exaggerated, since only twelve deaths have occurred in 12,000 cases, and in many of these the injection was given as a last resource. This being the case, and there not having occurred an instance of visual disturbance, the drug will not fail to achieve the object which its talented discoverer had hoped for it.

Benign Cyst of the Humerus.—H. Lett reports a case of this condition in a boy of thirteen years, the result of traumatism, and successfully removed. It is stated that the formation of the cyst is associated with a local process which is of the nature of an inflammation. This process has led to fibrosis of the marrow with destruction of old bone and the formation of recent osteoid tissue, membrane, and lamellar bone. The process is of long duration. The process has also led to the formation of hyaline cartilage, or possibly the pseudoinflammatory condition may have been provoked by the degeneration of an abnormal deposit of cartilage.

Anaphylaxia in Hay Fever.—G. Billard concludes that the majority of persons attacked by hay fever or asthma are hereditarily anaphylactic or have during their life acquired anaphylaxia. He refers to a recent clinical lecture in which Professor Hutinel says "that acetonemic vomiting may be considered a sort of digestive asthma. The bilious headache represents, on the other hand, a kind of nervous asthma; eczema, a cutaneous asthma; and gout, an asthma of the joints. The common ground of arthritis brings these diverse complaints into close connection. Thus it is common to find among the ancestors of asthmatic persons nervous troubles, gout, diabetes, obesity." In the author's opinion, all these manifestations depend on anaphylaxia, another manifestation of which, ranking prominently among the neuroarthritics, is urticaria. A case is cited of a physician whose ancestors suffered from arthritis of an acute form, and in whom the eating of shellfish produced poisonous nettlerash accompanied with asthmatic paroxysms.

Thrombosis of the Lateral Sinus.—J. W. Wood reports three cases of this condition. In the first of these the main points of importance were: Cessation of discharge; sudden onset of pain behind the ear; tenderness along the internal jugular vein; shivering (rigors); Griesinger's symptom (tenderness and slight edema over the site of the emissary vein, although no tenderness or swelling over the mastoid antrum); the disks normal, and consciousness unimpaired. In the third case the principal points were the remittent temperature with free perspiration, but absence of rigors; the headache and sickness; the absence of optic neuritis; the presence of Kernig's sign, but no symptom of meningitis beyond this, and the absence of Griesinger's symptom.

Treatment of Asiatic Cholera.—R. T. Hewlett states that Macfadyen found that by the trituration of cholera cultures in the presence of liquid air the intracellular cholera juice or "cholera endotoxin" possessed decided toxic properties and by the immunization of animals an antiendotoxic serum was obtained which possessed considerable protective power as well as agglutinative and bacteriolytic properties. The author was able last year to immunize a horse by the Macfadyen method with cholera endotoxin prepared by the trituration of virulent cholera cultures obtained from India. This antiendotoxic serum experimentally possessed considerable protective and curative powers tested on guinea pigs. Thus 0.0001 c.c. and 0.5 c.c. of serum protected against 10 and 50 lethal doses respectively of living cholera culture injected simultaneously intraperitoneally into guinea pigs. Curatively 1 c.c. of the serum saved the life of a guinea pig inoculated intraperitoneally with four lethal doses of living cholera culture six and a half hours previously. A trial of this serum was made in nine cases of cholera which occurred during the epidemic of last year in Russia. The clinical reports showed that of the nine cases four died and five recovered. The number was too small to base any conclusions as to the value of the serum, but it seemed worthy of more extended trial.

Chlorine and Water Containing Cholera Vibrio.—H. W. Harding found as the result of his experiments that most waters, if treated with one part of chlorine per 1,000,000 for fifteen minutes would be free from the cholera vibrio.

Scientific Observation. H. A. Miers.
Certain Intracranial Diseases Associated with Nasal, Aural, and Laryngeal Symptoms. P. Stewart.
Injuries to the Eye. A. S. Percival.

Scientific Observation.—H. A. Miers refers to two possible dangers that beset investigators under modern conditions of work. First, those whose attention is too minutely fixed upon one thing will fail to perceive other things which are equally discernible and equally important; and secondly, those who look or listen too intently for a thing may actually see or hear that which they desire, even though it be not there.

Intracranial Disease Associated with Nasal, Aural, and Laryngeal Symptoms.—P. Stewart directs attention to some primarily intracranial diseases in which the aural, nasal, and laryngeal symptoms only transpire incidentally, as it were, in the course of the malady, and in which, nevertheless, the recognition of these symptoms is of the utmost importance for a correct diagnosis. The first case was that of a tumor in the region of the optic chiasma, in which the voracious appetite suggested upward extension toward the temporal lobe on one or the other side. This case exemplified the importance of recognition of the cortical center for hunger situated in close proximity to the centers for smell and taste. The second and third cases were those of extracerebellar tumors arising from the auditory nerves, in which there were cochlear or vestibular symptoms. In the fourth case, that of intracerebellar tumor, there were no symptoms referable to either division of the auditory nerve. The fifth case was that of syringomyelia with nuclear paralysis of the larynx. In the sixth case, also one of syringomyelia, the process extended upward in the medulla to the nuclei of the hypoglossus and vagus.

Injuries to the Eye.—A. S. Percival states that in removing a foreign body from the cornea one should always use a lens. If an abrasion of the cornea occurs which has not perforated Bowman's membrane no scar will result. If, however, Bowman's membrane be injured a scar or nebula will result. If the foreign body have penetrated the eye, when magnetic it should be removed by a magnet. When not magnetic it must be seized by forceps through a suitable incision. In some cases the foreign body need not be removed at once. The most important point upon which one may at any time have to give an opinion is what cases of injury should be regarded as liable to give rise to sympathetic ophthalmia, and under what circumstances the injured eye should be removed at once. In almost every case of sympathetic ophthalmia the exciting eye has been previously perforated either by injury or by ulceration. Hence, every perforating wound which is not known to be aseptic is always a source of great anxiety. The risk is extreme: 1. If the wound be in the ciliary region; this dangerous area may be defined as the zone one-quarter inch in width that surrounds the margin of the cornea. 2. If the wound be septic—often this can only be recognized by its consequences; it should, however, be noted that wounds giving rise to suppurative panophthalmitis are not liable to induce sympathetic ophthalmia. 3. If a foreign body be retained in the eye, its removal being impossible. Immediate excision of the eye is indicated by the concurrence of two of these conditions, even though some sight be retained; by the occurrence of one of them if sight be irreparably lost, provided that the vision of the other eye be good, and that it shows no sign or iridocyclitis. Under other circumstances excision of the eye may be delayed until symptoms arise without much risk, but operative interference is necessary when there is persistent severe or recurrent iritis, when the eye is tender or when it becomes soft, or when the other eye is the seat of sympathetic irritation.

Berliner klinische Wochenschrift.

October 17, 1910.

Opsonins and Their Relation to Practice.—Michaelis of Professor Wassermann's Division of the Royal Institute for Infectious Diseases, Berlin, admits at the outset that German scientists have received the teachings of Wright with much reserve. Vaccine therapy is therefore a new resource in Germany. The author has applied the method and studied it thoroughly before publishing any conclusions. He concedes that in stephylococcus disease, as well as gonorrhea and colibacillosis, active immunization is indicated. Cases of these affections which could not be made to yield to other treatment succumbed to vaccine therapy with autogenous vaccines. In streptococcus discase the indications are more restricted, and a combination of vaccines must be used. Although quite enthusiastic for the outlook of vaccine therapy, the author cautions that this resource is still in the formative stage. Of the entire range of diseases susceptible to vaccine therapy, comparatively few seem to have been tested by the author—doubtless only those which presented themselves during the period of experiment. Incidentally he treated fifty cases of local tuberculosis with Koch's new tuberculin emulsion as a vaccine; the results obtained after prolonged treatment were decidedly inferior to ordinary surgical methods.

Hay Fever as Explained by Anaphylaxis.—Hoffmann concludes that the pollen disease is due to supersensitiveness of the mucosa of the respiratory tract to a heterologous albumin which exists in certain pollens. Another factor is also required, to wit, a diminution of the excitability of the vasodilator nerves. This condition is due, in some cases at least, to hyperthyroidism. Such views naturally require something better than mere deduction to support them, and the author attempts to prove his claims from clinical facts. 1. Basedow's disease, equivalent to hyperthyroidism, shows supersensitiveness in the form of urticaria and dermographism, which conditions are also common in hay fever subjects. 2. Thyroid enlargement in hay fever has been noted since the time of Mackenzie, but the subject has never been systematically studied. Recognition of slight enlargement is difficult and it is not necessary for a gland to be enlarged in order to be hypersecretory. 3. Hay fever may disappear permanently after strumectomy, and is sometimes benefited by thyroidin. 4. In hyperthyroidism gentle stroking of the nasal mucosa with cotton shows exaggerated vascular reflexes in the trigeminus area. This is most evident in the conjunctiva. 5. Patients with Morbus Basedowi react to subcutaneous injections of pollantin. 6. There is a certain parallelism between the syndrome of iodism and that of hay fever. In theory extirpation of the thyroid should be the radical treatment of hay fever.

Culture of the Spirochaeta Pallida.—Schereschewsky possibly does not regard the discovery of Ehrlich's arsenobenzol compound as final in the treatment of syphilis. He has spent a long time in attempts to secure pure cultures of the pallida in the interest of a vaccine therapy of syphilis. Cultures thus far obtained seem to represent an admixture. It is a striking fact that numerous other forms of spirochetes are readily cultivated, while the *Spirochæta pallida* is peculiarly refractory. It is, therefore, possible that in a given culture fluid containing the pallida the latter may not survive, while other forms accidentally present may flourish. At any rate such cultures cannot be made to communicate syphilis to any of the susceptible animals. Various other explanations are available. Thus the pallida may lose its virulence in the process of culture. A bit of syphilitic tissue which includes a normal culture of the pallida is readily inoculable. As with artificially cultivated spirochaetes in inoculation experiments, so with the same in the biological reactions. No agglutination could be

obtained; the precipitin reaction was absent. When used as an antigen positive results were obtained in Wassermann's reaction, but this fact proves nothing. We must either succeed in obtaining pure virulent cultures of the pallida or there will always be a flaw in the title of this microorganism to be the actual cause of syphilis.

Deutsche medizinische Wochenschrift.

October 20, 1910.

Nature of the Trachoma Exciter.—Herzog, who claimed recently that the trachoma body is only a mutation of the gonococcus, and who has been antagonized or merely ignored by all coworkers in the realm of trachoma, continues to write in the same confident tone. He first claims that in any case the chlamydozoa theory is untenable. He regards it as quite demonstrable that the trachoma parasite represents an involutionary and degenerative form of some Gram-negative diplococcus, and that this can be no other than the gonococcus. He is forced to admit that there are gaps in his theory, *i. e.*, a fresh culture of gonococci cannot produce trachoma. But if we pass cultures from one subject to another, with considerable intervals, the gonococcus finally undergoes a mutation which represents the trachoma body and possesses the ability to convey trachoma, being too weakened in virulence to cause acute gonorrhea. The author might have cited a somewhat parallel instance from the history of vaccination. A horse was once inoculated with human smallpox, matter from the pastules of which caused typical variola instead of vaccinia, in a human subject. Thereafter the inoculation was passed along from one horse to another. The pus in the fourth or fifth generation caused vaccinia, showing that mutation of some sort had taken place, with weakening of virulence.

Unusual Location of the "Lead Line" in Plumbism.—Most students are familiar with the gray line on the gums near the teeth which was believed to be pathognomonic of lead poisoning. Few ever learned that this line can fail completely in this locality. Knierim, who has made a study of the literature from old and recent writers, shows conclusively that the lead line or area may be found anywhere in the mouth, and may even involve the entire mucosa. The deposit of lead sulphide which is responsible for the discoloration may be seen as far back as the pharynx. That it has any real predilection for the gums appears doubtful. If a person with cleanly habits who practises hygiene of the mouth chances to contract plumbism his gums near the front teeth may escape a deposit, and this is true of toothless subjects. Generally speaking, this gum localization is absent in 50 per cent. of cases. Other localities may, however, be attacked, as the inner surface of the lips, the cheeks, the gums corresponding to the back teeth, the palate, etc. The author reports a case of one of the rarer localizations, viz., at the inner surface of the lips. The deposit was in the form of macules. There was a lead line on the gums, exactly opposite the deposit on the lips. The author makes an attempt to explain the lip location through contact of the lips and gums, the latter being possibly irritated by the carious teeth present. The lead may have been directly transferred to the lip, or may have passed into the saliva and been redeposited in the abraded surface.

Local Quartan Malaria Along the North Sea.—Mühlens discusses the appearance of this affection in Northwest Germany—or rather its reappearance, for it prevailed there extensively a generation and more ago. In discussing the phenomenon the author barely mentions the mosquito, beyond the remark that the anopheles has constantly been present in the locality, yet many years elapse without a case. Quartan parasites were now and then found, but without typical behavior in relation to the attack and otherwise. The theory of parasite carriers and of imported cases from the south could both be excluded. In fact, for this particular outbreak we are as helpless to postulate a cause as were the old observers of pre-scientific days. Quinine relieved single attacks but had no power to prevent relapses. The author is careful always to separate the new quartan form from the tertian, which is always present, pursues its own course and presents its own type of parasite. To what extent the latter is imported from warmer climes or is due to carriers is uncertain.

Münchener medizinische Wochenschrift.

October 18, 1910.

Anesthesia of the Tuberculous Larynx by Alcohol Infiltration of the Superior Laryngeal Nerve.—Roth refers to the pioneer work on this subject by Hoffmann in 1908. The chief aim was relief of the dysphagia. Sturmann in the following year succeeded in so infiltrating the superior nerves that the glottis remained insensitive for three months. These alcohol infiltrations were without unpleasant consequences such as follow the similar employment of cocain. Hoffmann later reported 16 cases in which anesthesia lasted for from 6 to 40 days. Since then there has been no new literature on the subject. The author and colleagues have, however, been at work on the subject and now report a material of 33 cases. The indication for the infiltration was always dysphagia. All but three of the patients had advanced pulmonary phthisis. The laryngeal lesions exhibited their usual diversity. Besides dysphagia most of the patients suffered from hoarseness or aphonia, and lancinating pains. The dysphagia was of some two months' average duration, and a variety of local anesthetics had been used without success. The dysphagia was naturally most pronounced for solid and semisolid food. The idea of the alcohol infiltration was adapted largely from Schlösseo's method of treating neuralgia, the technique being similar. The point for injection lay between the hyoid bone and thyroid cartilage where the internal branch of the superior nerve is given off for the sensory innervation of the larynx and trachea. In but one case was this point sensitive. The technique is principally that for aseptic injections in general. The injections were painful, the pains being at the seat of puncture and radiating. About 1 gram was the regular amount of alcohol required, the largest quantity used being 2 grams. In but a single case was the result negative. Anesthesia lasted from one to twenty-one days. The method appears to be a decided advance in the treatment of the dysphagia of tuberculous laryngitis.

Post-Traumatic Heart Disease.—Beckhaus sums up a series of cases as follows: Either a severe physical shock, involving the entire body, or one merely local, involving the left side of the chest, may at times be followed by a cardiac lesion. Some doubt must coexist as to the condition of the heart before injury. The case of a young man presents the greatest interest. He sustained a fall from a signal mast, about 20 feet. No external or internal injuries apparent, save for the urinary tract (bloody urine, casts). He soon improved, but continued to suffer from pains in the back, precordium, etc. Examination of the heart showed slight enlargement, a systolic murmur, tachycardia on exertion, and arrhythmia. The condition at first became worse, but four months after injury all had become normal. Psychic shock was also in evidence, as shown by the effects of reminiscences and associations. But the author found no evidence of typical neurasthenia or hysteria. The two other recorded cases occurred in elderly men who had worked at hard labor for years, although the heart in each was believed to be intact before the injury. None of the two made a complete recovery. The author's diagnosis of the exact lesion in the three cases was myocarditis with muscular mitral insufficiency.

Book Reviews.

Le Globulin des Mammifères. Par le Docteur M. Aynaud. Preparateur à la Faculté. Ancien Interne des Hôpitaux de Paris. Paris: G. Steinheil, 1909.

In this book of over 200 pages the author gives an exhaustive review of the writings of others on the blood platelets and presents the results of his own extensive studies of the subject. He describes the technique of observing this element of the blood in the living animal, using the mesentery of young rabbits, and also in shed blood, using paraffined glass ware or citrate solution to prevent coagulation. Like Bizzozero, Eberth and Schimmelbusch he describes the platelets as occurring in two forms, an elongated spindle-shaped type which is the one always seen in unaltered and circulating blood, and a rounded form, which is the one ordinarily found in the preparations as commonly made. The older writers believed that the spindle-shaped form represented simply the lateral view of biconvex disk, but Aynaud considers that the platelet is really a disk that is exceedingly thin and has perfectly plane surfaces. Its apparent thickness when seen from the side is due to very rapid oscillations of the platelet, which are normally continuous, and possibly depend on interchanges between its substance and the surrounding medium. When the platelet undergoes changes due to fixation or an alteration in the fluid medium its motion ceases and it presents itself as a disk. Why it normally always is seen from the edge is an open question. There is an excellent bibliography and the book is of interest to all workers in this field.

Hay Fever and Paroxysmal Sneezing. By Eugene S. Yonge, M.D., Physician to the Manchester Hospital for Consumption and Diseases of the Throat. With two colored plates. 150 pp. Edinburgh and London: William Green & Sons, 1910.

For the author this title is another way of saying, "vasomotor rhinitis." He adds a section on idiopathic rhinorrhea. Each one of the sections is introduced with an interesting historical chapter. In regard to hay fever the various theories are given full consideration. The author accepts the existence of a predisposition, some intranasal peculiarity and an exciting agent especially the various pollens. The book is readable, well printed, and interesting.

Die Praxis der Ernährungstherapie der Zuckerkrankheit. Von Dr. Hermann Schall und Dr. August Heisler, früheren Assistenten der medizinischen Klinik in Marburg. Mit 1 Kurventafel. Würzburg (Curt Kabitzsch): A. Stuber's Verlag, 1910.

The difficulties attending a really rational dietetic treatment of diabetes are increasing in proportion as the conditions underlying the successful management of the disease are being better understood. The inadequacy of the dietetic regulations contained in the ordinary handbooks is evident, still but little has so far been done to supply comprehensive and thoroughly modern, yet practical, working directions for use in every-day practice. The present brochure of 150 pages is admirably adapted to fill this need, and contains all the information necessary to regulate the diet of the diabetic so as to secure a maximum of therapeutic effect and entail a minimum of discomfort.

Studies in Immunity. By Professor Paul Ehrlich, Privy Councillor and Director of the Royal Institute for Experimental Therapy, Frankfort, Germany, and his collaborators. Collected and translated by Dr. Charles Bolduan, Bacteriologist, Research Laboratory, Department of Health, City of New York. Second edition, revised and enlarged. New York: John Wiley & Sons. London: Chapman & Hall, Limited, 1910.

Dr. Bolduan is already well known as the translator and editor of much of the German literature in the field of immunity and allied subjects, and his version of the collected studies of Ehrlich and his associates has won him the especial gratitude of all English-speaking laboratory workers. In presenting a new edition of the volume he has added Ehrlich's later studies, including his Nobel lecture on the "partial-functions" of cells, as well as some of his earlier papers that were not previously translated. The usefulness of the work has been still further increased by the preparation of an ingenious index of the hemolytic and bacteriolytic reaction described in the text, an index of the authors quoted, and a very complete index of the subjects discussed. Whatever the ultimate verdict will be as to the validity of Ehrlich's theory the importance of these papers cannot be overestimated, and they will always stand as masterpieces of research brilliantly conceived and elaborated with infinite patience. The difficulties of translation have been unusually great, but have been surmounted with signal success, and Dr. Bolduan fully deserves the appreciation of his skill that has been attested by the prompt exhaustion of the first edition.

Founders' Week Memorial Volume. Containing an account of the Two Hundred and Twenty-fifth Anniversary of the Founding of the City of Philadelphia, and Histories of Its Principal Scientific Institutions, Medical Colleges, Hospitals, Etc. Edited by Frederick P. Henry, A.M., M.D., John V. Shoemaker, M.D., Chairman of the General Committee on Scientific Institutions, Medical Colleges, and Hospitals of Philadelphia, and ex-officio of the Committee on Publication. Published by the City of Philadelphia in Commemoration of the Two Hundred and Twenty-fifth Anniversary of its Founding, Philadelphia, 1909.

On December 13, 1907, Hon. John E. Reyburn, Mayor of Philadelphia, appointed a committee to determine the year of the physical and legal founding of the City of Philadelphia. As a result of the labors of the committee, the year 1683 was settled upon as being the true date of the founding of Philadelphia as a separate government. The committee recommended to his Honor, Mayor Reyburn, that the 225th anniversary of the founding of Philadelphia should be celebrated in a suitable manner by commemorative exercises, under the auspices of the city government and a committee of citizens. This celebration occupied the entire week of October 4-10, 1908. The particular object of this memorial volume is to record the history of the hospitals, medical colleges, and allied scientific institutions of the city of Philadelphia. These histories are very complete and contain much interesting reading, for with the institutions are linked the names of many eminent men, pioneers and leaders in medicine. The introduction contains the reports of the various committees having the celebration in charge, together with the programs of the commemorative exercises.

Difficult Labor. A Guide to its Management for Students and Practitioners. By G. Ernest Herman, M. B. Lond., F. R. C. P., F. R. C. S., Consulting Obstetric Physician to the London Hospital; Consulting Physician-Accoucheur to the Tower Hamlets Dispensary; late President of the Obstetrical Society of London and of the Hunterian Society; formerly Physician to the General Lying-in Hospital, and to the Eastern District of the Royal Maternity Charity, and Examiner in Midwifery to the Universities of London, Oxford, Cambridge, and Durham, the Victoria University, the Royal College of Surgeons, and the Royal College of Physicians. With 180 Illustrations. New and Enlarged Edition, with added Chapters on Retroversion of the Gravid Uterus and Puerperal Eclampsia. New York: William Wood and Company, 1910.

The appearance of a fifth edition of this work is evidence of its popularity. The whole work has been revised, new matter and illustrations have been added, including chapters on retroversion of the gravid uterus and puerperal eclampsia. The object of the author has been to give the reader more definite guidance in practice than he gets from other textbooks. His experience in difficult labor has been such as to warrant his stating what he considers the best way of dealing with each complication of labor without giving all current opinions. This gives a distinct character to the book, which may be referred to for detailed information as to the management of every phase of difficult labor. The practical value of this is heightened by the absence of theoretical and controversial matter. The teaching experience of the author is discerned on every page, in the arrangement of the text, the use of heavy-faced type and italics as paragraph headings, all of which render the work available for quick reference. The illustrations are numerous and form a helpful complement to the text. The author advises closer co-operation between physician and midwife, the latter being competent to watch the progress of labor, and to report all abnormalities to the physician. The acceptance of this attitude may be a boon to the busy practitioner. The newly added chapter on eclampsia is an admirable contribution to the subject. The question whether forcible delivery is of any value in this condition is answered in the negative. An analysis of over 2,000 cases reported in various lying-in hospitals shows that after rapid delivery there is no diminished tendency to the occurrence of convulsions. The advice is given that labor should be permitted to go on naturally, and interference resorted to only if some other condition is present that would demand interference.

Society Reports.

MEDICAL ASSOCIATION OF THE SOUTHWEST.

Fifth Annual Meeting, Held at Wichita, Kan., October 11 and 12, 1910.

THE PRESIDENT, DR. G. H. MOODY, OF SAN ANTONIO, TEX., IN THE CHAIR.

ADDRESSES of welcome were delivered by Hon. C. L. Davidson, Mayor of Wichita; Dr. O. P. Davis, President of the Kansas State Medical Society, and Dr. E. J. Oldham, of Wichita, Kan., which were responded to by Dr. Joe Becton, Greenville, Tex.

Colica Mucosa.—Dr. E. H. THRAILKILL of Kansas City, Mo., had chosen the designation colica mucosa from the long list of names that had been proposed for non-infectious diseases of the mucous membrane of the colon. It was most appropriate, for it designated the passage of mucus and the attacks of colic. Formerly this was considered a constitutional disease, owing to the lack of scientific knowledge as to the etiology and pathology, but in recent years various views and opinions had arisen and had been published. He had adopted the following classification: 1. Those cases due to a motor and sensory neurosis he designated simple colica mucosa. 2. Those due to extra-colonic conditions, causing interference with the movement of the fecal discharges, he designated colica mucosa reflexa. 3. Those due to an extension of the inflammatory process from the rectum or appendix, or when due to the retention of hardened fecal masses, foreign bodies, or to the prolonged use of cathartics, causing an inflammatory condition, he designated mucous colitis. Inasmuch as the conclusion was that each class required a different treatment surgically and medically, he could conceive of no better way in which to illustrate this classification than to report briefly a case of each class. After reporting a case of each class, the author said that in chronic cases, or those due to a mechanical interference or an inflammatory process, the mucus was thick, tenacious and attended with considerable pain, due to the strong peristalsis of the bowel in its effort to dislodge and expel it. The majority of these patients gave a history of disturbed digestion or constipation, preceding the onset of this affection. He had had patients give a history of diarrhea preceding or accompanying this trouble. As a rule, the diarrhea was due to a diet, composed of a concentrated food, and the diarrhea was due to the lodgment of fecal crumbs throughout the bowels.

DR. ARTHUR E. HERTZLER of Kansas City, Mo., said the classification given was very sensible. The great difficulty that had arisen in the conception of this disease had been due to confusing the various classes of cases. In some cases the condition was neurotic; in others it was not. They had not used as much care as they should have done in separating the different cases. It was sometimes difficult to make a satisfactory diagnosis because the neurotic condition might be secondary to some organic disease. A patient might present a history of some neurotic condition, and the natural inference was that the trouble was the result of nervous disease, and yet the disturbance might be secondary to some abdominal lesion which was obscured by the existence of the organic trouble. Unfortunately they were not in possession of sufficiently clear knowledge of the abdominal conditions which developed in these nervous states to be of much avail. Most of the cases of colica mucosa he had seen had been in neurotic subjects, and they had responded to treatment by the neurologist. There were a number of cases attended by stomach disturbance, and in others by diverticular formations, and yet there was no definite symptomatology.

Dr. G. W. ROBINSON of Kansas City, Mo., said his experience with colica mucosa had been confined chiefly to cases among the insane. This condition was more frequent among them than any other class of patients. The conditions among the insane were favorable for its development. Constipation was very common among insane patients, and they found that there was a disturbance of the function of the cells of the central nervous system, and he believed this condition was chiefly a perversion of the secretory nerves as well as the motor nerves of the intestine.

Postoperative Care and Treatment of Suprapubic Prostatectomy.—Dr. D. W. BASHAM of Wichita, Kan., said suprapubic prostatectomy offered a marked exception to the expectant plan of postoperative treatment. The fact was that the after-treatment was fully as important as the operation itself. Many cases would either die or fail to recover without full functionation of the bladder without suitable treatment during convalescence from the operation. Suprapubic prostatectomy should not be performed outside of the hospital, unless an experienced male nurse could be left with the patient to attend to the details of the after-treatment. Most of these patients were in an enfeebled condition, brought about by years of catheter life with infection of the bladder accompanied with pain and vesical tenesmus. Frequent attacks of urinary stasis might have resulted in an ascending pyelitis. These conditions might all be aggravated by prolonged and crude efforts to pass the catheter. It was possible for pyelitis to be provoked after operation, provided the drainage was not absolutely unobstructed. Drainage was indispensable in most cases of suprapubic prostatectomy. There were a few cases in which the bladder might be closed and urethral drainage depended upon, but they were not numerous, and constituted exceptions to the rule of safe practice. The rubber tube having a diameter of not less than half an inch, fenestrated toward the end and having the edges pared to a feathery thinness, constituted the best method of drainage. If the tube was even larger in caliber it was still better. Hemorrhage might be controlled and treated through a large tube. The method of placing the drainage tube was important. Neither the drainage tube nor the bladder should be stitched to the abdominal parietes. It was better for these patients to get out of bed early. This facilitated both drainage and the early passage of the urine through the urethra.

Dr. JABEZ N. JACKSON of Kansas City, Mo., said he was a strong advocate of the perineal route in removing the hypertrophied prostate rather than the suprapubic. In his early practice he resorted to the suprapubic method, but abandoned it subsequently for the perineal, as one of the great difficulties attending the former was the establishment of proper drainage through the suprapubic wound. If he were going to do suprapubic prostatectomy as a routine measure, he should be inclined to employ the method of Senn, namely, do the operation in two stages, the first stage consisting of making an incision down to and exposing the bladder wall, followed by packing until the cellular space about the bladder was closed by granulations, then making an opening through the bladder. In this way, they did away sometimes with disagreeable infection which took place in the freshly exposed cellular tissues which ultimately interfered with the healing of the wound.

Dr. BRANSFORD LEWIS of St. Louis stated he had always advocated catholicity in connection with this subject and freedom from being restricted to any one operation, still his preference was for the perineal operation in selected cases. He had never been converted to the use of a large tube, such as was used by Freyer and others, because he had not been able to see the advantage of it, particularly when drainage could be accomplished just as effectually and satisfactorily by a smaller tube which would entail a

shorter time for convalescence and granulation than a very large tube. The formation of clots could be prevented by the siphonage apparatus of Bremmerman, of Chicago.

Dr. E. G. Mark of Kansas City, Mo., stated while he favored the perineal route in most cases, yet there were instances in which the suprapubic was unquestionably one of choice. The main thing after suprapubic prostatectomy was drainage, and cases of hypertrophied prostate requiring prostatectomy practically always had cystitis. To obviate the occurrence of hemorrhage and to secure efficient drainage, to do away as far as possible with the formation of clots following cystotomy, nothing in his hands had proven so valuable as continuous irrigation for twenty-four or forty-eight hours.

Dr. J. D. Griffith of Kansas City, Mo., stated he had done more operations by the suprapubic route than by the perineal. While he admitted the advantages of the perineal route, he thought with Freyer that there were many cases in which a suprapubic cystotomy was demanded, and that efficient drainage was the thing par excellence. He believed in irrigating the bladder and in siphonage. He believed in protecting the space of Retzius with gauze

Dr. Howard Hill of Kansas City, Mo., stated with regard to the use of a tube through the incision after suprapubic prostatectomy, he favored a large one, as he believed it was more advantageous than a smaller one. After the operation continuous irrigation, with hot water, with the patient propped up well and on the side, would control the hemorrhage. Hemorrhage was one of the serious objections to suprapubic prostatectomy, because it occurred from the time the operation was begun, and hemorrhage marked the first stage in the after-treatment of the patient. In regard to suturing around the tube to prevent leakage one could secure the skin and bladder together.

Dr. C. G. Norberg of Kansas City, Mo., said his experience had been confined very largely to operating on cases of hypertrophied prostate by the perineal route, and he preferred it to the suprapubic operation.

Dr. Basham, in closing, said it was evident from the discussion that the last word on prostatectomy had not been said. Each speaker had voiced his own convictions in the matter, and that spirit was to be admired because it was in that way they advanced their knowledge. This was an operation that must be done, and it behooved them to master all the details connected with it in order that they might increase the safety of the operation.

A New Method of Cure for Pelvic Infections in Women.—Dr. J. F. Kuhn of Oklahoma City said peritoneal infections of the pelvis were easily controlled, because with the Fowler position the infectious material was confined to the pelvic cavity, where toxins were more slowly absorbed than in the upper peritoneal regions, and in consequence the system produced antibodies rapidly enough to counteract their effects. He wished to lay special stress upon the treatment through the rectum with normal saline solution. By the method he suggested, the rectum was distended at six hourly periods with from one to four pints of the solution at 105° F., increasing the quantity gradually as tolerance for a larger amount was established. Intermittent periods of hyperemia were thus produced which hastened the destruction of the infecting organisms, induced more rapid absorption of the resultant plastic lymph, and prevented the formation of dense adhesions so commonly seen in the neglected cases. It had all of the other advantages of normal saline, stimulating and aiding the emunctories in ridding the system of the products of infection; fortifying the system during its struggle to produce antihodies and finally, by the action of heat locally, relieving the patient of the distressing pain which was her chief complaint. One of his cases illustrative of its value in this infection made such a complete recovery that he mentioned it in order to encourage others to a trial. Mrs. H., with streptococcic puerperal sepsis, was delivered March 10, 1910, and five days later had a chill with high fever and exquisite tenderness throughout the whole pelvis. Patient was placed on treatment as mentioned and continued on this treatment until March 31, when the saline was withdrawn for a few days, to be continued thereafter at twelve hourly intervals. She made a complete and uninterrupted recovery.

Dr. Arthur E. Hertzler of Kansas City, Mo., stated the question of treatment of the first stage of gynecological gonorrhea had resolved itself in his hands into purely deliberate, with malice aforethought, treatment. These women were put to bed, their bowels were moved, and practically nothing more was done. The result of this line of treatment ran something like this: About two-thirds of them recovered their health; about one-quarter of these two-thirds would conceive. The remaining third would come to operation. At the end of the first few days there would be a leucocyte count of from 15,000 to 25,000 which would drop down to normal in two or three weeks, which was preceded in its course by a drop of the temperature to normal. The temperature fell to normal usually ten days before the leucocyte count did. They had obtained excellent results from the use of autogenous serum in chronic cases of gonorrhea; but their experience with the stock serum had not been satisfactory.

Dr. J. A. Walker of Shawnee, Okla., said he had not tried the method that had been outlined by the essayist, but a reasonable time to wait for inflammation of the Fallopian tubes to subside and to incarcerate itself by the adhesions of the fimbriæ, and ordinarily by the occlusion of the uterine end of the tube, would isolate the pus cavity from the general peritoneal cavity, but it did not isolate it sufficiently to prevent the formation of strong adhesions to the surrounding tissues. As long as those adhesions were present the patients were going to have trouble. If the inflammation was of a streptococcic nature, the adhesions were more liable to be dense and lasting than if they were from the Neisser coccus, and when the adhesions were so strong and dense he did not believe it was wise to be too conservative and wait too long before breaking up the adhesions and removing the foreign body, which an old collapsed occluded tube was bound to be. His practice had been to wait a reasonable time for the inflammation to subside and, perchance, for the pus after having become sterile to be reabsorbed. If he thought such a thing had not occurred he removed the tube, leaving all ovarian tissue possible.

Dr. J. D. Griffith of Kansas City, Mo., said they knew how dangerous infection was from the Neisser coccus and how frequently they met it. He had used the serum in these cases, and he had used the knife. He had resected the tubes and tried to save organs that he thought would functionate, but the treatment the essayist had outlined in the acute stage of filling up the rectum with normal salt solution, with the patient in the Fowler position, he had never tried, but when the first case presented itself he was going to do it.

Dr. Kuhn, in closing, stated that if in a community not larger than Oklahoma City he could treat a series of twenty-eight cases with the treatment he had outlined without a failure Dr. Griffith and others could certainly achieve the same results in the larger communities in which they practiced. He hoped they would try the method.

Treatment of Patients Desperately Ill in Consequence of Accident.—Dr. Charles E. Bowers of Wichita, Kan., stated these patients demanded immediate and best attention. Many of them seemed to be beyond hope; others recovered notwithstanding shock, hemorrhage, or infec-

tion might be present. In these cases it became necessary to do what they could to save lives that were thus jeopardized. What resources had they at their command to assist reaction? What kind of intervention had they recourse to and by what signs did they know that their patients were exhausted on account of shock, hemorrhage, or infection? Prompt and efficient intervention was demanded. The term shock had been applied to the clinical phenomena of pallor, lowered temperature, lowered blood pressure, diminished respiration, weak pulse, feeble heart action, and mental torpor. In treating shock the first therapeutic agent indicated was something that would raise the body temperature, and the best was dry and moist heat. Perhaps a hot bath would do the most and then the other methods of dry heat. The second thing to do was to lower the head in order that they might benefit the circulation of the brain. It was the brain circulation that had much to do with shock, and with a better brain circulation very soon the patient would recover from shock. The third thing to do was to reestablish the normal specific gravity of the blood, and that could be done by saline solutions subcutaneously, by the rectum, or by the transfusion of blood.

Dr. Howard Hill of Kansas City, Mo., stated the various manifestations of lowered blood pressure, such as anemia, could best be met by the use of normal saline solution and the application of heat externally, and the internal administration of salines constituted practically all that had to be done. The author of the paper mentioned severe shock from severe burns, and the use of morphin to control the afferent impulses. It was beneficial in many cases of shock. It cut off the afferent impulses, and the application of heat externally and the inversion of the patient and the introduction of fluids into the body, such as normal saline solution, constituted all they could do.

Dr. John Punton of Kansas City, Mo., said whatever the shock might come from, whatever the injury might be due to, the prognosis in its relation to the case was always as important as the treatment itself. Women and men got well and the question was brought up as to appropriate treatment. He had discovered that shock spent its force on the vital organs, hence they had usually a disturbance of the pulse, the temperature, and respiration. He had found that shock was attended with more or less loss of consciousness, and the question of prognosis in the presence of loss of consciouness was oftentimes a very perplexing one to the surgeon as well as to the internist There was no surgical rule that enabled the surgeon to tell with positiveness whether the prognosis was favorable or not, but he had found that a very good rule to adopt in such cases was not to lengthen the time the loss of consciousness was present. The generally accepted view was that the longer the duration of the loss of consciousness the less chance there was for recovery. As a general rule, that was true, but it was subjected to so many exceptions that it was worth while for them to remember that in the presence of shock, and in the presence of loss of consciousness coming from shock, the respiratory center played a more important role in the prognosis than did the temperature or the increased pulse, so that where there was a question as to the prognosis it was wise to remember that the disturbed respiratory center was a very much more unfavorable sign than either the increased temperature or the accelerated pulse, and if the surgeons would adopt that rule it struck him that they would give a favorable prognosis when they might otherwise be led, in the presence of loss of consciousness, to give an unfavorable prognosis.

Dr. George A. Boyle of Enid, Okla., thought the personal equation entered into every individual case of shock There were individual characteristics. There were phlegmatic persons who would stand more injury with greater shock and recover than others who were highly organized nervous individuals. After twenty-five years of experience he was unable to determine just what the prognosis in a given case of shock was going to be.

Dr. D. A. Meyers of Lawton, Okla., stated Dr. Punton referred to the prognosis in cases of shock. In cases of infection, where they found the pulse and temperature divergent, they could nearly always make up their mind that if they gave a bad prognosis they would be on the safe side. But as soon as the pulse and temperature began to harmonize, they could begin to encourage the patient. The outlook was more favorable.

Postoperative Thrombosis.—Dr. St. Cloud Cooper of Fort Smith, Ark., read a paper in which he reported a case of postoperative thrombosis complicated with neuritis.

Dr. J. D. Griffith of Kansas City, Mo., stated in his surgical work he had encountered postoperative thrombosis of the lower extremities in six cases. Two such cases he had had within the last two or three weeks, and in five of these cases the thrombosis had occurred on the left side, and in one on the right side.

Dr. Edward H. Ochsner of Chicago stated that no one to his knowledge had been able to throw any light on the cause or causes of postoperative thrombosis, nor why it occurred more frequently on the left than on the right side. A thrombosis occurred after simple cases of appendectomy, and it took place in a larger percentage of cases on the left side than on the right after operation for appendicitis.

Dr. J. E. Gilchrist of Greenville, Tex., said they knew very little about the cause or causes of postoperative thrombosis. Thrombosis not only occurred following simple surgical operations, but it sometimes followed fevers and other conditions. He had seen severe thrombosis following typhoid fever, where the patient's limb would be greatly swollen and with blisters on it, attended with great pain, and all the symptoms of a surgical thrombosis. The treatment outlined by the author of the paper was rational, and in the cases he had had he had employed the same method of treatment.

Dr. Charles H. Cargile of Bentonville, Ark., recalled a case of thrombosis following exploration of the region of the kidney for obstinate pain. The pain was relieved by the operation. In this case the thrombosis occurred on the left side.

Dr. Howard Hill of Kansas City, Mo., stated that several years ago Franklin P. Mall, of the Johns Hopkins Hospital, conducted an investigation on cadavers in which he found in a number of cases in the common iliac vein before it joined with its fellow of the opposite side a constriction ring. This constriction ring led to slowing of the current in the vein in the region below. If these observations could be confirmed by some other anatomist, it would be an inkling as to why thrombosis occurred on the left side. He did not know the reason.

Dr. Cooper, in closing, stated he did not think the blisters he spoke of were due to a poor circulation, but were attributable to some trophic disturbance such as they had in Raynaud's disease.

Methods and Material, the Secret of Success in Local Anesthesia.—Dr. Arthur E. Hertzler of Kansas City, Mo., said cocaine as an anesthetic was efficient in all situations, but its congeners were less so. Quinine, on the other hand, was quite efficient as a local anesthetic in any condition. As to safety, cocaine was a dangerous drug. It was the fear of using a sufficient amount of cocaine to secure results that made the drug inefficient. If they used enough of it it was efficient, but fear came from the use of too little of it to get the desired results. Quinine was safer in any amount for local anesthesia. It was also efficient. Cocaine did not interfere with wound healing. Quinine did under certain conditions produce some dis-

turbance in wound healing. The anesthetic effect of cocaine lasted from twenty to thirty minutes. The anesthetic effect of quinine lasted all the way from several hours to several weeks. That likewise could be controlled by the method of application. With these materials at hand, they were able to select in a general way the material which was satisfactory under all conditions. Cocaine, where a small amount was used, would produce the desired anesthesia, where it was particularly desirable that primary undisturbed wound healing should take place. This applied to small operations around the face in which the plastic results were the prime requisites. Operations about the throat, the tonsils, the rectum and anus could be performed under quinine anesthesia. Here disturbance of wound healing was a matter of slight importance because primary wound healing was impossible about the rectum and anus. Dr. Hertzler then gave reasons for using local anesthesia and said that by using certain anatomical principles in making use of local anesthesia for the purpose of surgical operations much more exact results were possible than by the old method.

Dr. E. B. Emory of Winfield, Kan., stated in operations about the face for the removal of moles he had found cocaine produced perfect anesthesia, and he thought with less scarring than any other agent he had employed.

Dr. D. W. Basham of Wichita, Kan., said that he had had considerable experience with local anesthesia in the removal of glands and lipomas, and had done laparotomies with it, but his experience had been confined to the use of cocaine, using Schleich's No. 2. He used Schleich's No. 2 solution because it contained a low percentage of cocaine, and he used it in accordance with the method described by Dr. Hertzler.

Dr. Ward of Texas stated he had not had much experience in the use of local anesthesia, but last year he saw a well-known Mexican surgeon resort to spinal anesthesia in three cases he operated on with good results. One was a case of knee-joint trouble; another a case of hip-joint disease, and another a case of prostatectomy.

Dr. J. D. Griffith of Kansas City, Mo., stated he had operated on cases of varicocele with injections of normal salt solution. He had used endermic injections of normal salt solution in the removal of lipomas. He had operated below the umbilicus under spinal anesthesia. He had done seventy-eight capital operations under spinal anesthesia, such as hysterectomies, prostatectomies, etc., and while he had had no bad results so far it would not surprise him to hear of some at any time.

Dr. George A. Boyle of Enid, Okla., said he had used weak solutions of cocaine for local anesthesia in cases in which this drug had brought about a condition of collapse, and since then he had been afraid of it. After Schleich's method was brought out he used it some and lately he had been using hyperchlorate of quinine and urea with gratifying results. His assistant had also obtained excellent results from its use.

President's Address: Fatigue.—Dr. G. H. Moody of San Antonio, Tex., selected this subject for his address. Among other things, he said that fatigue was, of course, relative in degree and followed prolonged excessive activity. The degree of fatigue which might follow a given amount of activity or strain would depend upon the nervous integrity, and the healthfulness of the individual. Also the amount of fatigue which an individual might be able to overcome promptly by rest and sleep was likewise dependent upon the recuperative capacity of the individual, and upon his opportunity and inclination for adequate rest and recuperation. The more normal and robust the individual the more easily, naturally and irresistibly would sleep and rest follow and continue until the fatigue was fully overcome. On the other hand, the more delicate and neuropathic the individual either from bad heredity or disease or prolonged strain, or from whatsoever cause, the less would be the capacity for rest and pleasurable repose, and the fatigue of each day's activities might not be fully restored from day to day, and there would result finally a chronic irritability and restlessness which rendered impossible adequate recuperation voluntarily. This tended to produce a condition simulating brilliancy in which greater efforts were encouraged in the young, until there ensued an acute breakdown or a chronic exhaustion. The forms in which these results of prolonged fatigue and exhaustion generally appeared were indigestion, malnutrition, the various fatigue neuroses, known as the occupation neuroses, insomnia, neurasthenia, psychasthenia, hysteria, the acute insanities in which the strain of the climacteric played a part; dementia and paranoia which were generally misfortunes of the developmental period of life; drug and alcohol addictions, the majority of which were developed as the result of a conscientious effort to bear the burdens of life by means of stimulating, anesthetizing, or narcotising overfatigued feelings in order to make life bearable for a while, with the hope that a change in conditions might perchance finally come; locomotor ataxia and paresis in which continued strain and fatigue played an important part together generally with a syphilitic diathesis and a neuropathic constitution. In fact, while the best authorities maintained that there was a specific constitutional basis in these cases, they seemed never to develop without the long continued fatigue and the neuropathic constitution in which adequate rest was difficult through life. These two diseases were known as parasyphilitic diseases. A degenerative process had already done permanent damage by the time the characteristic symptoms appeared, the syphilitic poison having found a favorable soil in the cerebrospinal system and its coverings, apparently because of the fatigued and neuropathic irresistiveness. Formerly these cases degenerated rapidly and dementia and death came early. In the light of recent investigations it was found that the decline should be brought to a standstill in most of these cases and that the tabetics especially should be able to have a comfortable and fairly useful life, not shortened materially by reason of the disease, and that the paretics should become able to live at home comfortably for many years, their degree of satisfaction at home depending upon the time and the course of the disease when the diagnosis was made and proper treatment instituted. A positive Wasserman reaction was found in almost every one of these cases and should be made at once in every suspected case. It was hoped that in these parasyphilitic conditions the 606 of Ehrlich would prove of great value by eliminating at once, and for all time, all syphilitic poison and at once stop the disease process, after which much improvement might follow through some degree of regeneration and through proper enforcement of rest and recuperative treatment, and through the various practical methods of reeducation, exercise and redevelopment of dormant activities and functions. Much was already being done in these directions through the proper administration of mercury and arsenical preparations, preferably hypodermically in both instances. These preparations seemed to modify favorably lowered metabolism in these and other conditions such as neurasthenia. The one precaution he would like to make most forcible in the treatment of these cases was not to give them the iodides. They regenerated the patient rapidly and did no good. From whatever standpoint these cases were considered, the important elements of fatigue must be kept always in mind. The enumeration of conditions and diseases in which fatigue played an important rôle could continue, but these would suffice. In such purely physical disorders as gastroenteroptosis and other conditions of similar origin, they more readily took into account the general condition of fatigue and the dimin-

ished general muscular tonicity of the patient and reckoned with it in whatever other medical or surgical procedure thought to be indicated. It was not too much to hope that in time there would be a universal attempt on the part of the public at a scientific estimate of the individual capacities and limitations of each child. With this estimate correctly made or even approximately so, with the aid of scientific authority, individuals would pass through the educational and developmental stages of life into maturity without so much apparent uncertainty concerning their future.

The Prevention and Treatment of Septic Infections of the Extremities.—Dr. Edward H. Ochsner of Chicago selected this subject for the oration in surgery. He said that the severer wounds that naturally came to the physician from the very first they must divide into two classes, the more superficial wounds that were likely to be infected with ordinary pyogenic microorganisms only, and those which were likely to be infected with the tetanus bacillus in addition. In the latter the same method of disinfection was used as in the former with the addition that they always gave a prophylactic dose of antitetanus serum and if the wound was deep or likely to contain foreign material they laid it wide open, removed the foreign material and left the wound gaping and to heal by granulation subsequently. In some parts of Chicago tetanus was quite prevalent, and up to seven years ago they had quite a number of cases, but since they had followed the above routine they had had only one case of tetanus develop and that in a case of severely infected compound fracture that came to them on the sixth day after the injury. All fresh wounds were treated in the following manner when they first came in: If the laceration was very extensive the patient was given a general anesthetic; if less severe the extremity was immersed in a two per cent. carbolic acid solution in tepid water, from five to ten minutes. This was an excellent local anesthetic and made it possible to thoroughly scrub the parts without causing undue pain. They now scrubbed the extremity thoroughly with soap and sterile water by the aid of a brush or pieces of sterile gauze; then washed it off with ether, scrubbed it well with turpentine, swabbed it with tincture of iodin, rinsed it with alcohol and finally put on a sterile dressing. If in spite of the above precaution or because of their neglect septic infection did develop, by instituting and rigidly adhering to a definite plan of treatment they could secure healing with practically no mortality, rarely, if ever, lost a member and usually without permanent impairment of function. Thus in a period of over fifteen years he had not lost a case, amputated even a finger or toe and had not one single clawhand to his discredit in cases which came to him before incision had been made. How could they destroy the bacteria, or, at least, materially reduce the virulence without at the same time injuring the tissues or impairing the resistance of the individual? Such remedies they had in carbolic acid, boric acid, alcohol, and tincture of iodin, and by their proper combination and judicious application one could practically always obtain the desired results. Ninety-five per cent. carbolic acid was a very powerful germicide and could be safely applied with a cotton swab over the reddened, inflamed area, until the area turned white, if it was then quickly washed off with strong alcohol. It would instantly destroy innumerable pathogenic microorganism, almost instantly relieve the pain without injuring the skin in the slightest, providing, of course, that it be properly applied. After this preliminary application the extremity was encased in a large hygroscopic elastic wet dressing. For wet dressing he used a saturated solution of boric acid in water, to which 1/16 to 1/2 of 95 per cent. alcohol was added. As to drainage, the veins and lymphatics could be drained by simply elevating the affected extremity, and this could be done so effectually that incision rarely became necessary. This drainage by elevation was assisted by the dehydrating power of the alcohol.

Colitis.—Dr. William H. Stauffer of St. Louis, Mo., stated errors of digestion as a cause of colitis had been much exaggerated. As causes of gastritis and enteritis, they easily took first rank. In most cases of colitis the important factors were how, when, and where we ate rather than what we ate. Syphilis, tuberculosis, and impairment of the nervous system were responsible for at least fifty per cent. of all the cases that had come under his observation. Most children, and not a few adults, responded to the call of nature only when compelled to do so, with the inevitable result that what in health was a pleasant duty was soon transformed into a painful pathological process. The most valuable diagnostic aid was the proper use of the sigmoidoscope. This instrument had not been sufficiently used by the general practitioner. Dr. Hanes, of Louisville, had rendered invaluable service by suggesting the inverted position in examining and treating patients with colitis. The treatment of colitis until recently had been very unsatisfactory. Tubercular ulcerations might be primary and entirely local, and as such would respond to local antiseptics and nourishing food So-called membranous colitis was generally organized retained mucus, and would respond by giving the parts rest and drainage. When possible direct application to the diseased part should be made through the sigmoidoscope, or a Walls bougie always placed in position under direct observation. Jacobi, Tuttle, and Soper had demonstrated the impossibility of passing a rectal tube into the colon unless there was some abnormality of the sigmoid. The medication depended upon the pathology and every indication must be met as it arose. Ichthyol and argyrol in various percentages were of signal service. Oil of eucalyptus or thyme in olive oil had given him excellent results. Appendicostomy or cecostomy should always be employed in amebic dysentery. Experience had shown that there should be no haste in closing the fistulæ.

Dr. L. P. Warren of Wichita, Kan., believed it was the consensus of opinion among expert proctologists that it was practically impossible to pass a tube into the descending colon. The sigmoid itself and rectum might be inspected, but it was not possible to pass the proctoscope sufficiently far to see into the descending colon.

Dr. S. N. Mayberry of Enid, Okla., said that the general practitioner was not always able to interpret correctly what he saw. He asked the essayist as to the clinical appearance of early tuberculosis of the anus before the patient complained of any symptoms to speak of. Personally, after introducing the sigmoidoscope, he was unable to tell in some cases whether there was a tubercular condition or not. He had had two cases of rectal disease in which he could not make a satisfactory diagnosis.

Dr. Stauffer, in closing, said it was not possible to pass a tube in all cases into the colon, but it could be done in fifty per cent. of them. It took great care and a great deal of cooperation on part of the patient. It could not be done the first time always any more than the practitioner could pass a stomach tube the first time. As to the clinical appearance of disease about the anus, he said the best comparison they could make of ulceration or of the various pathological conditions in this region was that they simulated very much conditions of the throat. In fifty per cent. of the cases, if one found a syphilitic ulcer in the rectum, he could look into the patient's throat and find a similar condition. Its edges and everything would compare with the one seen in the rectum.

Gastric Röntgenology.—Dr. E. H. Skinner of Kansas City, Mo., said the use of the *x*-ray in gastrointestinal diagnosis practically dated from the work of Prof. H. Rieder, of the University of Munich, in 1904 He pub-

lished his classical studies in stomach pathology by means of fluoroscoping the stomach *in vivo* after the ingestion of a wheat pudding containing 40 to 60 grams of bismuth salts. At the present day no more satisfactory bismuth meal was offered, but the improvements in fluoroscopic apparatus had been interesting. The peculiar superiority of fluoroscopy over radiography depended on the ability to study the peristalsis and surgical anatomy of the alimentary tract. Esophagus.—The patient was placed in the right-anterior oblique position and offered a small bismuth capsule. When the current was applied he was instructed to swallow. The route and rate of the capsule in the esophagus were noted until it reached and passed through the cardiac orifice of the stomach. Succeeding larger types of capsule were then offered and their course noted. By this means they were able to determine the location and lumen of the esophageal stricture. The capsule did not always find the orifice of a diverticulum; therefore, they employed the bismuth paste (about a level teaspoonful of bismuth carbonate and sac lac half and half). This was swallowed at the suggestion of the operator after the *x*-ray was turned on. The use of bismuth and water (2 drachms of bismuth to 2 or 3 ounces of water) was then employed. By carefully noting the passage of the paste and the water mixture, one could determine the presence of esophageal strictures, diverticula, abnormalities due to adhesions, cardiospasm, dilatation, pleuritic tugs, esophageo-bronchial fistulæ, carcinomatous filling defects and alterations of outline, and pressure of aneurysms or tumors upon the esophagus. The description of fluoroscopic symptomatology of each of these conditions was worthy of a separate descriptive paper. Stomach.—Succeeding the fluoroscopy of the esophagus by these simple measures, they instructed the patient to slowly eat 10 or 12 ounces of bismuth porridge. (a) Pyloric Stenosis: Fluoroscopic symptoms: 1. Dilatation of the stomach, both longitudinally and transversely. 2. Antiperistaltic waves running from the pylorus to the greater curvature. 3. Interference with the emptying of the stomach, the exit of food being delayed 18 to 48 hours. The suspicious symptoms which should be noted were: More or less degree of distention of the stomach, weakened peristalsis, food delayed in exit twelve to twenty-four hours, adhesions of the pyloric area, which produced a fixed pylorus, pyloric filling defects, absence of any peristalsis at the pylorus, the wave running only from the greater curvature to the prepyloric area. (b) Carcinoma. 1. Irregular filling defects in the outline of the stomach wall. 2. Abnormal peristalsis, there being no wave at the site of the filling defect; or, if the carcinoma involved the pylorus, antiperistaltic waves were seen. 3. Hourglass contraction where there was involvement of the middle portion of the stomach. The bismuth meal or water may be seen trickling through the narrowed lumen. 4. Adhesions of the stomach to adjacent organs, due to perigastric inflammation. 5. The lumen of the stomach was usually much smaller than normal, excepting where the carcinoma involved the pylorus, we might have a dilatation. (c) Gastric ulcer. 1. Filling defects, which were not as irregular in outline as in carcinoma, the filling defect being due more to an irritation of the muscular action than to irregular outlines of mass changes in the stomach wall. Where the ulcer involved the pylorus we had the additional symptoms previously noted when there was interference with the exit of the food. (d) Precancerous stomach. The precancerous stomach that he offered for consideration depended upon a clinical symtomatology of chronic gastritis, with loss of appetitte and weight, epigastric uneasiness and the craving of small quantities of food preferably meats. There was no hyperchlorhydria demonstrable. But the fluoroscope would reveal a stomach of lessened lumen, placed rather high in the left hypochondriac region. There was a small *magenblase*. The pylorus was frequently the lowest point of the stomach shadow, and the filling shadow of the stomach was funnel-shaped. We had here an atrophy of the stomach, dependent upon a certain degree of starvation. (e) Gastroptosia. The outlines of the stomach were so exactly recorded by the bismuth shadows that we could easily determine the relation of the lesser and greater curvature to the umbilicus and bony skeleton. It was apparent that this *x*-ray method of stomach examination offered much that could not be obtained by other means. The work must be done by those familiar with it, so that the results shall be of such value that the method cannot fall into disrepute through over-zealous workers.

Pyloric Obstruction Due to Extrinsic Causes.—Dr. Gordon A. Beedle of Kansas City, Mo., spoke of the importance of adhesions in causing pyloric obstruction, and reported several cases in which relief was afforded by separating the adhesions. One patient, very fat, and slightly jaundiced, with temperature of 102°, complained of cutting pains throughout the right hypochondrium and epigastrium extending through to the back or right side, opposite the lower thoracic vertebra; tongue coated; nausea and vomiting. The stomach was distended. No peristaltic wave could be elicited by massage. Extension upward and backward of the left arm caused an increase of pain, and tenderness was diffused over the epigastrium. A diagnosis of gall-stones complicated with adhesions involving the stomach was made, and operation advised. Incision revealed a mass at the site of the gall bladder which proved to be a reflected portion of omentum containing a hard caseous mass of tubercular deposit, wedged down on the gall-bladder, and adherent in every direction. Careful ex section revealed the pyloric half of the stomach drawn down and firmly anchored, tumor pressure, and malposition caused by adhesions, clearly defining the cause of the obstructive symptoms. There was a slight amount of fluid in the cavity, and a few scattered tubercles could be felt on the peritoneum. The gall-bladder, although slightly dilated and full, appeared normal and was not opened. This patient recovered with complete freedom from her previous symptoms, and was in good health six months after operation. In this case had the stomach analysis been made the findings no doubt would have strongly indicated obstruction with dilatation and motor insufficiency, but decision as to the actual cause could be made positively only through incision.

Psoriasis; Diagnosis and Treatment.—Dr. William Frick of Kansas City, Mo., after detailing the essential features of the diagnosis of psoriasis, said that there were no specifics in the treatment of this disease. Cases could not all be treated successfully in the same manner or with the same drug. Patients must be studied as well as the disease. The general health of the patient should be cared for when there was occasion to do so. Many patients with psoriasis appeared to be perfectly healthy in every other way. In these cases we could find sometimes deficient elimination, imperfect assimilation, or some other imperfection in metabolic processes of which the patients were not aware. When these defects were discovered and corrected they were treated with better results. He reported a case which aptly illustrated this. Of recent years it was quite remarkable to see the rapid improvement under a few treatments with the *x*-ray. This improvement was not permanent, and must necessarily be supplemented by other methods of treatment. External treatment was resorted to in nearly all cases. Relief was obtained quicker by this means than by internal treatment. He mentioned the various drugs that were used in treating this disease, and said the essential thing to do for patients was to cure the existing disease and teach them how to avoid the causes, if possible, or how to check a beginning attack.

The following papers were also read.

"Germiphobia," by Dr. A. K. West, Oklahoma City, Okla.; "Appendicitis Obliterans; A Clinical and Pathological Study," by Dr. Horace Reed, Oklahoma City, Okla.; "Cardiac Murmurs and Their Clinical Significance," by Dr. Lewis J. Moorman, Oklahoma City, Okla.: "Pathology of Insanity," by Dr. G. W. Robinson, Kansas City, Mo.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. M. L. Perry, Parsons, Kan.; *Vice-President for Arkansas,* Dr. J. M. Griffin, Sulphur Springs; *Vice-President for Missouri,* Dr. W. H. Stauffer, St. Louis; *Vice-President for Oklahoma,* Dr. E. S. Lain, Oklahoma City; *Vice-President for Texas,* Dr. W. L. Allison, Ft. Worth; *Secretary-Treasurer,* Dr. F. H. Clark, El Reno, Okla.

Oklahoma City was elected as the place for holding the next meeting in 1911.

College of Physicians of Philadelphia: Section on General Medicine.

At a stated meeting held October 24 Dr. Alfred Gordon read a paper entitled "Optic Nerve Changes Associated with Cranial Malformations, apropos of a Case of Oxycephaly"; and he demonstrated the patient, a boy eight years old, with a dome-shaped head, a high-arched palate, a narrow visual field, chorioretinitis, and convulsions. On *x*-ray examination the convolutions of the brain were remarkably clear and distinct, and the skull-bones could be seen to be unusually thin. The conditions were thought to be due to changes in meninges and cerebrum, as well of nerves passing through cranial orifices in consequence of the bony malformation. Drs. T. M. Tyson and H. D. Jump presented a communication entitled "A Note on the Treatment of Ascites by Intraperitoneal Injections of Adrenalin Chloride," reporting the case of a man with chronic nephritis who had suffered from general anasarca and had been tapped on three or more occasions for the relief of ascites. Injections of from 8 minims to 2 drams of adrenalin chloride, 1:1,000 solution, were followed by increase in the amount of urine secreted and eventually by disappearance of the anasarca, including the ascites. Dr. David Riesman read a paper entitled "High Pressure Hypertrophy," referring to the observation of a series of cases in which patients complaining of dyspnea, retrosternal distress, flatulence, vertigo, lack of endurance were found on physical examination, particularly palpation and percussion, to have hypertrophy of the heart, with accentuated second sound and high blood-pressure, but without other accessible evidence of arteriosclerosis, while the urine generally was free from albumin. The condition occurs in men and women alike, but especially in those subjected to great nervous and mental strain. It is thought to represent a condition of arteriosclerosis in deep seated vessels, without obvious involvement of superficial vessels and tube-casts. At times an aortic systolic murmur is present. Angina pectoris may develop and terminate fatally. The treatment consists in adjustment of the diet and of life's activities in general and the administration of nitrites and iodides. Niemayer's pill of squill, digitalis, and calomel answer admirably in these cases for the relief of dropsy. Dr. E. J. G. Beardsley presented a communication entitled "Pulmonary Tuberculosis as Studied in a General Medical Dispensary." He dwelt on the difficulties of treating the ordinary tuberculous patient in the general medical dispensary, and he insisted on the need of a special service for this purpose in order that the patient may be instructed in the hygienic requirements of his case, drugs playing only a subordinate rôle. It is here that the services of a social worker become particularly useful.

CHEMICAL PROBLEMS IN DIABETES.*

BY ADOLF MAGNUS-LEVY, M.D.,

PROFESSOR OF MEDICINE IN THE UNIVERSITY OF BERLIN.

GLYCONEOGENESIS.

By glyconeogenesis is understood a formation of carbohydrates, and especially of grape sugar, from molecules which are not themselves carbohydrates, for instance, from protein or fat.

All the experimental procedures for the recognition of glyconeogenesis in the animal body involve the same suppositions and may be traced back to a simple algebraic equation. We must know in the first place, the total mass of carbohydrates present in the body, and secondly, the quantity of carbohydrates introduced during the experiment. Let us call the first A and the second B. If the total mass of carbohydrates found, at the end of the experiment, which we call C, be greater than A plus B, then the formation of sugar from non-carbohydrate substances is proved, and the greater this difference, the more conclusive the proof. The principal difficulties are, or rather were, that the quantities of carbohydrate present at the beginning, and added during the experiment could not be determined in most cases with sufficient accuracy.

Methods.—Five different procedures have been employed for the recognition of glyconeogenesis. Two of these, employed principally by Seegen, are absolutely worthless. These methods are, firstly the digestion of liver extract with peptone or fat, and the measurement of the increase of the carbohydrate content. The second procedure consisted is estimating the metabolic changes in the liver of the living animal by a comparison of the sugar content of the portal and of the hepatic blood. Seegen thought that finding an excess of sugar in the blood of the liver veins, compared to that of the portal blood, would prove a formation of sugar from protein. This assumption, however, does not hold good. I deem it unnecessary to enter into a criticism of these two methods, both of which are to-day recognized as worthless.

The third method, the oldest of all, consists in measuring the glycogen accumulation in the living animal, especially in the liver and muscles, after feeding with suitable food. However good service this method may have rendered for the study of glycogen formation from carbohydrates, it is impracticable for the proof of the formation of that substance from proteid or fat. Just as Külz considered the experiments of his predecessors to be inconclusive, so Pflüger has shown Külz's own experiments to be unconvincing. The reason for the insufficiency of this experimental method is to be found in the fact that not only is it impossible to determine with certainty the carbohydrate store of a single animal, but also that in spite of the greatest care in the choice of albuminous foods, the addition of carbohydrates could hardly ever be absolutely avoided, at least in the older experiments. And even if, as we can to-day say with certainty, glycogen really was formed from protein in most experiments of this kind, the greater part of this was again decomposed in the course of the experiment. At the end, only a very small part of the newly formed sugar was found as glycogen in the body of the animal; and this quantity was very seldom outside the limits of error existing in biochemical investigations. It is only recently that Pflüger has improved this method, so that it may be applied satisfactorily to problems of this kind.

The classical method for the recognition of glyconeogenesis is the fourth method: the examination of diabetic subjects. In this case, in contrast to the glycogen experiments on healthy beings, the new formed sugar is removed from the sphere of combustion and appears in the urine in a form easily determined. The urine sugar that can be obtained in a single day is much greater in amount than the glycogen that has ever been found stored up in the body after weeks of feeding with carbohydrates.

Besides this classical method there is still a fifth to be mentioned, viz., the examination of the artificially transfused liver. Although the procedure is in principle less valuable than the classical diabetic method, still it may furnish important material for the solution of certain problems, which cannot be decided by experiments on living animals.

As an example of the recognition of glyconeogenesis, I may refer you to Pflüger's well known experiments. These were the most recent of all experiments of this kind and were carried out on the largest scale.

A partly depancreatized dog, 12 kilos in weight, produced on being fed exclusively on codfish and nutrose, 3.1 kilos of sugar in the course of three months. Even if we accept the highest values for the original glycogen content of the animal and for the carbohydrate in the food at least 2.5 kilos of new sugar were produced.

The existence of glyconeogenesis is to-day no longer doubtful and needs no further discussion.

The Mother-Substances of Glyconeogenesis, Protein, Glycerin, Fatty Acids.—Is it the proteins that are the mother-substances of this newly formed sugar, or is it the *fat?* This is the important question which has been on the tongues of scientists for many decades. At the present time by far the greater majority accept the formation of sugar from protein as proved. A minority also assume in addition a sugar formation from fat. This

*The Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, Columbia University, New York, for 1910.

question has not yet been decided with absolute certainty. I should like to lay before you the salient points of this problem.

A direct, if I may say so a mathematical, proof for the production of sugar from protein would be furnished, if we could prove that a diabetic animal had decomposed only protein and no fat at all. This experiment has, however, its difficulties. It is almost impossible to ingest enough protein to cover the needs of a diabetic dog, which loses by its output of sugar a third part of the energy content of the decomposed protein. However, such a possibility seemed to have been realized in an experiment of Lüthje's. A depancreatized dog, only 5 kilos in weight, decomposed daily 164 grams of protein and produced about 70 grams of sugar. After deducting about 252 sugar calories, 430 calories derived from the decomposed protein were still at the disposal of the animal, that is, almost 90 calories per kilo. I am of the opinion that the animal could have made up its loss of energy almost exclusively by the oxidized protein, and that thus no fat had been decomposed. If this be correct, then the formation of sugar from protein would be irrefutably established. But the proof would require to be supplemented by a direct determination of the actual metabolism of energy by means of the respiration calorimeter. It would have to be proved that the total carbon output in the respired air, in the urine, and in the excrement, amounted to no more than corresponded to the nitrogen eliminated from the decomposed protein. With the magnificent appliances which you have here in America at your disposal, it would be easy to give this decisive proof.

As long as this proof is not given the view that protein is the mother substance of sugar rests, for the present, on the fact that in severely diabetic subjects the output of sugar and the decomposition of protein run parallel. Every increase in the combustion of protein is followed by an increase in sugar elimination. The first and most admirable experiments are connected with the name of Külz. The precision of his experimental conditions has never again been attained with diabetic patients. On being fed exclusively on casein, a severely diabetic man yielded the following quantities of sugar:

200 gm. casein	66 gm. sugar
240 gm. casein	66 gm. sugar
300 gm. casein	97 gm. sugar
500 gm. casein	127 gm. sugar
240 gm. casein	87 gm. sugar

Many years later Lüthje performed a similar experiment on a depancreatized dog. His results resemble those of Külz. The observations of Lusk and others on diabetic patients lead to the same results.

The increase of the sugar output with increasing protein decomposition is well known to every doctor who has had to deal with diabetic patients. This fact plays a great part in the therapeutics of to-day.

V. Mehring was the first to point out a certain proportion between protein decomposition and sugar output. Minkowski calculated the numerical value for this proportion. He found that in pancreas diabetes for every 100 grams of protein decomposed, 45 grams of sugar were eliminated, or, calculated for the nitrogen in the protein, that the D : N ratio was 2.8. However important and valuable this calculation was, still this quotient has in a way become a stumbling block for later investigations.

What Minkowski put forward only as a *possibility* was accepted as a fact, namely, that 45 grams of sugar was the maximum that could be obtained from 100 grams of protein. This, however, has never been proved. In any case the existence of a parallelism between nitrogen and sugar elimination is unmistakable, and this parallelism is the principal, or, we may say, the only, support of the doctrine that protein is the mother substance of sugar.

Pflüger, who for a certain time attributed the sugar formation to fat, and would not acknowledge the formation from protein, gave a somewhat complicated explanation of the undeniable parallelism between protein decomposition and sugar output. He was of the opinion that the aminogroup of the protein, on being separated from the carbon nucleus, transferred a certain energy to a carbon complex of the fatty acids. He conceived that by every splitting off of an amino group, one atom of oxygen was transferred to a carbon radical of the fat, and that this then condensed to grape sugar. The sugar would then really be formed from the material of the fatty acids, but this would have been made possible even then by the splitting off of the amino group, that is to say by the breaking down of protein, and the quantity of sugar formed would be controlled by the quantity of protein decomposed. Consequently we can recognize the formation of sugar from protein as extremely probable, even though it has not been proved with mathematical certainty.

Pflüger has quite recently become converted and now acknowledges sugar formation from protein. Strangely enough he has again used the old method of glycogen accummulation for his experiments, although he himself once designated it as incapable of furnishing proofs. Certainly he has perfected this method in an admirable manner. I can not give you the details of the work of this remarkable man who, still active in his eightieth year, carried out excellent experiments a few weeks before his death.

While Pflüger finally denied, in opposition to his earlier view, that a sugar formation from fat occurs in the animal kingdom, because *he* had not observed it in his experiments, still this is by no means decisive.

In most cases an increase in the fat given to a diabetic subject does not cause an increase in the sugar eliminated. I will mention only an example by Hübner: On being fed with 176 grams of albumin and 150 grams of fat a diabetic patient eliminated 51 grams of sugar, whereas on adding 160 grams of fat he yielded 50.

176 gm. albumin + 150 gm. fat	= 51 gm. sugar
176 gm. albumin + 319 gm. fat	= 50 gm. sugar
98 gm. albumin + 315 gm. fat	= 7 gm. sugar

The fact that the addition of fat does not increase the sugar elimination cannot be doubted and is amply confirmed by experiment and daily experience. However, the previously deduced conclusion that no sugar is formed from fat is completely fallacious. The 170 grams of fat introduced in surplus are not really catabolized, like the 150 grams of casein added in the above experiment of Külz, but are stored up in the body as reserve material. They have taken no part in the metabolism.

The fat combustion has in no way been increased by them. And, however much fat be added to the food, it has no power to expel other food materials from the metabolism and to take their place in contrast to protein, which is able to do so. Consequently the negative results of the experiments of Hübner and of other authors afford no evidence against the possibility of sugar formation from fat.

Neutral fat is composed of two quite different components whose relations to sugar must be sharply distinguished: *Glycerin* and *fatty acids*. The formation of sugar from glycerin has been proved with even more certainty than that of sugar from protein. Also in this case the proof has been furnished by experiments on diabetic patients. Of all the materials that have been examined in a similar manner, glycerin has the advantage that it can be introduced in enormous quantities and that the sugar output consequently also rises enormously. The sources of error are here much smaller than with other materials. A patient of Külz's eliminated in ten days, after a total introduction of 1,450 grams of glycerin, 760 grams of sugar over and above the average output. A dog of Lüthje's 12 kilos in weight, after being given 400 grams of glycerin, brought its sugar output up to 160 grams in the course of twenty-four hours. From a chemical standpoint also, as I will show later, the formation of sugar from glycerin is very easily understood.

Accordingly two sources already come into consideration for the formation of new sugar, namely: protein (A) and glycerin, (B). Hence it will be difficult, to recognize a third substance, the fatty acids, (C), as being also a mother substance of sugar. That will be possible only when the sugar output (D) has become so high, that the "preformed" sugar of the body and of the food (E), the protein (A), and the glycerin (B), are insufficient for its production. Experiments must bring forward this proof, since no direct proof is possible. And in fact, all efforts tend toward this direction. Here, too, just as in the general problem of glyconeogenesis, we have to do principally with a simple mathematical equation. (D >A+B+E). This equation is, however, difficult to solve for the reason that not enough is known about several of its components. The supposition, that we knew the maximum formation of sugar from protein is, indeed, not true. In the case of glycerin it is highly probable, from its chemical constitution and from the results of experiments *in vitro*, that it can yield the theoretical quantity, that is to say, 100 per cent. of sugar. For protein Minkowski's famous quotient was adhered to, and accordingly it was accepted that 100 grams of protein could yield only 45 grams of sugar. There is no real proof, however, that this is the case.

The first experiment for the recognition of a sugar formation from fat in men was carried out by Rosenquist. With animals a particularly good experiment was made by Hartogh and Schumm. Still a critical anaylsis of all experiments of this sort shows, that in the first place the carbohydrate content of the food has been estimated much too low, that formation of sugar from glycerin, which with a high combustion of fat reaches 20 grams and more, has not been taken into consideration, and many other things as well. The doubters are right in claiming that the formation of sugar from fat is still completely unproved.

They bring forward as a reason, that sugar formation from protein was underestimated. Theoretically 100 grams of protein could, if all the carbon of protein were transformed into sugar carbon, yield 135 grams of sugar. This is certainly not the case; but so long as the maximal sugar formation from protein is unknown, a sugar formation from fat will be recognized as proved only when the above value of protein sugar was employed in the calculation of an experiment. The prospects of being able to obtain definite proof, either in this or another way, are not very great. Personally, however, the majority of the experiments brought forward, as well as general biochemical considerations, make me incline in favor of a sugar formation from fat. Only, I am of the opinion that this process, both for chemical and other reasons, generally takes place on a far smaller scale than the formation of sugar from protein.

We may now inquire concerning the sequence of the sugar formation from the three above sources. When the transition from moderate to severe diabetes is taking place, when the patient is just beginning to yield sugar that does not arise from carbohydrates (a point which naturally can never be sharply recognized), it may be asked: are these first grams of newly formed sugar derived from protein, or from glycerin, or from fat? Looked at from a purely chemical standpoint the formation of sugar from glycerin seems the simplest process. For this reason one might be inclined to place this process first in point of time. However, it is not possible to-day to deduce either a quantitative or a chronological precedence in the formation of sugar from protein or glycerin. But that the sugar formation from protein precedes that from fat is borne out by the unmistakable dependence of the sugar output on the mass of the decomposed protein, even in moderately severe cases of diabetes.

As to alcohol, no experiments so far show that it is a source of sugar. This possibility may therefore for the present, be left unconsidered.

Glyconeogenesis in Normal Life.—This question is of the very highest biological importance. In another form it runs thus: Is life possible without carbohydrates? Does a carnivorous animal differ fundamentally and in principle in its metabolism from an herbivorous animal?

However probable it may be that the healthy organism can, in case of need, carry out the process which takes place in a diabetic subject, still I agree with Pflüger in that the results of all the former so-called glycogen experiments do not hold good, so that the glyconeogenesis in normal life was not then established beyond question. Zuntz with a procedure of quite another sort, which I have not yet mentioned, has furnished a proof for sugar formation in healthy fasting men. This method is that of respiration experiments, the decisive criterion is the behavior of the respiratory quotient.

This amounts, as is well known, to 1.0 for exclusive carbohydrate combustion, to about 0.8 for exclusive metabolism of protein, and to about 0.7 for fat. If, in a starving animal, after the using up of the glycogen reserve, the metabolism be performed at the cost of fat and protein exclusively, it must be about 0.71. Zuntz and Lehmann saw that with fasting men in a state of rest, the value sank to 0.66-0.64. With muscular work it rose appreciably over 0.71. So in this case oxygen had been retained by the body. Now, thanks to Durig's

decisive experiments, we know that elementary oxygen is not stored up by the body. Accordingly the retained oxygen in Zuntz's experiments was used for the oxidation of bodies poorer in oxygen, and produced thereby bodies richer in oxygen. This is the case when sugar, which contains 54 per cent. of oxygen, is formed from protein or fat, whose oxygen content amounts to only 12-20 per cent. Other similar processes are known, for instance, the formation of oxybutyric acid, a body rich in oxygen, from protein and fat. Therefore and also for other reasons a disappearance of oxygen, a sinking respiratory quotient, give no absolute proof that the stored up oxygen was employed for sugar formation. Moreover, even in the most technically accurate experiments, certain sources of error have also to be reckoned with. A proof deduced by this method is, in spite of all probability, always only indirect and requires to be supplemented by a direct proof. Pflüger has furnished this by means of the method of glycogen accumulation. He was able to show that, in the case of fasting frogs, the glycogen content of the whole body rose distinctly from week to week. He employed for each of these experiments dozens of animals and in this way was able to overcome objections on the ground of chance and of inequality in the glycogen content of single animals.

A proof of the formation of new sugar in the normal body having been given with this distinctness, the conclusions which Zuntz drew from his experiments, are also confirmed. They show once more the special preference of the carbohydrate molecule for the yielding of mechanical energy in the body. In times of rest the body forms glycogen from protein, so as to have this most easily combustible material at its disposal at the beginning of muscular work, at least in certain quantities.

The constant presence of grape sugar in the blood of fasting animals must not be understood in the sense that the fasting body is not able to make use of this last carbohydrate reserve. It shows rather that the body replaces every using up of sugar by constant new formation. No life without carbohydrates! This principle seems just as certain to us as, *omnis cellula e cellula*. But certainly this transformation of protein or fat into sugar takes place only when there is a *need* for it, that is to say, when no or insufficient carbohydrates are introduced with the food. Seegen's view that with simultaneous carbohydrate ingestion all the protein and all the fat must first be converted to sugar in order to impart chemical and mechanical energy to the body, is absolutely unproved and improbable. This view is certainly just as wrong as the opposite one of Pavy, who stated that a direct use of grape sugar in the body was impossible, and was of the opinion that all the sugar must first be transformed into fat.

Glycocoll = C_2 =
Alanin = C_3 =
Cystein = C_3 =
Leucin = C_6 =
Phenyl-alanin = C_9 =
Lysin = C_6 = $CH_2 \cdot NH_2 - C_5H_9 - CH \cdot NH_2 - COOH = R_4$ "
Glucosamin = C_6 = $C_4H_9O_4 - CH \cdot NH_2 - CHO = R_4$ Glycin*aldehyde*

The Chemical Aspect of the Formation of New Sugar.—How are we to understand the chemical process of new sugar formation: We are to-day no longer satisfied with the establishment of a new sugar formation; we want to know the exact way in which this transformation takes place. In the case of glycerin the chemical process is the simplest and most easily understood. Glycerin, $C_3H_8O_3 = CH_2OH - CHOH - CH_2OH$, with its richness in oxygen and its constitution stands so near to the carbohydrates that it can hardly be regarded as a true fatty complex. Its transformation into $C_3H_6O_3$, that is to say into a triose, either into dioxyacetone, $CH_2OH - CO - CH_2OH$, or into glycerin aldehyde, $CH_2OH - CHOH - CHO$, requires only the addition of one atom of oxygen and takes place in a test tube with remarkable ease. The polymerization of such a triose, which means a carbohydrate with three carbon atoms, into a hexose, has been successfully accomplished by chemists. It is only one example from many in which lower carbohydrate groups condense to higher ones. And the animal body also is surely able to accomplish this oxidation of glycerin and its polymerisation to $C_6H_{12}O_6$, a hexose. This has been proved at least for the sorbose-bacterium by the most excellent work of Bertrand. And we shall surely have this simple way possible also in the body of higher animals.

In the formation of new sugar from protein we have to take into consideration its components, the aminoacids. Certainly we are far from a precise knowledge of the protein molecule; the real amount of the known components is not established, and we may still expect to find a number of new components. Neither from the qualitative nor from the quantitative side has the working up of the decomposition products given sufficient results. We know but little about its structure and about the arrangement in space of its components. In spite of all these objections we have already a certain conception of the protein molecule. In the same sense as the starch molecule is to be looked upon as a combination of innumerable molecules of grape sugar, so can we look on the protein molecule as made up of innumerable glycocoll groups.

Glycocoll, $CH_2NH_2 - COOH$, is the simplest α-aminoacid. We can consider all known aminoacids as derivatives of glycocoll. Alanin is a methyl-glycocoll, cystein a thio-methyl-glycocoll, leucin an isobutyl-glycocoll, phenyl-alanin a phenyl-methyl-glycocoll, and so on.

$CH_2 \cdot NH_2 - COOH = R_2$ Glycin
$CH_3 - CH \cdot NH_2 - COOH = R_1$ "
$CH_2 \cdot SH_2 - CH \cdot NH_2 - COOH = R_1$ "
$C_4H_7 - CH \cdot NH_2 - COOH = R_4$ "
$C_6H_5 - CH_2 - CH \cdot NH_2 - COOH = R_7$ "

Of all the decomposition products now known, only one, glucosamin, differs in structure from these; it is an α-amino-aldehyde, but it also contains the amino group in the α-position like the other components.

Since most of the linkages in the protein molecule are linkages between the amino group of one aminoacid and the carboxyl of another, protein could be regarded as a *polysubstituted polyglycocoll.*

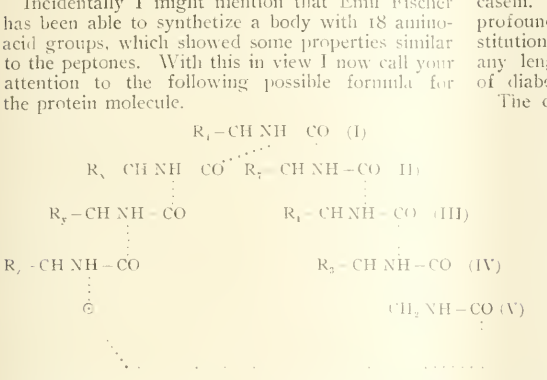
I present here the formulæ of a simple and of a complex polypeptide, of glycyl-glycin and of glycyl-glycyl-alanin, which are types of synthetical products made by Emil Fischer.

Glycyl-glycin = $CH_2 \cdot NH_2 - CO$
$\vdots$
$CH_2 \cdot NH - COOH$

Glycyl-glycyl-alanin = $CH_2 \cdot NH_2 - CO$ (I)
$\vdots$
$CH_2 \cdot NH - CO$ (II)
$\vdots$
$R_1CH \cdot NH - COOH$ (III)

You can see that glycyl-alanin may be considered as a compound of three glycocoll groups, in which one is substituted by a methyl (R_1). I call your attention to the fact that at the first glycocoll group, an isobutyl group can be readily substituted and we obtain a leucyl-glycyl-alanin, and so on until we come to the higher polypeptids.

Incidentally I might mention that Emil Fischer has been able to synthetize a body with 18 amino-acid groups, which showed some properties similar to the peptones. With this in view I now call your attention to the following possible formula for the protein molecule.



It consists of a series of substituted glycocoll groups: you see that the first is a leucin, the second a phenyl-alanin, and then follows alanin, valin, and glycocoll and so on. Of course, this gives no idea of the arrangement of the protein molecule in space, nor does it take into consideration the optical properties of the molecule, still it represents an easily conceived possibility.

Of course, other linkages, important for the constitution of protein and for the function of the protoplasm also occur in the protein molecule, and perhaps also other components of quite a different hitherto unknown type may still be found. If so, the classification of protein I have chosen would have to be extended and altered. Although this designation of protein as a *polysubstituted-polyglycocoll* may, perhaps, prove to be chosen too early, it takes away the mysteriousness with which the nature of protein has up to the present been surrounded in the eyes not only of physicians but also of chemists.

The riddle of sugar formation from albumin appeared for a moment solved, when Pavy found a preformed carbohydrate complex in protein. But it was soon discovered that this body, whose osazon is identical with that of grape sugar, was not grape sugar itself, but glucosamine. Its mass amounts at most to 30 per cent. in the glucoproteids, but in the true proteids is present only in minimal quantities or is totally absent. Accordingly, it is insufficient for the production of large quantities of sugar. And feeding experiments with free glucosamine, with glucosamine hydrochloride, or glucosamine ester showed that this body produces absolutely no sugar in the animal body. Also in the test tube the conversion of the glucosamine into grape sugar, which was originally expected by reason of the close relation of the formulæ has not yet been realized.

It has even been shown by an examination carried out from another point of view, that precisely that very proteid in which no glucosamine and no preformed carbohydrate are present, casein, yields the highest quantity of sugar in the diabetic body. It was a question of great practical importance to know which proteid would yield the smallest quantity of sugar. This would certainly be the most advantageous for a diabetic subject. The differences which were observed in feeding experiments on diabetic patients are not very great. Plant proteids certainly yield somewhat smaller quantities of sugar than animal proteids and especially than casein. But for superficial and also for more profound reasons, a more or less complete substitution of plant albumin for animal protein for any length of time is impossible in the dieting of diabetic subjects.

The question of sugar formation from proteid is to be reduced to the question of the different aminoacids. Lusk and Stiles have shown that, on feeding with completely digested protein, that is to say, with the aminoacids *in toto*, the sugar output in the case of a phlorhizinized dog rises as high as on feeding with natural protein. But special difficulties stand in the way of the examination of the single aminoacids. The method of glycogen accumulation in animals which have been freed from glycogen is impracticable also on feeding with aminoacids. For this purpose, also, investigation of the diabetic organism is the only practicable way. But on account of their irritative action, only small quantities of aminoacids can be introduced, and for this reason the differences in the sugar output were in general relatively small. Embden and Salomon in their best experiments found that after feeding with 20 to 40 grams of alanin the urine sugar rose from 7 to 17 grams, that is to say about 10 grams. And it is very doubtful, on account of the spontaneous variations in the sugar output, whether these 10 grams have really arisen from the introduced alanin, all the more so, because the experiments of the various authors do not quite agree. The most recent experiments of Graham Lusk, however, speak in favor of the transformation of glycocoll, alanin, aspartic acid, and glutaminic acid into sugar.

Karl Grube has tried to apply another method for the solution of this question. He had found that the tortoise liver, on transfusion with artificial serum, was a most excellent test object for the examination of glycogen formation. He used this method also for the examination of the amino acids.

But in contrast to other substances these bodies failed to accomplish glycogen formation in the experiments on the tortoise liver. Certainly the liver, the most general and important chemical laboratory of the body, takes part in the formation of new sugar, as has been proven by various experiments, but still Grube's experiments have shown that this organ is not *in itself* capable of effecting the complete transformation of the aminoacids to sugar. It seems that a preliminary part of the work necessary for this purpose must be carried out by the other organs. And thus the negative results in the case of the isolated tortoise liver do not prove the non-existence of sugar formation from aminoacids in the organism. Even Pflüger, in the last work of his long and glorious life, was converted to the belief of sugar formation from glycocoll.

If, with a certain reserve, we may rely on these investigations of the different authors, their results may be generalized as follows: It appears that aspartic acid, glutaminic acid, alanin, and also glycocoll are sugar producers, while leucin and tyrosin are not.

As to their connection with sugar formation the aminoacids are to be divided into two opposite classes, and this division is also justified by their different behavior in another biochemical process; that is to say, by their relationship to acetone bodies. I would emphasize the fact that the two groups of aminoacids are directly opposed to one another in relation to the production of oxybutyric acid and of sugar. Alanin, aspartic acid, glutaminic acid, and glycocoll, which yield sugar, seem to diminish the elimination of acetone bodies, while those aminoacids which yield no sugar, such as leucin and tyrosin, cause a decided rise in the oxybutyric acid output. This is extremely important for the understanding of both processes.

However doubtful the relationships of the single aminoacids to sugar may be, still they permit some conclusions to be drawn in respect to the chemical changes which must occur. Friedrich Müller supposed leucin to be the real or the most important source of sugar, because this aminoacid contains six carbon atoms like sugar. But it is precisely from leucin that according to our present knowledge, no glucose is produced. A sugar formation from the lower aminoacids with four, three, and two carbon atoms, aspartic acid, alanin, etc., supposes a synthesis of a chain of 6 carbon atoms from chains of 2, 3 or 4 carbon atoms. Pflüger some years ago would place such a synthesis outside the possibilities of the animal body. But I need only to remind you of the formation of fat, that is to say, of fatty acids with from 16 to 18 carbon atoms, from grape sugar, in order to refute Pflüger's objection. A synthetical condensation is also present in the case of sugar formation from glycerin, which has been established beyond doubt. Here the synthesis consists in a linking up of 2 chains of 3 carbon atoms each.

The question here arises as to whether complexes with 2 or even with only 1 carbon atom can also be used in the body for the synthesis of sugar. In the case of alanin we have the following alternative. Alanin can by the loss of an amino group be transformed into lactic acid $C_3H_6O_3$, which is isomeric with glyceric aldehyde. It could be assumed that the first by an intramolecular rearrangement might pass into its isomeric form and this be condensed to sugar.

A second possibility is the following: Emil Fischer and Neuberg have effected a reduction of aminoacids to aminoaldehydes by the action of sodium amalgam. Perhaps a similar reduction may occur also in the organism, which has strong reducing forces at its disposal. Aminopropylaldehyde would then arise from alanin and the amino group would only then be split off.

$$\begin{array}{l} CH_3-CHNH_2-COOH \\ \quad\quad\quad\

Grube passed a very dilute formaldehyde solution for many hours through isolated tortoise liver and found an appreciable rise in the glycogen content of one lobe at the end of the experiment, in comparison with that of the other lobe, which was analyzed before the transfusion. I may mention in passing that it has been proved by numerous experiments that the glycogen content of the different parts of the liver is usually the same.

I can find no fault either in principle or analysis in Grube's procedure—Grube worked in Pflüger's laboratory—and, accordingly, I am inclined to consider his experiments as correct.* But by reason of the enormous importance of this result, a careful reinvestigation and a confirmation from other sides is extremely desirous.

Should Grube's results be confirmed, then a difference between plant and animal life, which has up to now been held as fundamental, would be wiped out and the limits of the synthethic capacity of the animal body would once more be widely enlarged. Certainly one difference will still remain, that is to say, the synthesis of protein. I consider it improbable that the animal body can unite free ammonia, which is not already combined with carbon, to carbon and in this way synthetize protein from its elements.†

We may draw a further conclusion from what has been stated. Even though the capability of the body be so manifold for the synthesis of sugar from chains of different length, it is certain that chains of 4 or 5 carbon atoms, as aspartic and glutaminic acid can be used for the synthesis without any splitting off of single carbon atoms. Such a splitting off will take place many times over. Some aminoacids will split off only one C atom; others more. Besides this there are certain aminoacids which do not yield sugar at all. Mehring's supposition that 100 parts of proteid should yield 135 parts of grape sugar is, according to this, incorrect.

The chemical process of the transformation of the high fatty acids into grape sugar can be specified with still less accuracy, even on the ground of supposition, than with the aminoacids. Pflüger's view that the 18 carbon atoms chain of stearic acid be directly decomposed into three chains of 6 carbon atoms each, is extremely improbable. It has absolutely no analogy in the entire field of chemistry and biochemistry. We know from investigations as to the production of oxybutyric acid that the decomposition of the fatty acids takes place by oxidation in the β-position and that the long carbon chains are in every case shortened by 2 carbon atoms. From stearic acid, palmitic acid is produced, and from caprylic acid, caprinic acid, capronic acid, and butyric acid. Here we may ask whether these 2 carbon atoms, which are repeatedly split off together, represent the material for the sugar synthesis: or is this material first set free, when the catabolic process has gone down to a lower fatty acid with 6 or 4 C atoms? It is impossible at the present time to express assumptions of any sort in respect to this.

But I feel inclined to consider the latter as being the more probable. In any case, I would like to emphasize the difference existing between the oxidation of the amino and fatty acids as being of the greatest importance for the formation of sugar. By the splitting off of an amino group, which is possibly the first process in the transformation of the aminoacids into sugar, an α-oxyacid is formed in each case, while by the oxidation of the true fatty acids a β-oxyacid arises. The oxybutyric acid is an actual representative of these β-oxyacids. It seems to me extremely probable that the combination present in the α-oxyacids, that is to say, the occurrence of hydroxyl and carboxyl in adjacent positions, highly favors the sugar synthesis, in opposition to the more distant position which these groups have in the β-oxyacids. Perhaps in this circumstance lies the solution of the riddle that protein yields dextrose so much more easily than fat.

FORMATION OF GRAPE SUGAR FROM OTHER HEXOSES.

The chemical process occurring in the transformation of the different hexoses into one another is to-day by no means so problematical as the processes which have just been described. The transition of levulose, galactose, and mannose into grape sugar has long been proved for healthy animals by the method of glycogen accumulation. It is further confirmed by experiments on diabetic subjects. It was thought for a time that the mutual transformation of the hexoses in the body was to be attributed to the same forces as in the test tube, that is to say, to the action of alkalis. Remember, please, gentlemen, the brilliant experiments of Lobry de Bruyn and von Eckenstein, who, on adding alkali to a solution of either dextrose or levulose or mannose, found after some time all three kinds of sugar present in the solution. Still the so-called alkalinity of the blood is insufficient for this transformation. Blood contains no sodiumhydroxide, nor sodium carbonate, but only sodium bicarbonate; it contains no hydroxyl-ions, and it is these only which cause the transformation in the test tube. No conversion of levulose into grape sugar takes place in the blood; it occurs only in the organs, partly in the liver, and it is performed probably by the action of ferments, which possess similar powers in the body as the hydroxyl in a test tube.

	LEVULOSE.	MANNOSE.	GLUCOSE.	GALACTOSE.
I.	$C{\cdot}H_2OH$	$C{\cdot}HO$	$C{\cdot}HO$	$C{\cdot}HO$
IIα.	$C{\cdot}O$	$OH{\cdot}C{\cdot}H$	$H{\cdot}C{\cdot}OH$	$H{\cdot}C{\cdot}OH$
IIIβ.	$OH{\cdot}C{\cdot}H$	$OH{\cdot}C{\cdot}H$	$OH{\cdot}C{\cdot}H$	$OH{\cdot}C{\cdot}H$
IVγ.	$H{\cdot}C{\cdot}OH$	$H{\cdot}C{\cdot}OH$	$H{\cdot}C{\cdot}OH$	$OH{\cdot}C{\cdot}H$
Vδ.	$H{\cdot}C{\cdot}OH$	$H{\cdot}C{\cdot}OH$	$H{\cdot}C{\cdot}OH$	$H{\cdot}C{\cdot}OH$
VIϵ.	$C-H_2O$	$C\,H_2OH$	$C\,H_2OH$	$C{\cdot}H_2OH$

Dextrose, levulose, and mannose differ from one another only in the different arrangements of the hydrogen and of the hydroxyl at the first and second carbon atom of the chain. Their mutual transformation is to-day explained by a certain liability of this arrangement which permits under certain conditions a mutual exchange of the H and the OH.

The difference between galactose and dextrose, however, is greater. They differ by an inverted arrangement of the H and OH at the fourth, the γ-carbon atom. Chemists have not yet succeeded in transforming these products directly into one another. In the body, however, galactose is certainly formed from grape sugar. This has been established by Porcher by means of interesting studies of lactating animals. Strong hyperglycemia occurs immediately before and after parturition. If the milk gland be removed, either before or after parturition, a decided glycosuria occurs after the

*Only in a remark contained in Pflüger's last publication could I find a support for doubts.

†In his last work Knoop, however, seems to have proven a synthesis of an aminoacid, namely, of benzyl-alanin from benzyl-pyrotartaric acid and ammonia.

birth. This may rise rapidly up to 7 per cent. of sugar, but declines rapidly also, and the glycosuria lasts only from one to two days. If the milk gland be present this hyperglycemia leads not to glycosuria but to lactosuria. It seems fairly certain that the liver empties its glycogen so as to impart to the glands the material necessary for the formation of milk sugar. If the gland be absent then a part of this unused grape sugar is eliminated in the urine. It is interesting that this sugar mobilization is not brought about by the mammary gland, for it occurs even if the gland has been removed long before the birth.

The question of the greatest interest for diabetic therapeutics is whether or not one of the above carbohydrates would be preferred to grape sugar and utilized to a greater extent. In this field also Külz was the first to carry out an experimental investigation. He has shown that a certain preference exists in cases of light diabetes for levulose and galactose or milk sugar over dextrose. It is still unknown which of these are benefited by the substitution of milk sugar for starch, or why it should be so. But with *severe* diabetes these differences disappear. The hexoses mentioned are almost quantitatively transformed into grape sugar. In extremely severe cases of diabetes, when the period of ingesting lactose sugar is longer than from one to two days, it is just as completely eliminated as grape sugar.

Although levulose also seemed to be eliminated just as completely as dextrose in severe diabetes, the use of inulin, the polymer of levulose, has very often been tried by reason of a striking, though still unexplained property of levulose. Minkowski found that the liver of depancreatized dogs, after feeding with levulose, again contains glycogen. This was never the case when even a very large quantity of dextrose was introduced. Von Noorden has confirmed this for diabetic human beings. As the glycogen molecule which is produced from levulose contains only dextrose molecules, levulose must first be transformed into grape sugar. Thus the difference between levulose and dextrose in respect to glycogen accumulation in diabetes is extremely enigmatic. The only possibility that I can conceive at present is, that the levulose can enter the interior of the cells where the chemical processes take place, and it is only there transformed into grape sugar, while it is impossible for preformed dextrose to penetrate into the cells.

The transitions of levulose and of galactose to dextrose are processes which are also reversible in the organism. Transformation of galactose into glucose appears in the healthy being and in the diabetic subject, and is performed in the liver. The contrary transition of glucose into galactose occurs in the active mammary gland. The transformation of levulose to grape sugar can also be reversed and be recognized under suitable conditions. This is apparently the case in levulosuria. In most persons levulosuria is only a question of elimination of exogenous levulose, that is to say, of such as is taken up in vegetables and cane sugar. Such patients seem to have lost the capacity of transforming levulose into dextrose. But in others a derivation of the urine-levulose from dextrose is occasionally recognizable. A patient of Zimmer's eliminated, besides grape sugar, up to 150 grams of levulose. Since such quantities were not taken in in the food, they must have been formed from another material, from grape sugar certainly.

On the whole the clinical significance of pure levulosuria is very small. The levulose elimination seldom exceeds 20 grams. Progression of the metabolic disturbance is not recognizable. In most cases it is usually sufficient, if cane sugar, fruit, and certain vegetables which contain large quantities of levulose be avoided, in order to put an end to the symptoms of levulosuria.

As to the pentoses, I need only mention quite briefly that they undergo no transformation into grape sugar. It is to be regretted that they cannot be employed even on a small scale as a substitute for the useless hexose molecules. Certain diabetic subjects catabolize large quantities of pentoses, 50 grams, and even more in the case of rhamnose, but with most patients the oxidative capacity is far lower. These "semi-foodstuffs" even in small quantities exercise a most violent irritation on the intestine, the kidneys, etc.

Von Noorden has been much more fortunate than Külz in his attempts to find a useful carbohydrate for diabetic patients. However variable the results of the so-called oatmeal cure may be with different patients, still this discovery of v. Noorden's has the highest importance for dietetic therapeutics, and the thanks of both doctors and patients are due to the fortunate discoverer. The action of the oatmeal is completely unexplained. It has been shown that it is not dependent on accidental conditions and that diminution of the proteid ingestion does not play the principal part. This has been shown by experiments with different cereals under similar conditions as to the amount of protein, fat, and starch in the daily food. The specific property of oatmeal is in any case a material one. It may depend on the peculiar properties of the oat starch itself, or on the non-carbohydrate complex of the oats. It is very striking that almost no attempt has as yet been made to solve this problem. It seems to be improbable that oat starch, which is composed only of glucose, should behave differently in the metabolism from other sorts of starch. Still Dr. Lang of Karlsbad, a highly trustworthy investigator, has found differences in the fermentative decomposition of oat starch as compared with other sorts of starch. Further investigations in this direction must be awaited with the greatest interest. I hope shortly to be able myself to take a part in these investigations.

THE CAUSES OF DEATH FROM SHOCK BY COMMERCIAL ELECTRIC CURRENTS, AND THE TREATMENT OF THE SAME.

By E. MacD. STANTON, M.D.,

SCHENECTADY, N. Y.,

AND

ARTHUR KRIDA,

ALBANY MEDICAL COLLEGE.

With the present widespread use of electricity in almost all manner of human activities, serious and often fatal accidental shocks are of frequent occurrence. The question, therefore, of the best means to be employed in the resuscitation of individuals suffering from the effects of accidental shock is one of decided practical importance. Particularly is this true in a community such as Schenectady, where the chief industries are largely associated with the use of powerful commercial currents.

Certain recent discoveries concerning the possibility of resuscitation after nominal death from other causes, together with the development of practical forms of apparatus for maintaining artificial respiration over indefinite periods of time, have made it seem to the writers worth while to systematize the available knowledge concerning the effects which follow, and the causes of death which results from the application of commercial electric currents and to formulate as far as possible a rational procedure to be carried out in cases of injury by electric shock.

Throughout this paper we have used the term "commercial current" referring to circuits in which the energy is such as is used in ordinary commercial work. The actual amount of current passing through the body varies so much in individual experiments, depending on the resistance of the animal and the character of the contact, that it has been found impractical to attempt detailed ampere readings. Suffice it to say that throughout this paper it is to be understood that the circuits referred to are not of a low-energy source such as galvanic cells, but that a current of up to at least ten amperes may be sustained without an appreciable drop in voltage. In the conclusions reached it may be assumed that the current varies anywhere between one-half and ten or more amperes, depending upon and varying with the resistance of the subject.

Any rational method of resuscitation must be based directly upon a knowledge of the physiology of death from electric currents. This knowledge is in its main aspects readily ascertainable by direct experiments upon animals, controlled as far as possible as regards man by clinical observations in cases of accidental shock, and by observations made at the time of the electrocution of criminals.

The extensive and accurate researches of Prevost and Battelli give us a fairly complete knowledge of the effects produced upon experimental animals by direct and alternating currents of varying potentials up to 4800 volts. Previous to the work of Prevost and Battelli, investigators had arrived at widely different conclusions concerning the cause of death from electric shock; this was due to the fact that the chief cause of death varies with the current used, and that each of the individual investigators had, for the most part, used different currents in his investigations.

For the purposes of systematic study we may consider the lethal effects of electric currents under the following heads:

1. The actual destruction of tissues whereby they are so altered as to be no longer capable of performing their physiological functions. This is often seen locally in the form of electric burns, and the well-known tendency for the tissues in the regions of these burns to slough far beyond the original visible limits of injury suggests the possibility of the widespread destruction of tissues by the currents. However, these burning effects are seen only at the site of high-resistance contacts, and it is certain that the actual physiological destruction of tissue is of but exceptional occurrence and of minor importance as a cause of death.

2. Interference with the action of the heart. This is one of the most common causes of death by electricity, especially when relatively low-tension currents are encountered. Electric currents passing through the heart tend to interfere with the normal rhythmic contractions of the heart muscle and to throw it into a state of so-called fibrillary contractions, in which the individual muscle fibers or groups of fibers contract in an utterly incoordinate manner, and thus absolutely interfere with the normal beating of the heart. The ventricles are particularly susceptible and a current as low as one volt when applied directly to the heart may be sufficient to induce fibrillary contractions.

3. Arrest of respirations by paralysis of the nerve centers governing this function. The central nervous system is highly susceptible to the influence of electric currents, more especially to the influence of the higher tension currents, and it is probable that the respiratory paralysis is the result of a profound anesthesia comparable in many respects to that produced by overdoses of ether or chloroform.

Experimental investigations have shown beyond a doubt that fibrillary contractions of the heart and respiratory paralysis are the chief causes of death from electric shock. And, furthermore, experimental results seem to show a fairly definite relationship between the character of the current employed and the effects produced upon the heart and central nervous system.

There is considerable variation in different animals as regards their susceptibility to electric currents, and particularly as regards the susceptibility of the heart. Thus Prevost and Battelli found that alternating currents of low tension cause only temporary arrest of respiration, but that fibrillary contractions of the ventricles are induced. In dogs these fibrillations always persist after the current is broken, so that once the fibrillary contractions have appeared it is impossible to resuscitate the animal. In guinea pigs and rabbits the fibrillations may sometimes disappear and the animals recover, whereas in rats this latter result is invariably noted, the rat being apparently immune to low-tension currents.

It is thus seen that the data obtained from animal experiments are not necessarily entirely applicable to man, and due allowance must be given for the variations in susceptibility, man being apparently quite immune to currents which are fatal to the dog. Clinical observations, however, seem to show that the cause of death in man is the same, namely, either respiratory or cardiac failure, and that while one animal may be more susceptible than another there is probably no essential difference as regards the fundamental effects produced by the different currents.

The writers in describing the effects produced by the different currents will follow closely the results obtained by Prevost and Battelli, who used the dog, rabbit, guinea pig and rat in their experiments. We will indicate possible corrections for man whenever data is obtainable on the subject.

Direct Currents; the Heart.—The effects produced by direct currents depend upon a number of factors, such as the strength of the current, the duration of the contact and the course of the current through the body, and, furthermore, the steady effect of the direct current is complicated by the sudden shocks due to the make and break of the current.

In dogs fibrillary contractions of the heart may be produced by the shock at the break with currents as low as 10 volts, whereas with stronger currents neither the shock of make nor break is necessary to produce the fibrillary contractions, the heart entering upon the stage of fibrillation during the passage of the current. Indeed, at times, with currents of 400-500 volts the shock of break may

serve to re-establish rhythmic contractions in a heart already in a state of fibrillation during the passage of the current; but if the shock of break of these stronger currents be suppressed by a gradual shutting down of the current, *e.g.*, by the use of a rheostat, the cardiac paralysis remains final.

Considerable variation is noted as regards the cardiac susceptibility of different animals, for, as stated above, a current of 70 volts may be sufficient to produce ventricular fibrillations in dogs, and except in the case of the higher potential currents, where the rhythm may be re-established on breaking the current, practically no tendency is seen toward a spontaneous re-establishment of heart action. On the contrary, in rabbits and guinea pigs, although even low-tension currents produce fibrillary contractions, a well-marked tendency is seen in these animals for the heart to spontaneously re-establish its normal rhythm, and a few of the animals recover spontaneously unless respiratory paralysis is also present, in which case artificial respiration may be necessary to resuscitate the animal. With rats, spontaneous recovery of the cardiac rhythm is the rule, they being apparently almost immune to cardiac paralysis from direct currents up to 550 volts.

No accurate data are available concerning the behavior of the human heart under the influence of direct currents, but it seems altogether probable that ventricular fibrillations may exist at least during the passage of the higher tension currents, and that the failure to re-establish the normal cardiac rhythm is the cause of death in most cases.

Nervous System.—The effect of direct currents on the nervous system seems to be in direct proportion to the strength of the current used and the duration of the contact. Currents of low voltage (100 volts) produce little effect except the muscular contractions at the make and break. Higher currents (200-400 volts) produce tetanic muscular contractions, quickly followed, if the contact is prolonged, by a flaccid paralysis and respiratory failure; whereas with currents of still higher tension (550 volts) the anesthesia of the nervous system may be produced so promptly as to show no tetany, respiratory failure from paralysis being almost immediate under these conditions.

From a clinical viewpoint the writers believe that the effect produced by the higher tension currents on the central nervous system may be conceived as a state of anesthesia quite comparable to chloroform or ether narcosis, except that the respiratory centers are more promptly involved than in surgical narcosis. While possibly this conception may not be absolutely correct, it is of practical use in enabling one to make comparisons with the abundant clinical data concerning respiratory failure during surgical narcosis, and the researches of Robinovitch seem to show that electric anesthesia is quite definitely comparable to ether or chloroform anesthesia.

Alternating Currents.—The effects produced by the alternating current depend largely upon the tension of the current, the frequency of the cycles, the duration of the contact and the course of the current through the body. As a rule, low frequencies (25-150 cycles) are for a given strength of current more dangerous than higher frequencies (1720 cycles). We have been unable to find any reliable data concerning the effects of variations in the curve of flow during the reversals of the current, but it is quite probable that the nearer this curve approaches the sine curve the less irritating it becomes.

The Heart.—In experimental animals, currents of low frequency and relatively low tension almost uniformly produce ventricular fibrillations, whereas the effects of currents of high tension are more noticeable in the central nervous system.

Prevost and Battelli found that under favorable conditions a current as low as 15 volts at 30 to 150 cycles would produce fibrillary contractions in the heart of the dog. With low-tension commercial currents (about 130 volts) cardiac fibrillation is constantly produced, and in the dog these fibrillations always persist after the current is broken, so that once the fibrillations have appeared it is impossible to resuscitate the animal.

In guinea pigs and rabbits the fibrillations may sometimes disappear and the animal recover, whereas in the rat the heart invariably regains its normal rhythm, this animal being quite immune to low-tension currents either direct or alternating.

This cardiac paralysis with low-tension currents in susceptible animals presents certain very striking clinical features: the heart is essentially the only organ affected by the current, and after the interruption of the current the animal may continue to breathe and retain consciousness for a minute or more, the respirations and consciousness finally failing only as a result of an anemia of the central nervous system produced by the failure of the circulation.

As the tension of the current is increased, decidedly less tendency is seen toward the production of fibrillary contractions, and when these do come on they are less liable to be final than when produced by low-tension currents. Guinea pigs may recover from the fibrillary contractions following the application of a current of 240 volts, when they do not recover from one of 120 volts; rabbits may not show fibrillations with a current of 600 volts, when they do with one of 240 volts. Even dogs fail to show fibrillary contractions on the application of high-tension current (1300-4800 volts), but, on the contrary, the heart-beats become quicker and stronger and the blood pressure rises. Crile and McLeod have, however, found that even with currents of 2300 volts, if the contact be prolonged from 5 to 10 seconds, the blood pressure falls to zero, and the animal cannot be resuscitated by artificial respiration.

Not only do very high-tension currents (4800 volts) show little tendency to cause fibrillary contractions, but Prevost and Battelli have shown that the application of a high-tension current (4800 volts) may re-establish normal heart-beats in a heart previously paralyzed by a low-tension current, provided the high-tension current is applied before the blood pressure has fallen to zero.

The failure to reestablish the heart-beats after the blood pressure has fallen to zero is explained by the well-known facts that the maintenance of cardiac contractions is largely dependent upon a sufficient pressure in the coronary arteries. With cardiac paralysis, blood pressure falls to abscissa in about 15 seconds, so that the time for the application of this method of resuscitation must be very sharply limited, unless it be possible to again artificially raise the blood pressure by some method such as the adrenalin-salt solution injections of Crile and Dolly.

All writers seem to agree that very high frequency currents (1720 cycles) are much less liable

to produce cardiac paralysis than those of low frequency (25-150 cycles) with similar voltage.

But very little accurate data is available concerning the behavior of the human heart when subjected to various tensions of alternating currents. The medical reports of the executions in New York State since 1890 seem to agree that with a current of about 1500 volts, 15-50 cycles, 2-7 amperes, the heart continues to beat and the respirations show a tendency to re-establish themselves when the contact is broken after a few seconds; but that with a longer application of the current (45-87 seconds) the cardiac action is entirely suspended.

Central Nervous System.—As before stated, low-tension alternating currents may kill by causing cardiac fibrillations without producing any noticeable effect upon the central nervous system; even consciousness may be but little affected, and both consciousness and respirations finally fail only as a result of the anemia of the central nervous system resulting from the stoppage of the circulation. Medium-tension currents (600 volts) cause loss of consciousness and respiratory paralysis, usually accompanied by cardiac fibrillations. On the other hand, currents of high tension (2300-4800 volts) cause instantaneous loss of consciousness with almost instantaneous respiratory paralysis, accompanied only very infrequently by cardiac fibrillations.

If the contact is prolonged with the higher tension currents the anesthesia produced is most profound and may last for half an hour or more, and yet the patient ultimately recovers under artificial respiration, provided there has been no cardiac paralysis. One case is on record in which a man is said to have recovered after four hours of artificial respiration.

Variations in Effects Produced Due to Different Points of Application of Electrodes; Freak Accidents.—The markedly variable results from accidental shocks are well known to all; fatal accidents sometimes result from contacts with currents ordinarily hardly considered dangerous, and individuals at other times escape from contacts which under ordinary conditions would seem necessarily fatal. This must in part be accounted for by the poor contacts often formed in accidental cases, as contrasted with the carefully planned contacts of experimental work. Also, due to the arcing tendencies of high-tension currents, portions of the body may sometimes serve only as a means of completing the arc, the current not permanently passing through the body.

In experimental work wide variations are seen in the results, depending upon the points selected for the application of the electrodes; this must also be an important factor in explaining the effects produced by accidental contacts. When the electrodes are placed in the mouth and the rectum, the current must necessarily traverse the region of the heart, and with all strengths of current cardiac fibrillation is far more likely to occur than if the electrodes are placed on the head and one fore-limb, or one fore-limb and one hind-limb, in which case the heart does not lie in the direct path of the current; on the other hand, the respiratory mechanism is far more rapidly affected if the medulla oblongata lies in the direct path of the current.

TREATMENT OF ELECTRIC SHOCK.

With a definite understanding of the mechanism of death from electric shock, the indications for treatment become clearly outlined. The possibilities of resuscitation are inseparably connected with the factors of respiratory and cardiac failure. In the cases of simple respiratory failure resuscitation depends upon the maintenance of respiration by artificial means until such time as the anesthetic condition of the central nervous system shall have disappeared. The cases with ventricular fibrillation are apparently utterly hopeless from the very first, unless some means be devised whereby rhythmic cardiac contractions of the heart may be promptly reestablished.

Artificial respiration may be maintained either by manipulating the body itself in such a manner that the chest cavity is alternately compressed and expanded, or by the use of a pump or a bellows so manipulated as to force air at regular intervals through the trachea and into the lungs in sufficient volume to expand the chest and properly fill the lungs. Expiration is accomplished by simply releasing the pressure and allowing the chest walls to collapse. As the pressure required is not more than 8 mm. of mercury, a simple hand or foot bellows of sufficient capacity will serve perfectly as an air pump, but as the tube must be inserted into the larynx, a suitably curved metal or hard rubber cannula should be provided for this purpose, and provision must be made for the release of pressure during expiration. It is very essential that no effort be made to forcibly suck the air from the lungs, as this causes a collapse of the smaller bronchioles, which effectually seals the air in the alveoli and prevents emptying the lung.

While artificial respiration may be maintained for some time in a fairly satisfactory manner by manual methods, it is always difficult, and except when performed by skilled operators the exchange of air is barely sufficient to maintain life. A properly constructed apparatus for maintaining artificial respiration is very easy to manipulate once the tube is properly inserted into the larynx, and such an apparatus with some one capable of inserting the tube into the larynx should always be on hand in testing laboratories and places where accidents are particularly likely to occur. Artificial respiration should be begun by manual methods at once and maintained until this apparatus can be brought to the patient.

A possible point in favor of maintaining artificial respiration by means of this apparatus is the fact that all manual methods require energetic manipulation of the chest wall with more or less accompanying massage of the heart, and from a study of the experimental results it seems quite possible that any traumatic impulses transmitted to a heart through which a current has just passed may tend to establish fibrillary contractions in the heart which would otherwise not occur.

In order that the blood supply to the respiratory centers may be maintained as well as possible and in order that the heart may be well supplied with blood, it would seem to be always advisable to keep the patient in the head-down position, best maintained by laying him on a plank or table with the foot end elevated at an angle of 35 degrees. Whereas cases of simple respiratory failure give fair prospects of recovery with properly maintained artificial respiration, the cases of cardiac failure are at present absolutely hopeless from the onset, and will probably remain so unless some practical means be devised for re-establishing the normal action of the heart.

Prevost and Battelli have shown that the application of a high-tension current (4800 volts) may re-establish the normal heart-beats if applied at a time before the blood pressure has fallen too low; that is within less than 15 seconds after the time of injury. Robonvitch has secured similar results with the Leduc current, but methods requiring application within 15 seconds are obviously impossible of execution in practical work.

Within the past few years the researches of Crile and Dolly have added enormously to our knowledge of the factors which maintain the normal cardiac rhythm. These investigators have shown that it is quite possible to re-establish normal heart action in animals killed by chloroform or asphyxia, even after the heart has been entirely stopped for periods up to 5 minutes or more. Crile and Dolly have shown that the limit of time of resuscitation is not determined by the heart itself, but by the susceptibility of the central nervous system to injury by the anemia resulting from the suspension of the circulation. While the heart's action may be re-established after intervals greater than 5 minutes, the central nervous system cannot stand an absence of blood supply for a much longer period, so that the animals recovering after this period show permanent evidence of brain injury, remaining in the more extreme cases practically as decerebrates.

Sollman was the first to show that ventricular contractions depend upon a sufficient pressure in the coronary arteries, and that the quiescent heart may be made to beat if some fluid, even metallic mercury, be forced into the coronary arteries. Crile and Dolly finally devised a means of producing this necessary pressure in the coronary arteries with the heart in *situ*, using the following method: First, the arterial system is rapidly filled with salt solution by injecting the solution toward the heart through a suitable peripheral artery, and at the moment when the arteries are nearly filled a sufficient quantity of adrenalin chloride is added to the salt solution. This causes the vessel walls to contract, and thus rapidly raises the blood pressure within the arteries. At the proper moment the heart is stimulated by a few quick compressions on the chest wall, which causes it to immediately jump into action, beating very vigorously from the first beat.

The possibilities of this method may be well shown by reporting in detail the results of one of our resuscitation experiments.

Dog No. 11. Small fox terrier. Chloroform anesthesia. 12:40. Respirations ceased unexpectedly before the apparatus was ready for the experiment. Very slight heart action for a few seconds after respirations ceased. Laryngeal tube inserted and artificial respiration alone tried without avail, the heart action soon ceasing entirely. 12:44. Carotid artery exposed and cannula inserted toward the heart. No bleeding from artery. Artificial respiration maintained constantly. 12:46. Saline infusion into carotid artery with the bottle at a height of 5 feet above the table, and 1 cc. of 1/1,000 adrenalin chloride solution injected into tube near cannula after salt solution had been flowing about 10 seconds. Indirect cardiac massage by pressure on the chest wall. No response from the heart. 12:49. Salt solution, adrenalin and massage repeated. 12:49:30. Heart begins beating strongly. 12:51. Respirations begin, irregular at first, then become more regular, and animal soon begins to struggle. 12:55. Contact of 10 seconds' duration, alternating current of 118 volts, 60 cycles, with electrodes on neck and abdomen. 12:56. Salt solution and adrenalin chloride solution administered as previously, with artificial respiration. Opened abdomen, examined the heart and massaged the same through the diaphragm. Fibrillary contractions of the ventricles, auricles beating. No return of normal beats. Continued to massage heart until 1:15; experiment abandoned.

The technique of Crile and Dolly is so simple and easy of execution as to make it practically possible to carry out the same in such a place as the testing department of the General Electric Company, where a trained man is always in readiness to care for such emergencies. The writers have therefore made a number of experiments to determine the applicability of this technique as a method of resuscitation in cases of heart stoppage by electric shock.

Our results as regards resuscitation from chloroform poisoning confirm the work of Crile and Dolly, and as regards the death of dogs from low-tension alternating currents, our results are in full accord with the findings of Prevost and Battelli and others; but in no instance were we able to re-establish rhythmic contractions in a dog's heart by the normal salt-adrenalin chloride technique of Crile and Dolly once fibrillary contractions had been induced.

The following is a summary of our experiments:

Dog No. 1. Large male setter. Killed by chloroform anesthesia. Attempted Crile and Dolly technique, but with too small a cannula and salt solution bottle elevated only 3 feet. Result negative.

Dog No. 2. Medium-sized bull dog. Treated as dog No. 1. Results negative, except that a few feeble heart-beats were established by direct cardiac massage after 10 minutes.

Dog No. 3. Large pointer. Treated as dog No. 1. Result negative.

Dog No. 4. Large bulldog. Previous errors in technique corrected by raising salt-solution bottle to a height of 5 feet above the table and substituting a cannula of suitable size. 1:06. Dog killed by chloroform. 1:08. Normal saline infusion toward heart, ½ cc. adrenalin chloride, artificial respiration by machine, indirect cardiac massage. Prompt recovery of heart-beats, with high blood pressure, forcing bloody liquid back into solution bottle. Re-establishment of normal respirations. This dog was again killed by re-administration of chloroform, and second attempt at resuscitation after an interval of 5 minutes failed.

Dog No. 5. Mongrel puppy, weight about 2.5 kilos. Chloroform anesthesia, femoral artery exposed and prepared for insertion of cannula. Inserted laryngeal cannula. Dog almost out of the anesthesia at the time of application of current. 5:30. Ten seconds contact, 118 volts, 60 cycles, electrodes at side of head and abdomen. 5:30:15 and 5:30:30. Same contact repeated. No evidence of pulsation in femoral artery after first contact, but repeated spasmodic respiratory efforts led us to make repeated contacts. Prevost and Battelli noted that dogs may breathe well and retain consciousness for some time after fatal heart failure. 5:33. Saline infusion into femoral artery, with 1 cc. adrenalin chloride, artificial respiration. Indirect cardiac massage. No result. 5:34:30. Same repeated. No result. Opened pericardium through

abdomen and diaphragm. Auricles beating but ventricles contracted with marked fibrillation. Direct massage. No result. The contracted fibrillating ventricles with beating auricles were in marked contrast to the distended heart found at similar periods after chloroform death.

Dog No. 6. Mongrel puppy. Weight about 10 kilos. Chloroform anesthesia, femoral artery exposed, laryngeal tube inserted. 6:00. Ten seconds contact, with a current of 118 volts, 60 cycles, electrodes at side of head and abdomen. 6:02. Saline infusion into femoral artery, artificial respiration by machine, adrenalin chloride, 1 cc. Bimanual cardiac massage with one hand inserted through incision into abdomen, and the other on the outside of the chest wall. No result. 6:04. Repeated infusion, adrenalin, and massage. 6:07 (approximately). On stopping artificial respiration after a period of rather violent cardiac massage, the dog made a few gasping respirations, raising his head somewhat at the same time, and we thought that there were a few spasmodic heart-beats at the same time, but accurate observations were impossible during the spasmodic contractions of the chest wall. 6:08. Exposed heart and found usual fibrillary contractions of ventricles, with beating auricles. Direct massage produced no results.

Dog No. 7. Mongrel puppy, weight about 7 kilos. Chloroform anesthesia, femoral artery exposed, tracheal cannula inserted. 7:30. Ten seconds contact, 118 volts, 60 cycles. 7:31:30. Saline infusion into femoral artery, allowed to flow 10 seconds, artificial respiration. 7:32. One c.c. adrenalin chloride. Cardiac massage bimanually, with one hand inserted through abdominal incision, and other on chest wall. 7:34. More saline. 7:35. One cc. adrenalin chloride. Cardiac massage continued. 7:50. No return of respiration or circulation. Experiment abandoned. Heart definitely in fibrillary contraction when first palpated through the diaphragm. No evidence of circulation in femoral artery at any time.

Dog No. 8. Mongrel puppy, weight about 4 kilos. Chloroform anesthesia, femoral artery exposed, tracheal cannula inserted. 11:30. Ten seconds contact with current as previously. Cannula which had been held in the divided femoral artery by Crile clamps slipped at moment of contact and had to be replaced. 11:32:30. Saline infusion into artery. Artificial respiration. One cc. adrenalin chloride. Bimanual cardiac massage. 11:38. More saline, with 1 cc. adrenalin chloride. 11:55. No return of circulation or respiration. Fibrillary tremulation from moment of contact. No hemorrhage when clamps slipped. Absolutely no effect from salt solution and adrenalin. Violent massage just before abandonment of experiment forced blood high into solution tube by the action of the massage alone.

Dog No. 9. Small mongrel dog, weight about 7 kilos. Chloroform anesthesia, femoral artery exposed, tracheal cannula inserted. 11:00. Ten seconds contact, current as in previous experiments. 11:02. Normal salt infusion into femoral artery. One cc. adrenalin chloride. Artificial respiration, bimanual cardiac massage through incision below diaphragm. 11:05. A slight flutter may be elicited from the heart after prolonged massage through the diaphragm, but no decided heart-beat. Dog gave a few gasps at this time, raising his head at each gasp. These subsided in a short time, and experiment was abandoned. Autopsy shows lungs to be in good condition; the heart is contracted and practically empty.

Dog No. 10. Small fox terrier. Chloroform anesthesia, carotid artery exposed and cannula inserted into proximal end. Tracheal cannula inserted. 11:45. Began chloroform; pushed same until heart ceased beating. Respirations cease. 11:50. Heart has ceased beating. 11:53. Normal saline infusion into carotid artery, about 75 cc. One cc. adrenalin chloride. Artificial respiration and bimanual cardiac massage through incision below diaphragm. 11:55. Heart begins to beat forcibly and rhythmically. 11:58. Spontaneous respirations begin. 12:05. Ten seconds contact, with current as in previous experiments. 12:07. Saline infusion with procedure as above. 12:20. No return of pulse or respiration.

Dog No. 11. Reported in detail on page 900.

Dog No. 12. Large mastiff. Chloroform anesthesia changed to ether. Carotid artery exposed, cannula inserted. 11:30. Heart and respiration suddenly and unexpectedly cease. 11:35. Saline infusion, 1 cc. adrenalin chloride. Artificial respiration. 11:40. More saline, with adrenalin. Bimanual cardiac massage. No return of heart-beat, found to be due to over-distension of heart with the saline infusion.

In conclusion it may be said:

1. That there are many questions concerning this subject which remain as yet unsolved.

2. The two great causes of death are cardiac fibrillation and respiratory paralysis.

3. Low-tension currents tend to kill chiefly by producing cardiac fibrillation.

4. As the tension is increased the effect upon the heart becomes less pronounced, but at the same time the effect upon the central nervous system becomes more and more certain as the tension is increased so that with high-tension currents death is more likely to be caused by respiratory failure, although if the contact is prolonged the heart is also stopped.

5. We have been unable to find any reliable data concerning the action of commercial currents of more than 4,500 volts, but all evidence points to the central nervous system as being the chief sufferer from the effects of currents of more than 4,800 volts.

6. Cardiac fibrillation is fatal under known methods of treatment.

7. In cases of simple respiratory paralysis the patient may be kept alive by artificial respiration until the nervous system recovers from the effects of the shock.

8. Further investigations should be conducted to see if the method of Crile and Dolly may not be combined with the high-tension contacts of Battellior or those of Leduc and Robinovitch whereby resuscitation might be brought about in cases of cardiac paralysis during periods of up to 5 minutes following the accident.

THE USE OF THIOSINAMIN IN THE TREATMENT OF CICATRICIAL FORMATIONS FOLLOWING BURNS.

By J. EWING MEARS, M.D.,

PHILADELPHIA, PA.

In the Spring of 1908 I was asked, in the absence of the family physician, to see a young girl, who in running from the dining room into the kitchen, at the home of a friend, collided with the range and upset a kettle of boiling water, which flowed over her left arm, producing a scald which extended over

FIGS. 1 and 2.—Appearance of the arm before treatment was begun.

the outer surface of the arm from just below the apex of the shoulder to a point about four inches above the wrist. On the arm the scald encroached upon the inner surface to a slight extent, not quite reaching the median line. On the forearm it involved the greater part of the inner surface from the elbow to the level of the scald on the outer surface.

At the time of the receipt of the injury a dressing of antiphlogistine was applied by the family and the child removed to her home. This temporary dressing was permitted to remain in place until the morning following, when it was removed, the numerous blisters opened and evacuated, a dressing of boracic acid ointment applied and the arm,

enveloped in aseptic gauze and cotton, was placed on a pasteboard splint in the position of an obtuse angle. The dressing gave the child relief from undue pain so that it was not found necessary to administer any sedative.

On the return of the family physician the patient was placed in his care, and I did not see her until the following month of August, when photographs of the arm were taken which showed the mass of cicatricial tissue which accompanied the reparative process as illustrated in Figs. 1 and 2.

An examination of the growth made it evident that operative interference could not be successfully instituted, owing to the extent of the mass, which would not admit of the complete covering by adjacent integument of the denuded surface after removal, nor was it deemed prudent to produce wound conditions in a structure of such character as that which was present.

Fig. 3.—Appearance of the cicatrix after an equivalent of about one year of continuous treatment.

Further study of the case led me to make an effort to produce absorption of the mass, if not entirely, at least to such an extent as to remove the great disfigurement which was present and, possibly, to check the tendency to any further growth.

To accomplish this the child was placed upon thiosinamin, both by internal administration and local application. Internally the remedy was used in the form of pills and externally as an ointment. At the beginning of the treatment one grain was taken after each meal; latterly some nausea supervened, which was attributed by her mother, who administered the remedy, to the quantity given, and the dose was reduced to one-half a grain three times daily. The ointment was of the strength of 8 per cent. As some irritation appeared after somewhat constant use during a period of six months it was deemed desirable to reduce the strength to 5 per cent. The ointment was applied on sheet lint which was held in place by a gauze bandage and permitted to remain in place during the night. I should have preferred to have used the remedy by hypodermatic injection, which would have undoubtedly yielded prompter and more pronounced results than by the method employed, but this was not possible as I had the opportunity to see the patient only at long intervals. Fig. No. 3 was made from a photograph taken one year ago and two years after the beginning of the treatment. In that time the remedy, owing to intermissions, was not actually administered more than twelve months and not as continuously as was desirable.

In the year which has intervened since the taking of the photograph (No. 3) the remedy has been administered with the effect of a still further reduction of the cicatricial mass, so that at the present time the scarred surface is quite on the level with the normal integument and it has lost the bluish color which was so marked in the early stage. It is proposed to continue the use of the remedy with the hope of securing quite entire removal of the scarred tissue and approximate return to a normal condition of the skin.

Thiosinamin was introduced into medicine by von Hebra (*Internat. klin. Rundschau,* September, 1892) and the following interesting statement is made with regard to its action and uses: "It exerts no influence upon the general system, its action is directly upon the blood-making organs. Several hours after injection the leucocytes in the blood are greatly diminished in number, falling, according to von Hebra, from 14,000 to 4,000. This condition lasts but a short time, followed by a pronounced hyperleucocytosis, during which a marked destruction and absorption of exudates, of cicatrical, and other poorly nourished tissues occur. It has been used by clinicians in the treatment of lupus, old cicatrices, chronic glandular inflammations, keloid, urethral strictures, corneal opacities, and sclerotic conditions of the ear with consequent deafness, fibrous tumors, syphilitic lesions, and smallpox scars. It may be administered internally in capsules in ½ to 3 grain doses. Locally it may be applied in soap or plaster, 5 to 20 per cent. It may be injected hypodermatically 1 to 4 grains in alcoholic solution, preferably in the intrascapular or gluteal region. In overdoses it produces toxic effects." Care should be taken to obtain the pure drug and that only which is dispensed by reliable pharmacists.

Hemiplegic Chorea.—R. Massalongo and U. Gasperini report cases of a thirteen-year-old boy and an eleven-year-old girl who presented complete left-sided paralysis complicating chorea. The peculiar choreic movements, as well as the paralytic manifestations that may arise in chorea, are attributed to a toxic, infectious agent acting upon the motor cells in the cerebral cortex, producing either paralytic or excitatory changes.—*Rivista di Patologia Nervosa e Mentale.*

CONCERNING THE RESTORATION OF INHIBITORY QUALITIES IN LIVER EXTRACTS.

By D. M. KAPLAN, M.D.,

NEW YORK.

DIRECTOR OF LABORATORY NEUROLOGICAL INSTITUTE OF NEW YORK; SEROLOGIST TO THE MONTEFIORE HOME.

The Wassermann reaction with its five components remains up to date an unsolved problem. The statistical compilation of clinical facts as furnished by the application of this reaction to syphilology permanently places it among the better and at the same time among the most difficult tests in the laboratory. Its practical application has been the subject of many hundreds of communications and most physicians to-day know to what extent it is valuable for treatment and diagnosis. This, however, is not the case with the theoretical and technical part of the reaction. The situation is particularly intricate considering the peculiar mode of action of the various extracts for inhibition of hemolysis, and many workers here and abroad busied themselves to solve this seeming paradox. It was very early recognized that from the point of view of the side-chain teachings of Ehrlich there is nothing in the various extracts used for the Wassermann reaction to justify their classification among true antigens. This is generally accepted and the use of the apellation antigen from the immunity standpoint is more a custom than a fact. We know that many substances when suitably treated are capable of furnishing very useful extracts.

Having worked with extracts from human organs luetic and nonluetic as well as with bovine heart and liver extracts, I came to the conclusion that it mattered very little whether the organ was heart or liver, luetic or not. One fact, however, became apparent and that is, no matter how useful an extract may prove to be at the initial standardization there is very little to guide us in the knowledge as to the manner in which its inhibitory powers will behave in the future. As a matter of fact some of my extracts proved useless a very short time after their initial unit dose was established. I know that many workers hoped to throw considerable light upon the chemistry of these extracts by attempting to obtain in a pure state the complex molecule responsible for the inhibition.

The general opinion arrived at concerning the molecules responsible for the prevention of hemolysis in syphilitic and other sera is that they are substances closely related to bodies of a fatty nature, although what these lipoids may be structurally has not as yet been suggested. Whatever these speculative themes may disclose in the future is uncertain; for the present we are far from the truth concerning the chemistry of the inhibitory principle in the various organ extracts. In order to be able to render more dependable reports on the Wassermann reaction in a given serum some workers resorted to the use of more than one extract. Seligmann employed three different inhibitory extracts and claimed very gratifying results especially in dubious sera.

The above fact and many others point to the uncertainty regarding the adaptability of one extract. It is self-evident that no one is quite sure as to the usefulness of an antigen while preparing the same from any organ. This is true of syphilitic or nonsyphilitic, watery or alcoholic extracts. The unit dose once established, no one can vouch for its strength on the day following. As mentioned before, a very powerful inhibitory extract may in a short time become powerless to inhibit.

Disregarding all these shortcomings as to the unstability of extracts, Wassermann still maintains that the only extract suitable for the test bearing his name is the one prepared from syphilitic fetal livers. In America the majority of workers, including myself, believe that the aceton insoluble fraction of an alcoholic extract from any liver may furnish as useful an inhibitory extract as the watery extract of Wassermann.

The choice of an extract seems to me to be more a matter of individual preference, for when properly used one extract is as good as another. There are tendencies to harmonize the functions of the inhibitory extract (antigen) in concordance with the laws governing immune processes in general, an undertaking which, in my opinion, is untenable so far as the Wassermann reaction is concerned. Steps were also taken to construct (hypothetically) the graphic body of the inhibitory molecule. It seems to me permissible to assume the existence of a central body with a number of side-chains. There is evidence that some workers were enabled to obtain extracts without some of their side-chains. It is to be borne in mind that these opinions are only conjectural; at the same time there is sufficient evidence at hand to permit of thought on these lines.

It has been established that there is a difference in action between the various side-chains of the inhibitory molecule and also that they react differently from the central body (Leistungs-Kern). Some extracts owe their poor inhibitory powers to an overabundance of side-chains of a hemolytic or anti-inhibitory nature. These hemolytic side-chains are, according to U. Friedmann (*Archiv. f. Hyg.*, Bd. 69), insoluble in water-free ether. The inhibitory molecule, according to F. Lesser (*Berliner klin. Woch.*, No. 21, 1909), is soluble in ether.

As practised by Ehrmann and Stern (*Ber. klin. Woch.*, No. 7, 1910), the inhibitory molecule can be separated from its side-chains or purified. These experimenters worked with watery extracts from acute yellow atrophy and streptococcic livers. A closer acquaintance with these hemolytic bodies or constituents of the antigenic molecule were furnished by Joannowicz and Pick (*Ber. klin. Woch.*, No. 20, 1910), who determined that the unsaturated fatty acids were responsible for hemolytic qualities while the aceton-precipitable lipoids carried the inhibitory principle.

It was lately observed by J. Zeissler (*Ber. klin. Woch.*, No. 21, 1910) that extracts kept on ice for four weeks lose their hemolytic property whereas the inhibitory qualities remain intact. If the organ mass from which the extract was prepared was permitted to remain in the same vessel it was found that both properties, hemolytic and inhibitory, remained intact. These observations together with others suggest that the inhibitory molecule consists of an inhibitory nucleus and one or more hemolytic molecules as side-chains. These hemolytic side-chains are comparatively tempolabile, *i.e.* become chemically altered in the course of time and incapable of hemolyzing. In cases where the organ particles are kept together with the extract the tissue sediment seems to be capable of supplying the hemolytic principles for a long time. The above observations furnish facts that could be utilized practically, but the various workers do not state to what extent.

The only one who furnishes figures relative to the return of inhibitory powers in deteriorated extracts is Stuehmer (*Centralblatt fuer innere Medizin*, No. 14, 1910), who worked on the plans of Bencke, who in 1908 believed that the reason why syphilitic liver extracts were more efficient in furnishing suitable antigens lay in the fact that such organs were usually the seat of extensive breaking down processes.

Stuehmer worked with guinea pig livers, making alcoholic extracts from them and subjecting them to different influences.

1, Was not treated in any way; 2, was kept for twelve hours at 38° and was decomposed by bacteria; 3, kept for fourteen days in icebox, bacterial decomposition; 4, kept for nineteen days at 18°, bacterial decomposition; 5, for four weeks on ice, sterile, dry. The extracts showed the following behavior: *a* = absolute inhibition, *b* = partial inhibition, *c* = incomplete hemolysis, *d* = complete hemolysis:

Quantity.	1	2	3	4	5
0.25	*a*	*a*	*d*	*a*	*a*
0.125	*b*	*b*	*b*	*a*	*a*
0.06	*c*	*b*	*a*	*a*	*a*
0.03	*d*	*c*	*a*	*a*	*a*
0.015	*d*	*d*	*a*	*a*	*b*
0.007	*d*	*d*	*a*	*a*	*c*
0.004	*d*	*d*	*a*	*a*	*d*
0.002	*d*	*d*	*b*	*b*	*d*
0.001	*d*	*d*	*d*	*c*	*d*

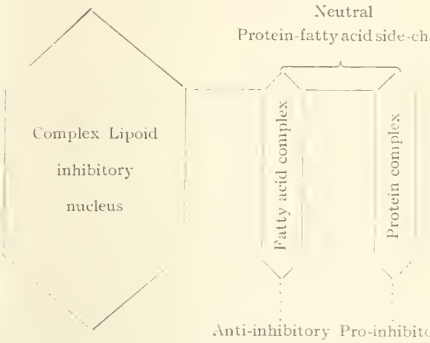
The above table shows that the extract 4 was the most potent as it contained in the small dose (0.004) sufficient inhibitory powers to prevent hemolysis.

The above observations suggest different methods for increasing or restoring the inhibitory qualities in extracts; purifying by extraction or permitting the interfering molecules to break down and utilize the extract in a decomposed condition. Having had two years' experience with making and using of various antigens I had sufficient opportunity to study their behavior.

Those who keep their extracts of liver or heart in its cerumen-like consistency and appearance sooner or later note that the light color becomes gradually darker until it is almost black. This is not due so much to the action of light as to the oxidative powers of the air. Kept tightly corked and covered with aceton the original extract remains of a dark yellow color for months. This retention of color, however, has very little to do with its inhibitory qualities. Its color may remain intact while its usefulness as an extract for deviation may be nil, and that shortly after the initial standardization. The rapid loss of inhibitory powers can be readily detected by observing the control tube with extract (extract, complement, amboceptor tube): if the latter hemolyzes in from ten to fifteen minutes or at the same time as the tube with amboceptor efficiency control it becomes imperative not to use the extract any longer in its present state of activity.

I have on such occasions tried to redissolve my extract stock in ether, to do away with the hemolytic principles, decant after standing the clear supernatant fluid and reprecipitate the remaining mass with aceton. The obtained inhibitory unit was rather large (0.1 c.c.) and I thought of trying the method of ageing. It seemed to me at that time that while precipitating with acetone, our intention of obtaining the inhibitory molecule in a pure state was rendered futile by the presence or coexistence of a complex unsaturated fatty acid-proteid combination in the obtained precipitate. The efficiency of the extract during its initial standardization to my mind is due to the integrity of this proteid-fatty acid combination; as soon as the proteid portion begins to decompose its neutralizing effects upon the fatty acid molecule vanish and the acids are left free to prevent or to interfere with inhibitory action of the central antihemolytic nucleus. In the presence of large quantities of such liberated bodies hemolysis occurs as readily in the antigen control as in the amboceptor control tube. Keeping the entire stock of extract under methyl alcohol renders it a little more stabile, but even this is subject to deterioration.

The suppositional formula for the entire complex capable of inhibition at first, then deteriorating, finally acquiring inhibitory powers anew, can be pictured as follows:



While working with antigens I have observed that most extracts behave in the following manner: (1) They undergo decomposition, which causes the initial inhibitory power to diminish or even disappear. (2) This weakening is the result most likely of liberation of certain bodies of an anti-inhibitory nature. (3) These liberated bodies can be eliminated by certain treatment. (4) The advanced breaking down causes the inhibitory powers to reappear in increased strength. The first observation is known to all who worked with the Wassermann test, and it seems to me is due, if we go back to the structural picture, to a breaking down of the protein portion of the fatty-acid protein side-chain of the inhibitory body. These proteins tend to neutralize the anti-inhibitory effects of the fatty acids, which influence is done away with as soon as the protein molecules break down. The more such neutralizing molecules are set free the less potent does the extract become. Finally the extract becomes entirely incapable of inhibition. If the decomposition is still further prolonged the fatty-acid molecules themselves break down and thus remove their anti-inhibitory influence over the central inhibitory body, rendering the extract useful again and to a much stronger and powerful extent than at the first standardization. This point is brought out by Stuehmer and as will be shown directly, also by myself. In January, 1910, an alcoholic extract of a normal human liver was prepared. The aceton insoluble fraction was obtained and utilized in ordinary fashion—0.15 grams were dissolved in ether and after slight evaporation brought up to 100 c.c. with 0.85 NaCl. Three lots were prepared

and after the initial standardization it was found that the extract was capable of inhibition with luetic sera in 0.1 c.c. doses, while nonluetic sera were not affected by four times this quantity. The extracts were placed in the ordinary ice chest, No. 1 without any sterile precautions; No. 2 was preserved with sterile precaution; No. 3 was used for everyday work.

The extract 1 was tested in June, 1910, was found to be greatly decomposed and foul smelling. No. 2 was also decomposed and malodorous. No. 3 had lost all inhibitory qualities at the end of two months. The inhibitory power of the extracts 1 and 2 were as follows:

Using luetic serum.			Using nonluetic serum.		
Dose.	1	2	Dose.	1	2
0.1	*a*	*a*	0.1	*a*	*a*
0.05	*a*	*a*	0.05	*a*	*c*
0.025	*a*	*b*	0.025	*c*	*d*
0.01	*a*	*b*	0.01	*d*	*d*
0.005	*a*	*d*	0.005	*d*	*d*
0.003	*a*	*d*			
0.001	*b*	*d*			

It becomes at once apparent that extract 1 furnished the best workable extract with the least trouble. The dose 0.01 c.c. multiplied by four gave no inhibition with normal sera, while luetic sera were completely inhibited.

All antigens ought to be used in as small doses as possible with syphilitic sera and the quadruple dose should not inhibit with normal sera.

Extract 1 gave a positive reaction with sera from tabetics whose serum was negative with extract 3 after being five weeks in use.

In my opinion the greatly putrefied extract 1 contained the central inhibitory body plus functionless complexes, the remains of the interfering side-chains. In their present decomposed condition these bodies no longer interfered with the inhibitory functions of the extract, hence its increased powers to inhibit. The above extract is useful for the original Wassermann test as well as for the Noguchi modification, excepting that in the latter instance half of the dose is required. It is no longer necessary to saturate papers with the extract and I believe Noguchi himself is not against the use of the extract in a fluid state.

Summary.—1. Inactive extracts can be made active; 2. this can be accomplished in two ways, by reprecipitation or decomposition; 3. prolonged decomposition gives a powerful inhibitory molecule which is stabile; 4. hypothetically, the inhibitory body apparently consists of a central nucleus of a lipoid nature with complex side-chains capable of interfering with the functions of inhibition; 5. these side-chains are tempo labile, whereas the central inhibitory body is comparatively permanent.

30 Beekman Place.

A NEW THEORY OF ECLAMPSIA.

By JAMES R. MITCHELL, A.B., M.D.,

FORT WORTH, TEXAS.

LECTURER IN OBSTETRICS, FORT WORTH MEDICAL COLLEGE.

Eclampsia is an acute disease, intimate with pregnancy, and characterized by tonic and clonic spasms with coma following. It occurs approximately once in every five hundred pregnancies; some years not often seen; in other years encountered so frequently as to suggest an epidemic. The nearer the pregnancy to term, the more liable the development of eclampsia. Primiparæ contribute 70%. Twin pregnancies increase the possibility five-fold. So, given a twin pregancy in a primipara, near term, and we have the best chance for a case of eclampsia.

In many essentials an attack of eclampsia resembles a seizure of epilepsy. The patient's eyes at first are fixed with pupils dilated, then may roll to either side. Spasms, more often clonic in type, but at rare times tonic, attack the mouth and rapidly extend to the arms, body, legs. Respiration becomes rapid; stertorous. Face is congested; lips cyanotic; mouth foams. The duration may be ten seconds, or as much as two minutes—then coma. Coma may be permanent, or interrupted by more convulsions, or may pass off and the patient appear normal. Death may ensue shortly from edema of the lungs; or, if the case lingers moribund, an aspiration penumonia or an intercurrent infection spells the fatality. Other symptoms may be associated. A fever of 104 to 108 may be present, even when there is no evidence of an intercurrent infection, to which eclamptic women are so readily liable. Retinitis, so often noted, indicates edema of the brain. In a small number of cases, jaundice occurs, usually late, always prophesying a fatal prognosis. The urine may be normal, but usually is lessened in amount, reveals albumin, casts, blood, and a disturbed nitrogen partition, with lessened amount of urea, and an enormous increase in the ammonia compounds of nitrogen. There is only one constant feature to the post-mortem pathology—a hemorrhagic hepatitis. Nephritis and edema of the brain are inconstant. Bronchopneumonia and pus infections have terminated prolonged cases. From gross and microscopical pathology we can deduce nothing of value.

Eclampsia has well been termed by Zweifel "The Disease of Theories." As it is the purpose of this paper not to review the old theories, but to present a new one, I will merely mention them: Nervous, uremic, edema of the brain, bacterial, placental, pressure on the ureters, infectious, intoxication (a) fetal, (b) maternal. The last theory—maternal intoxication—is now generally accepted, and it is the purpose of this paper to set forth the exact agency of the intoxication: that eclampsia is a complex symptom of the mother's need for calcium. Calcium is a physiological necessity. This element, the most abundant of the minerals, is found loosely combined in all fluids and cells of the body, existing, however, in largest quantity as the tertiary phosphate of bone. Bones, poor in calcium, are brittle and fracture readily. On calcium depends the density of the teeth. Witness the tragedy of phosphorous workers whose teeth are ruined by the action of yellow phosphorus upon the enamel. The presence of calcium in the blood maintains blood pressure and its proportion determines the coagulation time of the blood. The continuance of the heart beat depends upon calcium; the influence of a solution of calcium salts upon the beating, excised heart is too well understood to need description. All ferments need calcium. Rennet is inactive upon casein in the absence of calcium. The amount of calcium in the urine helps to regulate the excretion of albumin, sugar, and urea. Calcium maintains tone in the muscles and the nerves. Decrease its amount and excessive irritability results; remove calcium entirely and all irritability will cease. When the blood-vessels of the pia mater are filled with blood rich in calcium by intravenous injection, it is difficult to stimulate the cerebral cor-

tex by any external agent. But if the vessels of the pia contain blood poor in calcium (as obtained by an intravenous injection of normal salt solution) any weak stimulus produces abnormally strong and long-continued twitchings in the peripheral muscles.

In some respects, sodium and calcium salts are mutually antagonistic. Sodium salts promote twitchings. Simple immersion in normal salt solution of a muscle-nerve preparation in a short time produces twitchings. Add calcium to the salt solution and the twitchings cease. Sulphuric acid precipitates calcium. Inject sulphuric acid beneath a frog's skin, and the frog will throw convulsions. Now inject a calcium solution into the frog and the convulsions immediately stop.

The body's demand for calcium becomes doubly urgent in pregnancy. A slight relative decrease in the mother is considered physiologic, helping to soften the bones and ligaments for an easy delivery. The growing fetus is a calcium parasite—and a very exacting parasite. In Nature's conflicts the parasites thrive; the hosts perish. Let the mother beware! The fetus will have its calcium even at its mother's expense. If the mother is not a generous host, greatly enlarging upon her usual calcium intake, her penalty is to suffer with defective teeth, headaches, and nervousness. Among women who are "experienced" childbearers, the expression, "for every child a tooth," tells well the fact that women pregnant are especially liable to decay of the teeth. Each tooth is a storehouse for calcium, but each tooth to be sound and white needs its hoard. The bones, too, store calcium. Osteomalacia, so much more frequent in pregnant women, is further evidence that the fetus is an inflexible calcium parasite. For the fetus needs its minerals—needs them for its blood, its bones, for every tissue fluid, and for the foundations of the teeth which are to come. It has been conclusively shown in the menageries of Dublin and Philadelphia that lionesses fed upon meat, with bones too large to be swallowed, gave birth to cubs which showed a relatively large ratio afflicted with cleft palates. The fetus, then, is a most evident drain upon the calcium reserve of its mother.

Let us for a space consider tetany, another disease often associated with pregnancy. Tetany is marked by convulsions—in reality it differs from eclampsia, only by the fact that its convulsions are not followed by coma. In simple arithmetic: tetany plus coma equals eclampsia. Both tetany and eclampsia resemble epilepsy. The relation of altered calcium metabolism to epilepsy is indicated, but is still under investigation. Tetany, however, has been conclusively proven by Dr. MacCallum of Baltimore to be due to calcium poverty in the tissues. Tetany can be produced in any animal desired, by removing the parathyroids, the organs which govern calcium metabolism. So important are Dr. MacCallum's experiments and deductions to a proper understanding of my theory of eclampsia that I take the liberty of fully abstracting his paper:

"Tetany is commonly associated with: 1. Infections, as, typhoid, cholera; 2. Gastric dilatation; 3. Infants, especially at dentition; 4. Trades, as, shoemakers, carpenters; 5. Bone diseases, as, osteomalacia, rickets; 6. Pregnancy, lactation; 7. Thyroid removal. The spasms may be epileptiform. Destroy the parathyroids, and tetany results. When calcium chloride solution is applied to the cerebral cortex, a greater electrical stimulus than normal is required to stimulate muscular contraction. Sodium citrate, sodium oxalate, and sodium soaps have an opposite effect, causing spontaneous twitchings and epileptiform convulsions, which may bet neutralized by adding calcium chloride. One can apply sodium citrate solutions to one cerebral hemisphere, and calcium chloride to the other, with corresponding opposite results. Therefore, calcium has a permanent moderating function on the brain cortex, and it should be useful in epilepsy.

"Loeb finds that injecting any acid or salt liable to precipitate calcium will produce twitchings. He suggests that any abnormal acidity in the circulation might decrease the calcium content, and necessarily produce twitchings. Such cases might be cured by administering calcium salts. Immerse any muscle-nerve preparation into a sodium citrate solution. Twitchings result. Add a calcium salt to the citrate solution, or transfer the muscle-nerve preparation to a calcium solution; and the twitchings cease. It is difficult to stimulate the cerebral cortex after intraveneous injection of calcium chloride. The postmortem calcium content of the brain in tetany is remarkedly lowered. Calcium-free food increases excitability. The calcium content of the fetus increases rapidly toward term and must be a great drain upon the mother during later pregnancy. So, too, the amount of calcium excreted in the milk is high (.4 per cent. or, 6 to 7 grams per day). Loeb thinks tetany an undercalcifying of the nervous centers, for tetany has been benefited by treatment with calcium. There is an increased output in the calcium content of the urine when a child suffers with tetany. Erdheim produced tetany in rats and found their teeth fragile, opaque, brittle.

"The subcutaneous administration of calcium salts suppresses all symptoms of tetany. Potassium salts make tetany worse. The nervous system needs a certain proportion of calcium; neither sodium nor potassium can substitute. The blood of dogs during an attack of tetany contained only one-half the normal amount of calcium. At the same time the ammonium content was enormously increased—about ten times the normal amount. The brain revealed only one-half its normal calcium content."

Dr. MacCallum concludes that:

"Tetany is a disease in which the mineral balance is deranged—no specific toxin was demonstrated by injecting 'tetanic' blood into normal animals; that there exists an important relationship between calcium salts and the excitability of the nervous system; that tetany is a hyperexcitability of nerve cells due to decrease of calcium. He finds that injecting calcium salts checks tetany symptoms; that calcium is a therapeutic agency in human tetany. A spontaneous tetany can readily be explained by a draining of tissue calcium, by a calcium-poor diet, or by parathyroid insufficiency. Clinical research on animals suffering tetany after parathyroid removal shows: 1. Decrease in calcium content of the tissues, especially the blood and brain; 2. Increase of nitrogen excretion in the urine; 3. Increase of ammonium output in the urine; 4. Relative excess of ammonia nitrogen to urea; 5. Increase of ammonia in the blood."

We find these five symptoms of tetany also present in every case of eclampsia. Tetany is due to a deficiency of calcium. Both tetany and eclampsia have similar twitchings, a long-delayed coagulation time for the blood, and a disturbed nitrogen elimination. Eclampsia, which is tetany plus coma, is a manifestation of still greater deficiency of calcium Toxemia of pregnancy is a clinical moving picture

of the mother's need for calcium. In the early stage she may exhibit her need by eating chalk, slate pencils, or marbles—and her physician calls it idiosyncrasy. Yes, and the chickens that eat cracked oyster shells, and the dogs that gnaw bones, exhibit this same idiosyncrasy. Then her teeth decay. The dentist tells her the cause is her morning vomit. It's acid, you know. She gets softening of the bones—osteomalacia the doctor tells her such is to expected, as soft bones will make delivery easy. Gradually edema of the legs develops, and she gets purgatives and hot packs which do no permanent good, and diuretics of potassium which abstract more calcium and make her condition worse; and also poisonous heart stimulants which act in some unknown, unphysiological manner. The physician overlooks that calcium in the circulating blood is the necessary, natural heart stimulant! And what physician here has not seen the cutaneous edemas resolve like magic under a few doses of calcium lactate. Her urine shows albumin and a disturbed nitrogen partition—her physician's indication for more diuretics. Yet you can produce albuminuria, and the identical ammonia findings in the urine of any animal fed upon maize and distilled water, or any other diet poor in calcium. The fetus is nearing term. The mother's bones and teeth have yielded their store—now the nerves suffer their loss of calcium. The nerves writhe in protest, first with intermittent, tetanic twichings, later with frequent tetanic convulsions. Then the physician unknowingly heeds their cry to preserve their calcium by removing the guilty calcium parasite. The mother now stands seven chances in ten of getting well, but at the expense in most cases of her child's life.

We have seen that calcium salts relieve tetany. If the convulsions of tetany and eclampsia have the same underlying cause, then calcium salts must relieve eclampsia. Several clinical cases bear out the theory strikingly. I will record my earliest case:

K. V. T. entered the hospital at the sixth month of pregnancy on February 23, 1909, suffering with twitchings and convulsions. Diagnosis: tetany of pregnancy. Bromides were administered without any satisfactory result. On March 2 patient suffered two convulsions, both followed by coma. Diagnosis changed to eclampsia. Urine showed albumin, casts, decrease of urea, and high ammonium content. On March 3 the patient suffered four more attacks of convulsions followed by coma, and was given calcium lactate 10 grains 6 times a day. This treatment was kept up for two weeks, during which time no more convulsions took place, and the calcium lactate was discontinued. On April 2 patient had two more convulsions followed by coma, and the calcium lactate treatment was again instituted and maintained until her uneventful delivery.

For the mild toxemia of pregnancy I have been using calcium lactate 10 grains 6 times a day, given by mouth. For cases seen in profound coma I have used the drug in doses of 30 grains by stomach tube, by rectal tube, and intravenously. Calcium cannot be given subcutaneously, as in doses large enough it is too irritating.

The calcium theory explains many clinical features of eclampsia, viz.: The greater frequency in twin pregnancy; the greater frequency at term; the nervous excitability and convulsions; the delayed coagulation time of the blood; the decayed teeth; the urinary findings; the associated edema; the eclampsia of lactation and the newly born; the well-known cessation of convulsions under milk diet.

To prove conclusively that the convulsions, like the decayed teeth, are only a part of the symptom-complex of a calcium-poor toxemia, a thorough clinical test is necessary. From two years of investigation I feel sure that such a test will cause the cure of eclampsia to be written with chalk. It is interesting to note that in Fort Worth, where eclampsia is so prevalent, the city water supply shows that it contains practically no calcium salts.

Prefetal Vaginal Dilatation in Breech Presentation.—C. Sauvage discusses the use of the Champetier de Ribes balloon not only for dilatation of the cervix but also for dilatation of the vagina in cases of breech presentation. It has been employed by Pinard, at the Baudelocque, in 50 cases, 39 of which were breech cases in primiparæ, the others being multiparæ. There is absolutely no danger for the mother, and the prognosis for the life of the infant is made much better than ordinarily. It makes labor much easier and shorter, and facilitates any necessary manipulations. The period of expulsion is materially shortened. It prepares for a spontaneous delivery, and lessens the indications for extraction by the breech. It increases the strength of the child, betters its mortality by one quarter, and lessens the number of injuries it receives. Pinard believes that in every primipara with breech presentation the vagina should be dilated with a balloon. Among multiparæ it should be used in breech presentations whenever the child is large in size. The balloon should be put in place when the cervix is dilated to the size of a five-franc piece.—*Annales de Gynécologie et d'Obstetriques.*

The Suprarenal Capsules in Pregnancy and the Puerperium.—Luigi Sambalino has examined the suprarenal capsules in 26 cases of pregnancy which ended fatally at the hospital in Florence; of these ten died of eclampsia with albuminuria; four had chronic nephritis, four had sepsis, five had various complications, three died of hemorrhage. The author finds that the principal alterations of the suprarenal capsules consisted in an hypertrophy of the cortical substance, and vacuolization of its elements. He believes that, aside from the other diseased conditions found in these patients, pregnancy has been shown to cause a special reaction in the cortical substance, with pigmentation of the reticulated zone. It has not been demonstrated that the medullary substance is changed. In pregnancy complicated by nephritis and eclampsia there is a relative frequency of suprarenal adenomatosis. In infections complicating pregnancy and the puerperium, especially when there have been severe and prolonged inflammatory conditions, there is a small celled infiltration of the fasciculated zone and the medullary substance, even resulting in connective tissue proliferation.—*Annali di Ostetricia e Ginecologia.*

The Heart in Articular Rheumatism of Children.—P. Nobécourt says that rheumatism in children is peculiarly liable to affect the heart; the virus has a peculiar affinity for the endocardium and the myocardium. We may get valvular lesions appearing in slight cases without any fever. The lesions may take the form of endocarditis, pericarditis, or myocarditis. The most severe symptoms occur in the malignant cases in which there develop swelling of the jugulars, tachycardia, and cyanosis, and sudden death may result. In mild cases the immediate prognosis is good, but the remote results may be lesions that later result in death. These small patients in severe cases quickly emaciate and become cachectic. In mild cases there are no subjective symptoms, and the heart should be watched carefully to detect the physical signs. Treatment demands immediate rest in bed with milk diet and salicylates.—*Archives de Médecine des Enfants.*

THE STIMULATION OF OSSEOUS GROWTH BY MEANS OF FORMALIN.

THE number and variety of constitutional and local conditions affecting the growth of the bones are such as to impart peculiar interest to the recent investigations conducted by R. O. Meisenbach, and described by him in the *American Journal of Orthopedic Surgery*, for August, 1910. He notes that the effects of disease and trauma on the epiphyses are strikingly indicated in cases of tuberculosis, rickets, osteomyelitis, chondrodystrophy, poliomyelitis, congenital dislocation of the hip, congenitally shortened bones, traumatic separation of the epiphyses, shortening following fracture in the so-called epiphyseal line, and similar conditions. In some of these the epiphyses have been stimulated and in others retarded. With the object of studying the effects on bony growth by influencing the cellular structures of the epiphyseal cartilage, and of determining whether this growth can be influenced by chemical or mechanical means, Meisenbach experimented on young rabbits in the following manner: Into the right tibia just below the epiphyseal cartilage, there were inserted sterile water, sterile graphite pegs, *Staphylococcus pyogenes aureus* vaccine, containing 400,000,000 cocci to the cubic centimeter, sterile graphite pegs in addition to the vaccine, pure tincture of iodine, pure carbolic acid, 95 per cent. alcohol, pure formalin, or 2 per cent. formalin. Only one injection was given in each case, and the left tibia was used as a control.

The effects of these substances were studied after varying periods of time with the aid of radiographic and microscopic examination of the bones. It was found that while normal bone ossifies slowly, the stimulated bone ossifies rapidly. Mechanical stimulation chiefly affects perichondral bone formation, whereas chemical stimulation affects the epiphyseal line directly, causing proliferation of cartilage cells and increased zones of provisional calcification and calcified matrix, together with osteogenetic tissue chiefly derived from the perichondrium. Mechanical stimulation is slow, whereas chemical stimulation is rapid, and acts more universally, affecting the active bone-producing elements. Retardation of growth may occur if the zone of provisional calcification is destroyed, or if this zone is infiltrated by excessive blood-clot or by destructive processes. Of all the substances used formalin produced the best results, on account of its antiseptic properties and its affinity for protoplasm. Injected upon the epiphyseal and diaphyseal lines formalin acts as an insoluble compound, and therefore affects the epiphyseal line both mechanically and chemically with a distinct local rather than systemic tendency. It causes the formation of osteogenetic tissue by influencing the zones of provisional calcification and calcified matrix, and by increasing the number of osteoblasts derived from the perichondrium.

The results of these experiments showed that it is possible by artificial means to stimulate bony growth. They are all the more valuable in view of the fact that in each instance only one injection was employed. The effects of repeated injections of formalin and the use of other laboratory animals would probably yield results of additional value. The clinical value of these investigations is not altogether remote. It is suggested that they may serve as a stepping stone to a new method of treatment in many bone cases which have heretofore seemed hopeless as regards helping the patient, cases such as congenital shortening of the limbs, arrest of bony growth following poliomyelitis, tuberculosis of the bones, osteomyelitis, obstinate nonunion of fractures, and similar cases.

VIRCHOW AND BACTERIOLOGY.

EVER since the germ theory was first postulated it has been urged that Virchow regarded it with undisguised hostility, and upon the death of the great man the numerous obituaries and memorials showed plainly that the then current opinion of the profession remains largely unchanged. This belief did much to discredit the germ theory in the minds of the older members of the profession, and of the laity and lent aid and comfort to the enemies of scientific medicine, especially to organized and professed antagonists. Some medical men claimed that Virchow was not actively hostile toward the germ theory, but merely neutral. He had done his life's work as a mere morphologist, and would not venture into the subject of the dynamics of disease.

Professor Orth, the pupil and successor of Virchow, now puts forward the claim (*Berliner klinische Wochenschrift*, Oct. 20), based wholly upon the writings of Virchow, that the latter should never, even from the first, have been regarded as hostile or even neutral in his attitude toward bacteriology. In fact, he may even be regarded as an active supporter of the germ theory, at least thirty-five years ago; after which his support became intrinsically stronger with time. With all due thanks to Professor Orth for this exploitation of this thesis, it nevertheless seems strange that this claim was not made many years ago. There is no doubt that some influence is at work to neutralize the supposed passive opposition of Virchow toward the germ theory, and despite the convincing excerpts cited by Orth from Virchow's writings we cannot entirely overlook the fact that Virchow is also regarded as a consistent antagonist of Darwinism, and has often been cited by the clergy as a countercheck to the theory of evolution. The Lombroso school might readily explain

Virchow by their generalization that all great geniuses are opposed to new ideas. Thus Virchow, taking up the subject of morphology where others had left it, proceeded to develop it, while jealously hostile to anything actually new and revolutionary. Others, from a lower plane of view, have dwelt much on the fact that it is contrary to human nature for men to accept discoveries which they have blindly overlooked during years of opportunity.

The passages from Orth's article which appear to show beyond doubt that Virchow was always in sympathy with progress are in part convincing; but it is by the same process that followers of great leaders have always attempted to show that the latter have been cognizant of future "discoveries." It seems to us that the interpretation of these passages is often forced. By the same process of reasoning Paracelsus, Hahnemann, and others, to say nothing of classic writers, have anticipated that which was to be. Thus it is said that Virchow always recognized the "zymotic" element in the causation of disease, and especially of epidemics (he is even alleged to have devised the term "infectious diseases"). He made a distinction between virus and venom. The latter did its work while active, but the effect disappeared with the disappearance of the cause; "virus," on the other hand, represented a self-perpetuating or self-reproducing element—in other words, a living cause. Another passage appears to show that the latter was a plant, but that chemistry rather than botany was at the bottom of the pathogenesis. Orth hails this as a brilliant anticipation of modern teaching. Elsewhere Virchow has been made to speak of a contest between microorganisms and the body cells. It is not denied that Virchow indulged in sharp controversies with bacteriologists in regard to special claims advanced by the latter; but it is insinuated that these special pleas do not affect Virchow's position as a whole. The unprejudiced observer, we fear, can hardly rank Virchow as a constructive critic in progressive biology, for his position is too often essentially destructive. Upon the whole we believe that the profession would prefer to regard Virchow as a pure morphologist, rather than as a foreshadower of bacteriology. Virchow, like all others, must be judged by his crystallized utterances in textbooks, rather than by fugitive remarks made in society proceedings, perhaps erroneously recorded.

THE CONTAGIOUSNESS OF POLIOMYELITIS.

Until within a few years the disease commonly, though improperly, known as acute anterior poliomyelitis was considered to be a simple degenerative disease of the spinal cord. Some years ago the conception that it is an acute infectious disease began to take definite shape. To-day it is stated that poliomyelitis, or as Holt suggests that it be called "epidemic myeloencephalitis," is an acutely contagious disease, and by many boards of health it has been included in the list of reportable diseases. This contagious aspect of the disease is emphasized in a recent article in the September number of the *Archives of Pediatrics*, in which Holt compiles the statistics of all epidemics which have occurred since 1907 and calls attention not only to the frequency with which several cases have been observed in a single family, but also to several instances in which the disease appears to have been carried by a third party and others where children have contracted it by entering an infected house at the time harboring no acute case.

In an epidemic at York, Nebraska, referred to by Holt, "there were six families with two children attacked, these being the only children in the family in three of these; five families with three cases each, in every instance all the children of the family; three families with four cases each, these being all the children in one of the families; and one family in which every one of six children was attacked." In an epidemic in Tröstena, Sweden, a widely scattered settlement of 500 inhabitants, forty-nine cases of the disease occurred, forty-two of which could be traced directly to infection in the parish school. The first case of the disease in York appeared in a child nine days after the return of its mother and infant brother from an infected house in a distant town, the travelers themselves showing no sign of the disease. Next door to this child was a family of six children, all of whom came down with the disease in rapid succession. In a number of instances symptoms appeared just five days after a single exposure to an acute case or a few hours' residence in an infected house.

Such evidence strongly supports the theory of direct contagion of the disease, and considering the terrible results of an attack, often even more pitiful when not fatal, and in the light of the danger from contagion by the so-called abortive cases which, occurring in conjunction with paralytic cases, may be easily overlooked, but one equally dangerous, it would seem wise, during periods of epidemics at least, that all cases of the disease not only should be reported, but should also be rigidly quarantined.

Serum Anaphylaxis and Drug Anaphylaxis.

It has been predicted that in the near future study of the two sets of phenomena known as drug idiosyncrasy and serum anaphylaxis will throw much light upon the nature of both. Bruck has taken up the subject in a recent number of the *Berliner klinische Wochenschrift* (Oct. 17). The findings obtainable suggest various interpretations, so that time must elapse before they can be formulated to the satisfaction of all. Bruck chose antipyrin for experiment by reason of the common occurrence of antipyrin idiosyncrasy or supersensitiveness. One might urge in this connection that the word idiosyncrasy is better suited to the phenomena produced by a trivial dose, while supersensitiveness is a much broader term, denoting sensitiveness to ordinary medicinal doses such as cause no rash in the majority of patients. From this point of view one who is able to take subtoxic doses without reaction may be spoken of as subsensitive, which naturally suggests a relationship to immunity. Bruck reports a case of supersensitiveness to antipyrin in a patient with migraine. The latter was always promptly relieved, but aphthæ in the mouth

and later a dermatitis were present as toxic effects. The idiosyncrasy extended to all antipyrin derivatives. After this idiosyncrasy had been known to last for sixteen years Bruck used the patients' serum to inoculate mice and soon afterwards injected a solution of antipyrin subcutaneously. The animals died with convulsions, paralysis, dyspnea, etc., the controls remaining unaffected. The anaphylaxis was thus shown to be transmissible. Bruck has already shown that a similar transmissibility exists for mercury. As already stated, it is at present impossible to give a satisfactory detailed explanation of these phenomena. One point, however, may be brought in at this juncture. Ehrlich and all other workers in synthetics have shown abundantly that the most insignificant change in the molecule of a complex substance may produce a radical change in the action of a remedy.

News of the Week.

Health of the Canal Zone.—The Department of Sanitation of the Isthmian Canal Commission reports that during September, 1910, the total number of deaths from all causes among employees was 48, an annual average of 11.47 per thousand. For Septembers of previous years, the rate is given as follows:

1904.....	14.31	1906.....	57.34	1908.....	12.78
1905.....	32.00	1907.....	28.63	1909.....	12.76

The high rate in September, 1906, was due to an epidemic of pneumonia among the employees. The annual average per thousand of deaths in Panama, Colon, and the Canal Zone includes both employees and the civil population, and was 21.60 in September, 1910, against 19.01 in September, 1909; 24.91 in September, 1908; 32.93 in September, 1907, and 54.54 in September, 1906. Of the thirty-three deaths due to disease among the employees during the month, 4 were caused by malarial fever, 6 by pneumonia, 3 by pulmonary tuberculosis, and 2 by typhoid fever, leaving a balance of 18 deaths from all other diseases. No cases of yellow fever, smallpox, or plague were brought to or originated on the Isthmus during the month. The work of sanitation in Panama has proceeded satisfactorily, the cleaning of ditches and the removal or repair of defective house gutters receiving particular attention. The weather conditions during the month were favorable to the anti-malaria work; except in a few instances the control of fly propagation is well in hand, and there is a decrease in the number of rats being caught, although more traps are in use than formerly.

Infantile Paralysis.—Small epidemics of infantile paralysis have been reported recently from various parts of New York State. During the month of September ninety-seven cases of the disease were recorded with the State Department of Health, of which sixteen resulted fatally. Still more recently a few cases have occurred among the students at Cornell University and another small epidemic is reported from Logansport, Ind.

Plague in China.—Serious riots occurred in Shanghai on November 11, in connection with the sanitary work for the prevention of the spread of the plague, of which a number of cases have been reported. Reports had been spread among the natives that the health officers were poisoning their countrymen in the hospitals, taking out the eyes of babies by electricity, etc. Attacks upon the sanitary officers followed, and in the fighting which ensued several persons were badly injured.

Epidemics in Lisbon.—The United States cruiser *Des Moines*, while in port at Lisbon recently, was compelled to stop shore leave for its men owing to the prevalence of smallpox and bubonic plague in that city.

Cholera in Italy.—New cases of cholera have been reported daily in different parts of Italy, making it evident that while the port of Naples may be free of the disease, there is yet danger in the other infected districts.

Typhoid Fever Conveyed by Milk.—Forty-one cases of typhoid fever have been traced to the use of infected cream by residents of the village of Lime Ridge in Columbia County, Penn. It appears that a dairy farmer had been serving milk to his mother suffering from typhoid fever and bringing back the empty cans. In a short while typhoid fever developed in the immediate family of the dairyman. He in turn had been in the habit of exchanging milk with a neighbor, in whose family also the disease later developed. The second dairyman served milk and cream to an ice cream establishment in Lime Ridge patronized by almost the entire village. An epidemic soon followed and was controlled only when the supply of milk from the infected source was stopped.

City Death Rate.—For the week ending November 5 the death rate in New York was 13.31 per 1,000 of population, the total number of deaths being 1,226. For the corresponding week of 1909, the rate was 15.23 and the total number of deaths 1,333. Pulmonary tuberculosis caused 151 deaths, 11 more than last year, while pneumonia caused 153, or 47 less than the year previous. There were fewer deaths from all other diseases with the exception of diarrheal diseases, which caused 81, an increase of 13. Heart disease caused 137 deaths, against 158 for last year.

Public Health Museum.—The American Museum of Natural History, New York, has lately entered a new field for museum work in the form of a department of public health, "to develop scientific work along practical lines directly beneficial to the masses of people." Prof. C. E. A. Winslow, until recently assistant professor of sanitary biology at the Massachusetts Institute of Technology, has been appointed curator of the new department, which he proposes to develop along two lines—bacteriology and municipal sanitation. A bacteriological laboratory is now being equipped and in this the department will keep under cultivation a complete collection of bacteria. It will thus be in a position to supply the needs of schools and other institutions interested in such work. The public exhibits of the department will deal chiefly with phases of municipal sanitation. To illustrate these, temporary exhibits will be prepared, the first, for instance, dealing with water supply sanitation, the sources of the water supply and its collection for public use being shown by models, specimens, photographs, and charts. The chief features of each temporary exhibit will be preserved for a permanent public health exhibit such as several cities in Germany now possess.

The New York Child Welfare Committee held a meeting at the Colony Club on November 10, Mr. Homer Folks presiding, for the purpose of hearing reports from sub-committees and of arranging for

an exhibit to be held some time in January, dealing with every phase of child life in New York City.

Gaynor Fund for St. Mary's Hospital, Hoboken.—A movement, headed by a number of prominent men, is under way to raise a fund by voluntary contributions from citizens of New York, to be presented to the sisters of St. Mary's Hospital, Hoboken, as a testimonial of the gratitude of New York, for the care bestowed upon Mayor Gaynor while he was an inmate of the hospital. St. Mary's is supported almost entirely by voluntary contributions, and is at present much hampered by lack of funds. Such a gift will, therefore, be most welcome to the recipients, while at the same time the citizens of New York will be given the opportunity to share in the expense incurred by the Mayor as the result of an attack made upon him as an official of the city.

The Healthiest Town in New Jersey.—Dr. S. E. Armstrong of Rutherford, N. J., takes up the cudgels on behalf of his own town and disputes the claim of East Orange to be the healthiest municipality in the United States. As stated in the MEDICAL RECORD of November 5, the death rate in East Orange for 1909 is given by the Bureau of the Census as 9.5 per thousand. Dr. Armstrong, however, calls attention to the report of the New Jersey State Board of Health for 1909, in which East Orange is given a death rate of 10.15 per thousand, while that for Rutherford is but 8.77. New Jersey can evidently point with pride to the good health of its inhabitants.

Bequest to Hospital.—The will of the late Robert Steele of Philadelphia provides for a bequest of $5,000 to be paid on the death of the testator's widow to the Presbyterian Hospital of that city for the endowment of a free bed.

Instruction for Health Officers.—The New York State Department of Health announces a course of instruction for health officers, beginning on December 7 and lasting for three days. The course will consist of laboratory talks and demonstrations at the State Hygienic Laboratory in Albany on the general subject of water and sewage purification. Talks on the Chemistry and Biology of Water Filtration Methods; Pure Water and Methods of Disposal of Wastes for Isolated Houses; the Chemistry and Biology of Sewage Disposal Processes, and Methods of Sewage Disposal for Municipalities will be supplemented by inspections of the water filtration plants at Rensselaer and Albany, and of the sewage disposal systems at Ballston and Saratoga.

New Brooklyn Hospital.—The City of New York is the purchaser of a tract of land measuring 280 by 200 feet in East New York, Brooklyn, on which it is proposed to erect a public hospital. Plans are now in preparation, and it is probable that ground will be broken in the spring.

New Montefiore Home.—At a meeting of the Board of Trustees of the Montefiore Home for Chronic Invalids, New York, Mr. Jacob H. Schiff, president of the board, was able to announce that $850,000 had already been subscribed toward the new buildings for the institution, and that the work of construction would be begun early in the coming spring. A piece of land covering four blocks and equivalent to 162 city lots has been purchased in the upper part of the city along what is known as the Gunhill road, between Jerome avenue and 210th street, and on this it is proposed to erect buildings which will accommodate 600 patients, the entire cost being estimated at about $1,500,000. The old property has been sold for $525,000, the purchasers not to take possession until the new buildings are ready, probably about two years hence. Dr. S. Wachsmann, medical director of the Home, has recently visited a number of European cities, where he studied the arrangement and grouping of homes for the care of chronic invalids, and in drawing up the final plans the board will also have the advice of Dr. S. S. Goldwater, superintendent of Mount Sinai Hospital.

New Nurses' Home.—The Home for Nurses of the Jewish Hospital, Brooklyn, was dedicated on November 6, exercises being held in the new building on Prospect place, near Classon avenue. The Jewish Hospital has recently completed the fourth year of its existence. During its first year 1,544 patients were admitted to the hospital and 11,850 to the dispensary, while during the past year 4,127 were admitted to the hospital and about 30,000 were cared for in the dispensary.

St. Bartholomew's Clinic.—At a meeting of the Medical Board held on November 1 the following officers were elected for the coming year: *President*, Dr. John C. Lester; *Vice-President*, Dr. E. L. Leonard; *Secretary*, Dr. L. D. Alexander; *Executive Committee*, Drs. Alexander, J. M. Keyes, and G. W. Kunz.

Dr. Edmund L. Cocks has been appointed Consulting Dermatologist to Harlem Hospital, New York.

Civil Service Examinations.—The New York State Civil Service Commission will hold examinations on December 15, 1910, for the purpose of obtaining eligibles on the lists of physicians, both regular and homeopathic.

Removals.—Dr. Allan McLane Hamilton has removed to 950 Madison avenue, New York City. Dr. T. Wood Clarke has removed to 136 Park avenue, Utica, N. Y.

Dr. Horatio C. Wood, Jr., has been elected Professor of Materia Medica and Therapeutics in the Medico-Chirurgical College of Philadelphia.

Joint Meeting of Pathological Societies.—The members of the New York Pathological Society and of the Philadelphia Pathological Society held a successful joint meeting on November 9 at the New York Academy of Medicine. Preceding the meeting, the visitors were entertained at dinner at the Yale Club by members of the New York Society.

Harvey Society.—The next lecture of the Harvey Society will be given at the Academy of Medicine, New York, on Saturday evening, November 19 at 8:30. Professor Jacques Loeb of the Rockefeller Institute for Medical Research will be the lecturer, and his subject will be: "The Prevention of the Toxic Action of Various Agencies Through the Prevention of Oxidation in the Cell."

The American Academy of Medicine.—The fourth mid-year meeting will be held at the Lafayette Hotel, Buffalo, N. Y., on December 1 and 2, 1910, the subject for discussion being "The Sociologic Influence of Hospitals and Dispensaries." The first day's session will be devoted to a consideration of the economic influence of hospitals, and that of the second day to the educational influence of hospitals. A number of interesting papers are promised on each subject. The annual meeting of the

society will be held in Los Angeles June 24 and 26, 1911.

The American Public Health Association.—The 1911 meeting will be held in Havana, Cuba, December 4 to 9, at the Academy of Medicine, the use of which has been offered to the association. The changed situation in Cuba in reference to yellow fever is shown by the fact that, whereas a few years ago it would probably have formed the chief subject of discussion, the most prominent place on the program will be given at this meeting, on the request of local physicians, to tuberculosis. The question of the milk supply will also be considered.

New York and New England Association of Railway Surgeons.—The twentieth annual session of the New York and New England Association of Railway Surgeons was held at the Hotel Astor, New York City, on November 3 and 4, under the presidency of Dr. L. M. Bingham of Burlington, Vt., chief surgeon of the Rutland Railroad. Dr. John B. Deaver of Philadelphia delivered the address on Surgery. The following officers were elected for the ensuing year: *President,* Dr. F. A. Goodwin, Binghamton, N. Y.; *First Vice-President,* Dr. Walter Lathrop, Hazleton, Pa.; *Second Vice-President,* Dr. John W. Le Seur, Batavia, N. Y.; *Corresponding Secretary,* Dr. George Chaffee, Brooklyn, N. Y.; *Recording Secretary,* Dr. C. A. Pease, Burlington, Vt.; *Treasurer,* Dr. J. K. Stockwell, Oswego, N. Y.

American Association of Military Surgeons.—The annual convention of this society was held in Richmond, Va., from October 31 to November 4. Milwaukee was selected as the next place of meeting and officers were elected, as follows: *President,* Brigadier-General George H. Torney, Surgeon General, U. S. A.; *First Vice-President,* Surgeon Charles P. Wertenbaker, U. S. Public Health and Marine-Hospital Service, Norfolk; *Second Vice-President,* Surgeon W. C. Braisted, U. S. N.; *Third Vice-President,* Col. Charles Adams, National Guard, Illinois; *Secretary,* Major Charles Lynch, U. S. A.; *Treasurer,* Major Herbert A. Arnold, National Guard, Pennsylvania.

The American Association for the Study and Prevention of Infant Mortality held its annual convention in Baltimore last week. Officers were elected as follows: *President,* Dr. Charles Henderson of the University of Chicago; *President-Elect for* 1912, Dr. Cressy L. Wilbur, Chief Statistician of the Bureau of the Census; *Vice-Presidents,* Mr. Harold McCormick of Chicago and Dr. Henry L. Coit of Newark; *Secretary,* Dr. F. S. Churchill of Chicago; *Treasurer,* Mr. Austin McLanahan of Baltimore; *Executive Committee,* Professor Henderson, Dr. Churchill, Dr. J. H. Knox, Jr., of Baltimore, Dr. John S. Fulton of Baltimore, Dr. Mary Sherwood of Baltimore, Dr. Joseph S. Neff of Philadelphia, and Dr. Helen C. Putnam of Providence. Chicago was selected as the next place of meeting. The permanent headquarters will remain in Baltimore where they were established a year ago, Miss Gertrude B. Knipp being reappointed executive secretary.

Obituary Notes.—Dr. Thomas Coit Fanning, formerly of Tarrytown, N. Y., a graduate of the New York University Medical College in 1861, died at his home in Stamford, Conn., on November 4, aged 70 years.

Dr. John A. Leavy of St. Louis, Mo., a graduate of the Washington University Medical School in 1856, a surgeon in the Confederate Army during the Civil War, died suddenly at his home on October 24, aged 76 years.

Dr. Le Roy Lewis of South Bend, Ind., a graduate of the Jefferson Medical College, Philadelphia, in 1878, died at his home after a long illness on October 26, aged 55 years.

Dr. Charles B. Curran of Brooklyn, N. Y., a graduate of the Long Island College Hospital in 1893, died at his home of pneumonia on November 1, aged 37 years.

Dr. George Asbury Dewey of Brooklyn, N. Y., a graduate of the Medical Department of Western Reserve University, Cleveland, O., in 1849, died at his home on November 1, aged 82 years.

Dr. Charles A. Miles of Yonkers, N. Y., a graduate of the Jefferson Medical College, Philadelphia, in 1876, died at his home on November 9, aged 58 years.

Dr. J. Lacy Brayshaw of Friendship, Md., a graduate of the College of Physicians and Surgeons, Baltimore, in 1888, a member of the Maryland State and Anne Arundel County Medical Societies, died at the Sibley Hospital, Washington, after a short illness, on October 29, aged 55 years.

Dr. Ernest S. Albee of Oshkosh, Wis., a graduate of Rush Medical College, Chicago, in 1900, a member of the Wisconsin State and Winnebago County Medical Societies, and of the Oshkosh Medical Club, died at his home on November 1, of kidney disease, aged 34 years.

Dr. Samuel W. Edmunds of Alexander, Ill., a graduate of the Department of Medicine and Surgery, University of Michigan, in 1868, died at the Passavant Hospital, Jacksonville, Ill., of pneumonia, on November 1, aged 70 years.

Dr. John M. Allen of Liberty, Mo., a graduate of the Washington University Medical Department in 1854, a member of the American Medical Association, and of the Missouri State and Clay County Medical Societies, and Professor of Diseases of the Abdomen in the University Medical College of Kansas City, died October 31, aged 77 years.

Dr. Samuel H. Friend of Milwaukee, Wis., a graduate of the Department of Medicine of the University of Pennsylvania in 1888, a member of the American Medical Association, and of the Wisconsin State and Milwaukee County Medical Societies, died at his home after a long illness on October 30, aged 48 years.

Dr. James D. McGaughey of Wallingford, Conn., a graduate of the Jefferson Medical College, Philadelphia, in 1870, a member of the American Medical Association and of the Connecticut State and New Haven County Medical Societies, died at his home on October 31, aged 62 years.

Dr. Francis S. Mudd of Lafayette, La., a graduate of the Medical Department of Tulane University of Louisiana, died at his home on November 4, aged 82 years.

Dr. E. W. Stevens of Denver, Colo., a graduate of the Jefferson Medical College, Philadelphia, in 1884, a member of the American Medical Association, of the American Ophthalmological Society, and of the Colorado State and Denver County Medical Societies, of which last he was a former president, died at his home of disease of the kidneys, after a short illness, on October 30, aged 47 years.

Dr. J. H. Edwards of Ira, Tex., a graduate of the Medical Department of the University of Tennessee, and a member of the Texas State and Scurry County Medical Societies, died as the result of an accident, on October 25.

RESEARCH DEFENSE—ENTOMOLOGY—SLEEPING SICKNESS—BIOLOGICAL RELATIONS OF TRYPANOSOMES AND SPIROCHETES—THERAPEUTICS OF RADIUM—RATS AND PLAGUE—OBITUARY.

LONDON, October 28, 1910.

THE Research Defence Society has been working energetically of late, and this week the Earl of Cromer, who is president, went to Oxford to open a new branch and gave an address in the Town Hall, Prof. Osler occupying the chair. Lord Cromer, who is always listened to with attention, affirmed that the bacteriologist needed no defender in the eyes of thinking men; his praises are written in the hearts of thousands of homes where his discoveries have turned death from the door. In point of fact, it was not this society, but its opponents, who were on their defence and were obliged to resort to methods and arguments in the highest degree unscrupulous. Mr. Stephen Coleridge was never tired of saying England was the only country which had legalized torture of animals. If ever there was a clear case of suppression of truth and suggestion of what is false it was that. The real fact was, England was the only country which had passed a law to prevent animals being tortured; in all other countries they had no protection. His Lordship then quoted the statistics of the Punjaub. In a population of about 827,000 some 187,000 were inoculated before the outbreak and 640,000 were not. The deaths were only 314 among the former, but no less than 29,723 among the latter. In other words, it might be calculated that experimental science had saved about 8,000 human lives. Would any one be so bold, rather, he woud say, so inhuman, as to balance those lives against a few score or even a few hundred rats and guinea pigs? It was incredible that any one could doubt, but the course was not callousness, but ignorant and false sentiment. In fact, a distinguished American with the incisiveness of his race recently put the case in a nutshell to an antivivisectionist thus: "At how many rabbits or guinea pigs do you value your wife, husband, or child?" He was not aware whether any opponent was present who had refused when ill or when any of his family was ill to avail himself of knowledge acquired by bacteriologists. If such a strange phenomenon existed, he was prepared to do homage to his logical faculty, but, he must add, at the expense of regard for his sanity.

Entomology is taking a large place in medical research and threatens soon to be an addition to the burden of the curriculum. We have had for the last year or more an official Entomological Committee for Tropical Africa meeting four times a year at the Colonial office, with subcommittees at work during the intervening periods. In connection with this work a "Bulletin of Entomological Research" is being issued, which will record the investigations of the missions sent out to Africa to study the diseases prevailing there, and the insects which are the cause of some of them. I have from time to time reported to you the results of such missions before the Colonial office moved, as well as since. At present Mr. S. A. Neave is in Nyanaland and Mr. J. J. Simpson in Nigeria investigating sleeping sickness and the habits of the *Glossina palpalis* which is a most voracious insect with a special predilection for the blood of man, though in its absence feeding on lower animals. Dr. Rubert Boyce, who lately returned from Sierra Leone, so long regarded as the home of yellow fever, is convinced that that disease is a virulent form of malaria. So certain of this is he that in a recent address he said, "No malaria, no yellow fever." If that be so, the fly must be attacked as it has been in other districts and most in the larval stage.

At the opening meeting of the Pathological Section of the Royal Society of Medicine the president, Dr. Mott, discussed the biological relationship of trypanosome and spirochete infection as shown by the point of inoculation, the period of incubation, the local gland enlargement, followed by a general infection of the lymph stream first, and then of the blood associated with rashes due to migration of parasites, pyrexia, and constitutional disturbances. He said the effects of the two infections on the human nervous system present many points of similarity in symptoms and in histological change, besides which drugs which can avert nerve symptoms in one may, although rarely, avert them in the other. In trypanosomiasis (Dr. Mott would abolish the term sleeping sickness) all cases end in chronic inflammation of the central nervous system, progressing to a fatal issue; in spirochete infection only 5 to 10 per cent. produce neuroses. The trypanosomes always invade the subarachnoid space. The spirochetes do so only in 4 or 5 per cent. of cases, and then probably remain within the lymphatics and do not get free into the cerebrospinal fluid, as the trypanosomes do. Then mercury and other drugs have no effect, although they apparently do on the spirochetes in the lymphatics of the central nervous system. Then trypanosomes can easily be found in the blood, but not spirochetes, which seem only able to multiply in the lymph spaces and channels. Dr. Mott described the trypanosomes as extremely active and capable of penetrating the delicate capillary walls and so passing into the cerebrospinal fluid while the spirochetes moved slowly about in a screw-like fashion, which could seldom pass through the vessels. This, with the other points carefully enunciated by Dr. Mott, would seem to give us a clue to the explanation of trypanosome infection invariably leading to central neurosis, while the risk of spirochetes doing so is comparatively exceedingly slight. In both infections there is polyadenitis; in both there is lymphocytosis in the blood, and in one this is also in the cerebrospinal fluid.

Referring further to the British discovery of a new process for the production of radium, it seems likely that one of the first consequences must be a reduction in cost. This may perhaps lead to a more extensive exploitation of its therapeutic properties. Passing by its use in surgery, which has already received considerable attention, we may say that its medical qualities remain uncertain, although speculation has been rife as to whether it has not sometimes played the part of a concerted remedy in the presence of other substances. Thus it has been supposed that the good effects of some mineral waters may be due to radium, or its examinations and experiments have shown the presence of the unsuspected constituent. It is generally agreed that these waters are beneficial in a variety of arthritic troubles. Some springs have a reputation rather for catarrhal affections of the respiratory tract and some again for neuroses. In both these classes of springs experiments have proved there

are some which give off the emanations. This has led to the idea that the waters might be artificially charged but the evanescence of the emanations is an obstacle, and it has been suggested that this explains the fact so often asserted that some natural mineral waters bottled at the springs seem to lose their therapeutic value during transmission. Another suggestion for local joint troubles is a trial of cataplasms made of powdered pitchblende with water. It is even asserted that the material can be used more than once, for if on removal it is perfectly dried the radioactivity is again perceptible.

A determined attempt to exterminate rats is going on in a small district between the Rivers Stour and Orwell in consequence of circumstances connected with four deaths at Freston between September 16 and 29. Dr. Heath, of the East Suffolk Hospital, from bacteriological examination thought they were due to plague. The local governing board failed to confirm this, but subsequently rats and hares have been found dead in the locality and in three cases the plague microbe has been detected. The health committees concerned have conferred with Dr. Bulstrode, of the local governing board, and Prof. Simpson, of King's College, and detailed recommendations have been made as to systematic work at extermination of rats in stables, slaughterhouses, bakeries and graineries; for covering all receptacles of refuse and so on. In the meantime landowners, farmers, and others have been strewing poison and hundreds of rats, rabbits, hares, and even cats have been destroyed. No new cases of human illness traceable to such a cause have been reported.

The death has occurred of Dr. Thomas Wright, consulting surgeon of the General Hospital and of the Children's Hospital at Nottingham. He was 87 years of age, one of the oldest medical officers of the Volunteers, from which he retired as lieutenant-colonel. He took M.D. Ed. in 1844.

Dr. William Hall, general surgeon of Royal Lancaster Infirmary, died suddenly on Tuesday. He qualified in 1871-2 and took F.R.C.S. Ed. in 1886.

News has been received of the death of Dr. Edward Eldridge Blomfield, lecturer on medicine, University of Otago, N. Z. He went there in 1900. Was M.D. Lond. 1895, having taken various honors at the several examinations, as well as at the London Hospital, where he fulfilled his curriculum.

Surgeon Col. Francis H. Welch died on October 25, aged 71. Educated at the London Hospital, he qualified in 1860 and entered the army the next year. He took the F.R.C.S. in 1871 and was appointed assistant to the professor of pathology at Netley, which office he held until 1876. He served in the Hazara expedition in 1888 and was mentioned in despatches. He retired in 1895.

Lieut.-Col. R. Anderson, late of the R. A. M. C., died on October 24. He took M.R.C.S. in 1867 and entered the army the following year. He was in the Egyptian expedition in 1882 and was awarded the medal and bronze star. He retired in 1893 and has resided since at Bury St. Edmunds, where he was Mayor in 1907. He also served on the Suffolk County Council.

The death is also reported of Dr. Edward Adams, surgeon to Buckhurst Hill Medical and Surgical Home. He was M.B. and B.Sc. Lond. 1884-5, was 50 years old, and died after a long illness.

Richard Thompson Caesar, aged 72, ex-president of Salisbury Medical Society, died recently. He was a retired surgeon-colonel of Volunteers and qualified in 1859-62.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

CHOLERA IN GERMANY.—BREAST-FED CHILDREN.—THE EMPLOYMENT OF SCHOOL-CHILDREN.

BERLIN, September 30, 1910.

CHOLERA in Germany! About this there can be no doubt. A few cases have been reported in Spandau, at the very gates of Berlin. In this city there are being quarantined a number of individuals with suspicious symptoms. In the eastern provinces bordering on Russia several cases have been reported. There can be no doubt that with the energetic measures taken by the government there can be no fear of an epidemic arising; but is there no remedy for this annual scare. The best answer to this question is that which has been furnished by the Vienna bacteriologist, R. Kraus, in the *New Free Press,* August 25, 1910: "It is clear that the continual danger is to be sought in the low stage of civilization that Russia occupies; there the flame of cholera is never totally extinguished, and thence it spreads into every other country in Europe." Kraus makes an appeal for an international warfare against the Russian cholera. Thanks to modern progress in hygienic science, we are able to make an effective stand against this disease. If we could only apply our prophylactic measures in the neighboring provinces of Russia by isolating the separate cases that arise there would be no danger of a serious outbreak. There are two means of stamping out this disease from its haunts in Russia. The first would be the formation of an international union to persuade Russia to adopt drastic measures against this pest within her own borders. This would be a task for diplomats of all countries, a task greater than all others. The second plan would be the stationing of permanent international sanitary boards in the south of Russia, somewhat like those organized in Alexandria, Constantinople, Arabia, and Persia. The task of awakening the conscience of Russia to these needs is not a small one, but it is urgent.

The scientific attitude and the industry of the practical physicians are indicated by the many articles published by the school physicians of Berlin. The position of school physician is given only to practicing physicians who in most instances formerly have not been in the habit of conducting scientific work, and besides looking after a large general practice are still able to contribute valuable articles on social medicine. Thus Dr. Schäfer published "Statistical Investigations Into the Conditions Relating to the Breast-feeding of the Pupils of the National Schools of Berlin," in the *Medical Reform,* No. 23. As breast-fed children, only those were considered who had been nursed at least six months. Moreover the children were not classified in the manner customary with others who have written upon this theme, namely, according to their good or bad physical condition, but the numbers of breast- or bottle-fed children were calculated in relation to the number of necessary examinations to which these were later brought. The results were as follows: 25 per cent. had been nursed one year; 15 per cent., 9 months; 15 per cent., 6 months; and 10 per cent., 15 months. The children who had been nursed up to three years made no particularly good impression, so far as their constitution was concerned. The author conceives prolonged nursing as a sign of the dislike of the mother to endure the difficulties associated with weaning.

Among 2,796 children, 884 or 33 per cent. had been breast-fed, and 1,912 or 67 per cent. had been bottle-fed. In comparing the bottle-fed with the breast-fed as regards the number whose progress was retarded chiefly on account of beginning school at a late age, it was found that the former exceeded the latter to the extent of 56 per cent. On account of anemia, scrofula, and general weakness, 24 breast-fed and 42 bottle-fed children were kept back; on account of rickets and deformities of the spine, 3 breast-fed children and 30 bottle-fed children were kept back.

Another school physician, L. Hahn, read before the Berlin Association of School Physicians a paper entitled "The Child Protective Law and Industrial Child Labor in Berlin." For several years he had investigated the employments of school-children. In schools of about 800 pupils, nearly 60 were engaged in running errands, such as the delivery of milk, the products of bakeries, and messages, and in other pursuits. About half of the children worked for strangers; the remainder worked for their parents. The former received one to six marks weekly. In three schools were found 146 children who were thus employed. On this basis it was calculated that there were 7,300 boys and 2,175 girls in Berlin who were employed after school hours, a total of 9,500 children. If we accept the statement of the author that 15 per cent. of the employed children are either sick or in poor physical condition, we can realize that 1,400 children are subject to cardiac and other severe disturbances. These figures should certainly awaken the attention of the authorities. The author recommends that the employment of every school-child be investigated as to its compatibility with the health of the child. It is the duty of every school-physician to seriously consider the significance of this investigation.

Stomach Diseases from a Medical Standpoint. G. A. McEvoy.

Etiology of Gallstones.—W. I. Clark states that since hypotheses and the experimental evidence agree upon the stagnation of bile as the most important predisposing factor to gallstone formation, the first step in the sequence will be a stagnation of bile caused by one of a number of possible causes. Thus, the patient would have suffered from gastroptosis, pregnancy, or some condition mechanically hindering the free flow of bile; or, on the other hand, be a person of sedentary habit and chronic indigestion. Further careful anatomical investigation should show some hitherto undemonstrated etiological factors. In a large number of cases no preceding condition can be found except typhoid fever or chronic indigestion. The contraction of the gall-bladder is governed by a reflex established in the duodenum by the acid chyme, so that a chronic catarrh of the stomach and duodenum might produce a reflex congestion of the mucous membrane of the gall-bladder. This congestion would afford a fertile field for bacterial infection through the bile. An examination of the gall-bladder in the pregallstone stage would show a somewhat enlarged bladder with a congested mucous membrane; the bile is sterile and shows an increased percentage of cholesterin and calcium. Such a gall-bladder would give no symptoms. The next stage is that of beginning stone formation. Bacteria absorbed from the intestine are excreted in the bile and lodge in the congested mucous membrane of the gall-bladder. Here they establish a catarrh with an enormous increase in the mucous glands; with this there is an increase of mucus tending to cause a precipitation of calcium and a change of reaction of the bile, and increased necrosis and desquamation of epithelial cells, resulting in cholesterin formation. The next stage is the stage of development of gallstones. All the classical conditions for cholelithiasis are now present. The enlarged and relaxed gall-bladder is filled with stagnant bile supersaturated with cholesterin and calcium. The stones are soft and readily take impressions from their neighbors and from the contractions of the gall-bladder. A gradual increase in size and number of the stones takes place during this stage and their presence accentuates the catarrhal condition of the mucous membrane. An increase in virulence of the bacteria is more frequently the cause of pain than the passage of a stone into the cystic duct. Most recent authors believe the pain of cholecystic gallstones is due to acute infection rather than mechanical passage.

A Fallacy in Psychotherapy.—J. E. Donley states that in the sphere of the mental life it has long since been realized that spiritual conflicts are fraught with most disagreeable and disabling consequences. If there are many who escape the ill-effects of mental analysis, there are also many who suffer seriously from the wounds this tendency inflicts. Among the latter are nervous people, the evil genius of whose existence is morbid subjectivism. "Fighting it out" is but a continuous, systematic, deliberate perpetuation of this same subjectivism. Through a number of valuable researches one has come into possession of a vastly more comprehensive knowledge of the factors at work in the production and maintenance of different states of psychological instability. The researches of Jung, of Zurich, into the problems of association have opened up an entirely new and fertile field to students of mental life. Experimenting with a considerable number of persons Jung discovered that there are certain associations of ideas which liberate a marked emotional wave, and certain others which produce little or none. By means of psychological experiments for measuring the reaction time for association of ideas it is possible to determine that there are certain ideas for which the reaction time is lengthened. In these cases the cause of the prolonged reaction time, according to Jung and his followers, is that the association of ideas aroused by the stimulus word was of such personal and significant interest to that individual as to give rise to an accompanying emotional state which interfered with the rapidity of association, which blocked it, as it were, and caused a lengthening of the reaction time. By means of another experiment it may be determined that there are changes in the electrical resistance of the body during the formation of an association carrying with it a distinct emotional load. It may be demonstrated that a mere word which sets off an emotion produces a perfectly measurable electrical change. One may thus perceive the profound influence of certain associations of ideas upon one's emotional stability. Against the militant attitude of "fighting it out" another objection may be raised. Utilizing the method originated by Pierre Janet and further elaborated by Breuer and Frend, one has learned that the effort to crowd out of mind, to suppress, the memory of a disagreeable experience or set of experiences, in a word, to "forget it," is oftentimes the source of troublesome nervous disorders. This is most strikingly illustrated in the case of personal religious crises in which the fierce emotional struggle is frequently a source of discontent and unhappiness. Only an attitude of surrender

will terminate the latter. This same attitude may be attained through an appeal to religion, as well as to a common sense philosophy of life.

Spontaneous Dislocation of the Hip.—C. G. Cumston states that it is striking how frequently the hip joint is the seat of spontaneous dislocation, the most important causal factors of which are typhoid fever and acute articular rheumatism. Then, in order of frequency, come scarlet fever, influenza, smallpox, gonorrhea, erysipelas, and puerperal fever. The dislocation usually takes place during convalescence, and is particularly apparent in typhoid fever, while in acute articular rheumatism and scarlet fever the complication is prone to occur during the progress of the disease. Three factors must be combined in order to produce a spontaneous dislocation, namely, (1) a bad position of the limb, particularly favoring the functions of a group of muscles; (2) atrophy and paralysis of the antagonist; and (3) relaxation of the capsule and ligaments. This theory, however, is not satisfactory because there usually must also be some external cause in order to produce a dislocation. This external cause may be found in trauma even if ever so slight. One may briefly summarize the most important pathologic changes occurring in spontaneous dislocation of the hip as follows: (1) Comparatively slight changes in the joint, especially over the femoral head; slight cartilaginous outgrowths in the glenoid cavity; (2) connective tissue overgrowth in the glenoid cavity; (3) sloping or flattening of the roof of the acetabulum; (4) muscular atrophy with contraction of the antagonists. The symptoms are quite the same as in the traumatic type. Regarding the treatment of the dislocation, the principal aims to be obtained are, first, to reduce the dislocation if possible, and, secondly, if this is an impossibility, to transform the bad position of the limb into a functionally useful one. Two methods are at one's disposal, namely, the bloodless and the operative. The three operative procedures available are operative reduction, resection, and subtrochanteric osteotomy.

The Technique of Arthrotomy.—C. F. Painter and A. P. Cornwall continue their article upon this subject.

Stomach Diseases from a Medical Standpoint.—G. A. McEvoy concludes that if special attention be paid to the proper use of the tube as a diagnostic measure, and if the diseases of the stomach be treated according to the mechanical changes produced pathologically, better results will be obtained medically and fewer cases be referred to the surgeons.

Observations on 606.—J. A. Fordyce presents a history of this remedy, stating that already from 12,000 to 15,000 patients have been treated by it and that the drug has now been accorded a firm foothold in the therapy of syphilis.

Vital Statistics.—W. H. Guilfoy considers the question of mortality and mortality rates. The country that first entered the field of mortality statistics was Sweden, in 1749. It is not surprising that the lowest rate of mortality in Europe is to be found in the Scandinavian peninsula. Improved vital statistics is the demand of the hour, and in so far as further progress is made in this direction, then so far will corresponding advance be made in preventive medicine. It has been repeatedly shown that given two cities with varying age groupings of the populations, but with exactly the same death rates at these age groups, one city will possess a much lower general death rate than the other, due not to healthier environment but to the more favorable distribution of ages of the inhabitants; sex distribution modifies the death rate, the presence of a larger proportion of females than males in a population always tending to lower the rate. As affecting the death rate density of population is now viewed as of secondary importance, as compared with the immediate hygienic surroundings, the habits, and intelligence of the dwellers. The infant mortality is a good index of these latter influences; in New York, where the number of persons in one block reaches the astounding mark of 2,471 to each acre, the number of children dying out of every 1,000 births was one-half the number dying in blocks with a density less than one-half; it must be admitted, though, that all blocks with a density of 1,000 to the acre showed an increase in the infant mortality compared with that of the entire city. The following general factors affect the rate: Size of city, density of population, latitude, longitude, elevation, rate of annual increase, proportion of males, foreign born, of foreign parentage, of colored, or illiterates, of male wage earners, of ages, the mean annual maximum and minimum temperatures, and mean annual relative humidity; so that the general death rate is when analyzed found to be based upon a very complex set of props, and the influence of the most important must be measured before acceptance of it as an index of mortality. In reviewing the results obtained in New York since the organization of the Board of Health, more than forty years ago, it is noted that the crude rate has decreased from 26.61 to 16.21, almost 40 per cent.; the decrease percentage at age groups representing infancy, childhood, youth, maturity, decline, and old age was as follows: Infancy, 45; childhood, 42; youth, 32; maturity, 25; decline, 3; old age, 6. The death rate among females as compared with males is lower in each decennium and at each age group; by far the greatest saving in human life has taken place before the age of forty-five, and above this latter the saving is comparatively very small. The rungs at the bottom of the ladder of life are being carefully looked after; those at the middle of the ladder have been neglected; the physical welfare of the man has been lost sight of in the multitude of attempts at prolongation and betterment of the physical properties of the child; it is time that the vital statisticians should by investigations show that the mortality from the diseases affecting middle age is increasing, in order that man may be educated into following the ordinary rules of morality, sobriety, and moderation in all things, even in work. The diseases of the kidney, heart, arteries, brain, and digestive organs are growing apace.

Tuberculosis of Bones and Joints.—E. M. Brown states that the improvement in treatment along surgical lines has not been as great as one would wish. The study of the pathology of bone and joint tuberculosis has been neglected. There are three divisions to the treatment: first, general or constitutional; second, specific or serum treatment; and third, local treatment, which is subdivided into injection, mechanical, and operative. The general treatment includes fresh air, nourishing diet, good hygienic conditions, rest, exercise, massage, and cod liver oil. In the specific treatment tuberculin properly administered is of definite value. In the injection treatment the following substances have been used: iodoform emulsion, Calot's iodoformized oil mixture, sterile petrolatum, the Mosetig-Moorhof iodoform plug, bismuth paste, glycerogelatin formalin bone plug, and carbolic acid alcohol. In the superficial bones the *x*-rays have proved helpful. Bier's treatment of passive hyperemia is a valuable therapeutic measure in these cases. The rest secured by mechanical treat-

ment is obtained by fixation, relief from weight bearing, and by traction to prevent the pressure trauma of reflex muscular spasm. The advantages of operative treatment are: disease can at once be thoroughly eradicated, or so nearly so that the patient easily overcomes the disease; dissemination of the disease is prevented; the treatment is shortened; the general condition of the patient rapidly improves; the length of the limb and function of the joints are preserved to the best possible degree.

Diagnosis and Treatment of Tuberculous Joints.—P. P. Swett discusses four elements in the diagnosis, namely, the history of the case, physical examination of the part, radiographical examination, and tuberculin test; also the indications for the conservative and radical treatment. In a general way it is said that, contrary to the popular idea, joint tuberculosis in adults—considering fresh invasions and not merely the lighting up of old processes—is fully as amenable to conservative treatment as it is in children. The primary adult cases outside of this class are apt to be fulminating cases. Goldthwait gives the following reasons for the practice of radical surgery in adults: a. Impatience of conservatism, or inability to give up time to conservatism. b. Failure of conservative methods either to control or check the local advance of disease. c. Danger of general infection. d. Preservation of function in joint. e. Intolerance of apparatus.

Narcotic Drug Addiction.—G. E. Pettey states that in the treatment of a series of 200 cases the conclusion was reached that the retained excrementitious matter was the cause of all the dangerous and most of the painful symptoms incident to the withdrawal of an opiate, in fact, that, when the system was freed from toxic matter and the portal system disengorged, morphine or other opiate could be at once withdrawn without shock, collapse, heart failure, diarrhea, or other dangerous symptoms, and that the suffering incident to such withdrawal would subside in a few days' time without further treatment of any kind. It was also found that this suffering, severe as it would otherwise be, could be obviated and these days passed in comfort by the discreet administration of any member of the belladonna group of remedies. All desire for the opiate as well as all necessity for its use were removed by this course of treatment. The patient must be protected from severe suffering, nerve strain, and damaging mental impressions during the treatment, in fact, no cure can be expected from any plan of treatment which involves severe or protracted suffering such as do the reduction methods heretofore so much in vogue; that no drug patient can be considered cured until he has been made mentally and physically independent of all drugs, taught to rely on his own resources, and fully convinced of his ability to do so.

Inebriates.—C. C. Wholey discusses two types of cases. The first of these is one which in a city environment is considered practically hopeless for permanent cure. He is simply an adult child for whom the constant guardianship of an institution is the only remedy. The solution of the problem for such creatures is that the State shall care for them as it cares for its helpless and insane. They are true degenerates and will never gain sufficient stamina to resist temptation if circumstances place them in an unfortunate environment; after any course of treatment the same tendency to dissipate and the same perverse traits of character will remain. In custodial colonies such individuals can often be made self supporting, thus relieving society of the financial and demoralizing burden they now constitute. Every State must sooner or later provide for this class of derelict. The second type is one in which the habit is merely a symptom of some underlying neurosis or phobia. One may find in a large percentage of drug habitués some physical or mental cause, which, if one but take the pains to discover, often furnishes the clue for bringing about a cure of the addiction. For this class of patients treatment in a sanatorium, covering varying lengths of time, offers the surest means of successful and permanent cure.

A Theory of Senescence.—I. L. Nascher states that senescence is not due to any one cause. There is undoubtedly a determining factor which is the subject of the various theories that have been advanced. Upon the theory of tissue cell evolution life must cease when the cells have reached a stage in their evolutionary progress when the organs which they form are so changed that they cannot carry on the functions of life. It makes no provision for disease as a causative or even an essential factor in the production of senility, for disease is abnormal; it is an interference with the molecular condition or some property of the cell. It rejects arteriosclerosis as a causative or essential factor, but it includes it among the contributing factors of senility. Some of the contributing causes hasten senile changes by interfering with vital functions.

Spiritualism and Possession.—T. A. Williams believes that it is unfortunate that medical men of America are not better informed on psychopathology. To this is attributed the extensive vogue of spiritualism, clairvoyance, and the various cults of mental healing.

Cancer Prophylaxis.—C. H. Mayo says that one must consider the irritation of groups of epithelial cells as the primary origin of cancer, and that it is evident that there exists a precancerous condition. The unproved type, that of prenatal displacement, one is unable to recognize. The postnatal type one recognizes at least in tumors of a temporary benign character in their more regular and uniform arrangement of structure and cells, such as skin warts, vesical papillomata, cell inclusions in scars and the results of long-continued irritations to tissues. These growths resemble the embryologic development of cells merely in the power of cell multiplication and in the continuance of type in the metastasis and transplantation of the growth. Bashford shows that, while no race is exempt from cancer, the predilection for the disease in certain countries is more from local irritation than from climate, soil, and diet. Why it is not more common following chronic irritation it is impossible to say. It is not necessary to suppose a parasitic origin of the disease to account for its occurrence. In classifying the causes which may render precancerous conditions active one must apparently include nerve fatigue. Cancer of the stomach, bladder, and large bowel undoubtedly result from chronic local irritation, and the question arises whether the supposed repeated medical healing of gastric ulcers relieves the tendency to cancer, a large percentage of which develops on ulcers. The modern surgical tendency is to excise ulcers in their precancerous condition, and this should be the rule also with bladder papillomas. He also recommends it in case of hyperplasia of the prostate, even before it has caused distress, on account of the cancerous tendency of the organ. A rapidly growing, hard goiter should be looked on as a menace and early operation advised. Patients with

thyroid tumors indicate that an adenoma may cause carcinoma in about one in twenty-five or thirty cases. The irritative effects of tumors of the uterus are also noticed, and, while operation should not be advised in all cases, they should be removed if they cause symptoms, by myomectomy in the young and hysterectomy in the older individual as methods of choice. Tumors of the breast should be watched also with great care, and physicians should not assume the responsibility of delay, but inform the patients of the risk they run. He urges the early performance of the radical operation in early cancer of the breast. As to methods of cure one must admit a wide difference in malignancy, but there is also a wide difference in the resistance of the cases. Serum treatment seems to offer some promise. Patients should be informed in the precancerous stage of their disorder and realize that the danger is not in surgery, but in delayed surgery. It is this last which has caused it to fall into any discredit it has with patients at the present time.

Etiology of Skin Cancer.—L. Loeb states that the etiologic factors of skin cancer are external and internal. The external factors of importance are: 1. Light rays, especially the short-wave ones, which are active in the cancer of seamen and in that of old people which are found mainly on parts exposed to light. The *x*-rays are responsible for the cancer of *x*-ray operators. 2. Certain chemical factors are undoubtedly the cause of cancer, such as that of chimney-sweeps and paraffin and coal-tar workers. Arsenic, taken over long periods of time, influences the skin. 3. Certain mechanical irritations, such as heat, friction, etc., are also factors. 4. There may also be mentioned those conditions or organisms that cause lupus, psoriasis, and certain scars and ulcers. One has less definite knowledge of the internal conditions. Cancer arising from a congenital pigmented mole indicates that a certain localized and congenital hereditary condition is to be reckoned with, and there is undoubtedly a susceptibility to the ultraviolet rays of light in some persons. The author takes up the embryonic theory, but does not consider it sustained by facts. So far as old age is concerned, he also discredits it as a direct factor, as far as the epidermis is concerned. Instead of explaining various skin lesions as due to premature senescence, one should take the view that the senile changes are due to long-continued injurious external influences. While at the present time one should keep in mind the possibility of an etiologic significance of microorganisms, their connection with cancer seems to be hardly probable. The effects of irritants among the external causes are suggested as corresponding with the chemical activity of internal organs as a factor in cancer growth, by stimulating the overlying epidermis.

Cutaneous Carcinoma.—W. A. Pusey states that the only internal remedy which he thinks entitled to the slightest consideration is arsenic, which has a definite effect on the nutrition of the skin when given in large doses, and has cured some cases of sarcoma, while some careful observers think it is of benefit also in carcinoma. The most popular method is excision, which is the crudest method of treatment, since it takes no account of the ability of the tissues to assist in the defense against cancer. A clean excision must remove every cell of carcinoma to be successful, and, if it fails in this, the disease remains. Of other methods the author excludes from consideration all measures not vigorously destructive. Such are superficial caustics, substances like pyoktanin, which provoke epidermization and healing and which are especially dangerous in inexperienced hands, electricity, simple curettage, and electrolysis, which is occasionally used for minute epitheliomas, and refrigeration by liquid air, which is not sufficiently destructive and should be used with caution, if at all, and only in carefully selected cases. There remain the strong chemical caustics, arsenous acid, zinc chlorid, caustic potash, and acid nitrate of mercury. The successful treatment of epitheliomas with caustics requires acquaintance with the methods before undertaking their use, and knowledge and judgment are needed. No one method or technique is applicable to all cases. No one not blind to facts can deny that carcinomous tissue can be destroyed by the *x*-ray, and it has theoretical advantages.

Surgical Treatment of Skin Cancer.—J. C. Bloodgood states that the extent of the operation varies with the type of growth. In general it may be said that for sarcoma a local operation is sufficient, while in carcinoma of the squamous type the local operation should, in most cases, be combined with dissection of the neighboring lymphatic glands and surrounding tissues. His article is based on the study of sixty-five cases of malignant pigmented moles, forty-five cases of sarcoma of the derma, and 812 cases of epithelial tumors of the skin and mucosa. A study of the first class, of the congenital pigmented moles, illustrates the importance of the removal of certain forms of benign congenital moles which have a tendency later to become malignant. He gives his opinion that such moles should always be removed, especially when liable to trauma, and he urges complete excision with the knife in preference to any other method. In sarcoma of the derma there is generally a history of congenital nevus, of acquired or congenital fibroma, or the tumor has originated in scar tissue. In case of a nevus, the type is that of an angiosarcoma, and with few exceptions the malignant connective tissue tumor arising from a scar or fibroma is the fibro-spindle cell type. Several interesting cases of sarcoma from nevus and scar tissue are reported, and he specially speaks of the relation of scar tissue to different pathologic processes, especially keloid, which it is important to differentiate from fibro-spindle-celled sarcoma. If there is any doubt he should advise its treatment as sarcoma, though the local operation need not usually be very extensive in these borderline cases. There is also difficulty in the differentiation of fibroma and sarcoma of the skin. Other forms of skin trouble noticed are fibromyxoma, connective tissue cysts and lymphangioma, all rare of dermal origin. The prognosis and treatment of epithelioma according to site is taken up, and the public should be educated as to the importance of immediate consultation as to any ulcer, induration, wart, or scab on the mucocutaneous border of the lower lip. Cases of cancer of the tongue are too rarely submitted to the surgeon sufficiently early, and the operation has usually been too extensive in some respects and not sufficiently so in others.

Non-Epithelial Tumors.—F. B. Mallory concludes that it is advisable to discard certain loose and indefinite terms frequently used in connection with tumors and to strive for definite diagnoses and exact terms.

Malignant Skin Growths.—J. A. Fordyce states that the study of cutaneous malignant growths indicates a multiple etiology. Epithelioma developing from *x*-ray and sunlight or other radiant agency forms a strong argument against the parasitic nature of the disease, and the occurrence of epithelioma in xeroderma pigmentosum and like conditions of the skin coming on in old age or middle life, also points the same way. Further, he states that the action of chemical substances on epithelioma, such as arsenic, tar, tobacco, etc., shows that a variety of agents have the power to stimulate epithelial mitoses which may pass into malignancy. Cancers which develop on scar tissue or antecedent skin disease, like lupus, syphilis, etc., suggest that we are dealing with misplaced cells in some cases and in others with degenerative processes impairing the functional activity of the cells, followed as a consequence by vegetative activity.

Indicanuria.—G. Baar, on the basis of ten thousand examinations for indican, states that trauma to the intestinal wall is sufficient to produce indican, if sufficiently pro-

longed and severe, whether it occurs through mechanical injury in operation, adhesions or coprostasis. Enteroptosis may produce this latter condition and thus produce exaggerated intestinal putrefaction with its consequences. The constant finding of indican in constipation complicated with cardiac insufficiency is notable. Indicanuria exists in extreme hepatic insufficiency, and with gastric hyperacidity, especially with gastric and duodenal ulcers. In several cases of ozena and dental caries indicanuria was conspicuous, though there were no other signs of pathologic conditions. The insufficiency of pancreatic juice with its consecutive increase of intestinal putrefaction was shown in two cases of carcinoma of the pancreas with ever-present excessive indican. Bile insufficiency as a cause of indicanuria was not especially proven by his studies. About fifty cases of icterus with complete occlusion of the common duct showed indicanuria in only ten cases. In three of these there was drainage through a cholecystotomy with absolutely acholic stools. As regards treatment, he mentions three cases with excessive indican, one of pernicious anemia and the other of depressive neurasthenia, in which the indican disappeared and the condition markedly improved with the use of 1 per cent. ichthyol irrigations carried high up into the colon.

Common Germicides.—W. E. Post and H. K. Nicoll performed a series of investigations which showed the following results. 1. The reliability of the prompt action of a few simple germicides, such as tincture of green soap, alcohol in solutions above 50 per cent., silver nitrate solutions as dilute as 1 to 1,000, the iodin solutions, either as the tincture or in aqueous solutions with potassium iodid, phenol in 5 per cent. solution. 2. The unreliability of many agents prevalently supposed to be effective germicides. 3. The slow action of solutions of mercuric chlorid, although when given hours to act it is effective in high dilution. 4. The economic importance in the choice of germicides. This is of special interest to the managers of hospitals, since there is a great difference in expense between furnishing the much-advertised, high-priced (yet less effective) articles in concentrated solutions, and the simple, cheaper (yet more effective) articles in higher dilutions. In one hospital alone, where advantage has been taken of this difference, the saving has been several hundred dollars a year, and efficiency has been increased at the same time.

Hydrotherapy.—T. McCrae discusses this method of treatment under three heads: Internal, local, and general hydrotherapy. One of the most marked examples of its benefit is seen in the acute infections, in which the greatest danger lies in toxemia. In some of the lesser infections, such as tonsillitis, some forms of chronic arthritis apparently of toxic origin, and in some nervous diseases, the effects of the internal administration of water are marked. The absurdity of giving diuretic drugs without also giving water is admitted. One should consider the condition of the circulation and the kidneys, but, in general, these are more liable to be injured by toxins than by hydrotherapy. In typhoid fever, for example, one should try to have the patients pass at least 3,000 c.c., or, better, 5,000 c.c. of urine every day. In pneumonia one could hardly reach such amounts; probably 2,000 c.c. would be as much as could be passed. In septicemia again one may hope to obtain the larger amounts. In certain diseases, like gout, arteriosclerosis, or chronic arthritis, one advises the free ingestion of water as a routine measure, having regard always to the state of the circulation. Metabolism is probably helped and the excretion of toxins aided. The influence on the digestive tract should be kept in mind, however, as too much water might be injurious to an atonic stomach. In local hydrotherapy the circulatory and nervous systems are especially involved and it is sometimes difficult to say which plays the more important part. There are several factors at work. One of the most important is the influence on the blood-flow; another is the effect on osmosis, which is markedly altered in inflamed tissues. In some applications there is an important effect on deeper structures. The use of cold compresses to the thorax in bronchitis is mentioned. The effect on local nervous influences is shown by the relief of pain, and it is possible that the sympathetic system is also involved. General hydrotherapy is mainly employed by the use of baths, which are of value in both chronic and acute infections as well as in various nervous disorders. As in the local use of water, both the circulatory and the nervous systems are affected. The use of baths in fevers, and as relief for insomnia, is mentioned as well-recognized and illustrating both these uses. Friction as an adjunct to the bath is also mentioned as stimulating the circulation of the vasomotor system.

Paracentesis of the Drum Head.—H. Fuedenwald describes a modification of the schematic ear model of Bacon, by means of which a paraffin paper representation of the drum membrane enables the student to practice the operation many times.

Treatment of Tetanus.—A. J. Caffrey describes a case of tetanus successfully treated with large doses of tetanus antitoxin, a total of 45,000 units having been used.

Muffled Room in Treatment of Acute Insanity.—S. Brown states that the question of satisfactory muffling depends on the treatment of the doors, windows, floors, ceilings and partitions, and is a problem for the practical architect and engineer to solve. So far it has not been satisfactorily worked out.

The Chief Aim of Medicine.—S. Delépine believes that the object of preventive medicine is to keep the living organism in that state characterized by a certain duration of life, absence of pain, capacity for work, and power of reproduction, which is commonly known as health. One must look upon health as the normal reaction of the normal organism to its average environment and circumstances. The day may come when man will be in a position so to control the conditions of life as to raise the standard of health above the present level. During the past 48 years in England and Wales, as the result of preventive measures, the death rate has fallen from 21 to 14. Further progress is to be expected. An analysis of the chief causes of death in 1908 shows that more than one-half of the deaths were due to preventable causes.

Hematemesis.—Sir Dyce Duckworth discusses some of the causes of gastric hemorrhage and the appropriate treatment for patients suffering from it. The most common cause is gastric ulceration. Modern surgery has increased one's knowledge. Inspection of the gastric mucosa on the operation table in some cases of severe recurrent hemorrhage has revealed a lesion which had no resemblance to ulcer as commonly recognized in the post-mortem room, and conceived as existing beforehand. All that was apparent consisted in a series of small fissures, or chaps, from which blood oozed freely and continuously. Each of these being ligatured with fine thread ceased to bleed, and nothing further remained to be done; recovery followed. The oozing patch was regarded as an erosion, which, in-

deed, it appeared to be, hardly amounting to an ulcer. Cases of this kind have probably been regarded as instances of gastrostaxis, and one may assume that many of them cease to give trouble and heal kindly under appropriate treatment. The lesions may be multiple and it is certain that they are as apt to be serious sources of hemorrhage as are the deeper ones. Whatever the lesion, or the degree of it, the treatment of the patient is the same, and it consists in absolute rest, recumbency with head low, and morphine given hypodermically. Nothing whatever is to be given by the mouth, not even iced-water or pieces of ice. Saline solution, in half-pint quantities, should be given by the bowel, and nutrient enemata consisting of from eight to ten ounces of peptonised milk, with yolk of egg and grape sugar, repeated three or four times each day for at least three days. The mouth should be cleansed with borax, thymol, and warm water several times a day. As regards drugs, astringents are not now used as formerly. Subnitrate of bismuth and calcined magnesia are best employed a few days after bleeding has stopped. The lower bowel should be washed out daily. In cases in which ulceration is found near the pylorus, it is desirable to perform gastroenterostomy, on account of the risk of pyloric obstruction. Many patients suffer from gastric ulcer without any hemorrhage or with very small bleedings. As regards hemorrhages from cancerous growth in the stomach, this condition is not met with in persons under forty years of age, and there is seldom any serious loss of blood in such cases. Coffee-ground vomit is more common, although this is also met with in acute and chronic ulcers. Apart from gastric ulceration, the most formidable cases of hematemesis are those dependent on advanced cirrhosis of the liver. The bleeding commonly occurs from esophageal varices, and the loss of blood is sometimes enormous, recurrence being almost certainly fatal.

Acute Pancreatitis.—A. E. Barker reports a case of this condition in which recovery followed operation. The original attack in this case was not due to one of those fulminating processes in which wide sloughing of the pancreas occurs, from which no recoveries under any treatment can be expected. But the suddenness and severity of its onset, with fever, peritonitis, and fat necrosis, justify its being placed among the acute cases. The opportunity of examining the abdomen *in vivo* some eight months after an attack of pancreatitis showing the absence of any palpable evidence of damage from the earlier inflammation of the pancreas encourages the hope that prompt drainage from behind may serve to arrest the disease in other cases.

Phagocytosis of Erythrocytes by Endothelial Cells.—W. O. Meek as the result of a series of investigations comes to the following conclusions: 1. That preparations of endothelial cells are especially suitable for observations on hemophagocytosis. 2. Human blood sera, whether from "natural" or "immune" sources, which cause agglutination of other human red blood corpuscles, can be shown to also bring about phagocytosis of these erythrocytes by endothelial cells. 3. That the amount of "hemopsonin" in such sera is closely related to the amount of "hemagglutinin" which they contain.

Delayed Chloroform Poisoning.—E. D. Telford reports the case of a woman aged 47 years upon whom an operation for pyloric obstruction had been performed under chloroform anesthesia. After 36 hours, "coffee-ground" vomiting began, and with increased pulse-rate, delirium, and restlessness, continued till death occurred four days after the operation. At autopsy, the liver was found to be slightly enlarged, of bright yellow color, and showing an extreme degree of fatty degeneration. At the operation the liver had been found normal. A review of the literature of "delayed anesthetic poisoning" shows that the vast majority of the cases have occurred after the administration of chloroform, and that but few have been noted after the use of ether. It appears probable from both clinical and experimental work that any general anesthetic induces a state of acidosis, and the relative immunity from untoward results shown by the ether cases is probably due to the fact that the danger lies more in embarrassed excretion than in increased production of the acid bodies, and that ether hampers the kidneys less in their work than does chloroform.

Aconite Poisoning.—W. Edgecombe reports a case of recovery of an adult from accidental poisoning resulting from the drinking of an amount of a liniment containing the equivalent of about one-eighth grain of aconitine, or thirty-one times the maximum dose.

Nasopharyngeal Fibromata.—W. Guthrie describes two cases in which these growths were removed, in which the methods employed was that advocated by Brady, with the difference that the anterior bony nasal aperture is widened through an intranasal instead of an external incision.

Ascites and Subcutaneous Drainage.—P. Paterson describes his method of draining the peritoneal cavity in cases of ascites by means of a glass drain of such a shape that it will not slip into the peritoneal cavity. The drain consists of a perforated glass cylinder expanded into a flange at each end. This is introduced through an abdominal incision in such a manner that one flange should lie flat on the peritoneum and one on the abdominal aponeurosis, without any pressure being exercised on the intervening tissues.

Esophoria Not Caused by Refractive Errors.—R. A. Morrell describes a series of cases representing a large number of patients applying for relief from headaches, in which the only abnormality to be found is an esophoria when the patient is accommodating for a near point. This esophoria is at once relieved by placing a weak convex glass in front of each eye. Such cases are closely allied to those classed under the heading of muscular asthenopia, in which the symptoms are due to some kind of heterophoria.

Malignant Pustule.—L. A. Parry describes two cases of this condition, and states that the only treatment that need be referred to is that which is practically universally adopted—namely, destruction of the primary focus of the infection, either by caustics, the cautery, or the knife. The last is the best.

Treatment of Syphilis with 606.—W. Wechselmann, chief of the dermatological department of the Rudolf Virchow Hospital in Berlin, who has treated more cases with this remedy than anyone else, namely, 1,100 patients, contributes this paper. He concludes that it may now be taken as certain that the value of the new remedy is great, nay, more, that it is indispensable, and its danger is shown to be small. Further work will make known the limits of its efficacy, but under all circumstances the discovery of it and the creation of chemotherapy form one of the greatest and happiest events in the history of the natural sciences.

Berliner klinische Wochenschrift.

October 24, 1910.

Semen Findings and Male Sterility.—The fact that many women pronounced in perfect shape for childbearing and anxious for children do not conceive and that the husband appears equally potent has turned the attention of several authorities in recent years toward a research for overlooked causes of male sterility. Fürbringer has recently devoted much time to the semen findings, excluding such frankly apparent conditions as azöspermia, which is synonymous with obliteration of the seminal passages. Other forms of this condition are doubtful as shown by repeated examinations. It is an accidental and transitory condition, and even with atrophy of the testicle completely formed and active spermatozoa are sometimes present. The

best condition for study of the semen is the fresh and pure ejaculation as obtained in the condom. It is not easy to assert offhand just how few spermatozoids must be present to constitute oligospermia, but it may be an incidental and transitory condition is evident. Of much greater significance are changes in the form, mobility and tenacity of life possessed by the spermatozoids. Changes in form are extremely numerous and may be termed immature or degenerative in the absence of exact information. The dark field illumination has naturally come into use in this connection. The author knows of several men with badly deformed spermatozoids habitually present who have begotten healthy children. Those spermatozoids might be termed atrophic or dwarfish. Hence form seems no absolute barrier to potency. In regard to sluggish, weak or short-lived spermatozoids it is known to be a fact that disease anywhere in the seminal passages may be responsible for such behavior, but conception may occur in spite of it. It is a question whether spermatozoids so damaged may retain their vitality in the vagina. As regards absolute vitality of these bodies after ejaculation, they have been seen alive and vigorous for 60 hours later, even when produced by the aged. They do not always perish together. The gist of the whole matter seems to be that one cannot with positive certainty connect anomalies of form and motion in the spermatozoids with absolute impotence.

Accidents in Serotherapy.—Jochmann cites very many of these, some of which occur frequently and seem to possess a definite relationship to the reaction, while others are rare and problematic. Among the former are the rashes, which appear in great variety, and may simulate the examthems of infectious diseases. The latter or problematic kind include such phenomena as acute edema of the glottis. Naturally the results of second injections are not included in the primary series. The induced state of anaphylaxis has prompted the question "is serotherapy destined to defeat its own ends?" The author denies the existence of a single fatality from pure serum disease. It is now known that the latter tends to follow the larger doses. But these are necessary to produce curative results in cerebrospinal meningitis, streptococcus disease, etc. A good-sized immunizing dose is more valuable and safe than an extra large curative dose. The future of serotherapy must be bound up in the search for a practicable serum from some animal other than the horse, although the latter must be depended on in part, as for first injections. Anaphylaxis may be prevented in part by using other sera for successive injections. Serum disease may also be prevented to some extent by giving calcium chloride for three days before an injection. About one gram should be given on each of the three days, per os or subcutaneously. The author does not believe this resource to have any power in anaphylaxis. When serum disease has once appeared it must be treated symptomatically. The joint pains of serum disease, Jochmann says, do not yield to salicylic acid.

Recent Statistics Concerning the Warfare Against Tuberculosis.—Prof. B. Fränkel of Berlin devotes a few paragraphs to this subject. The method of collecting results in this connection takes cognizance of a zero stage (stage 0), which corresponds roughly to the pretuberculous stage and may readily be confounded with the "first stage" of common acceptance, unless sharply marked criteria are enforced. In fact, the 0 stage is set down as implying a condition somewhat superior to stage 1. It is of course, possible that under the new procedure many who would not come to consultation are rounded up, hospitalized and discharged cured, along with those who present slight, although manifest, evidences of infection. The death rate among those actually treated for phthisis is still heavy, but has shown a marked falling off. We note no figures as to the ratio of mortality from tuberculosis to the general mortality in the tuberculous years. It used to be an axiom in life insurance circles that a candidate for tuberculosis was relatively shortlived and that if he did not succumb to tuberculosis he would perish of some other affection. The entire movement against tuberculosis is doing good beyond expectations, but we should not grow weary of well-doing, nor should we believe that we have exhausted our resources. What has been done has been well done, but there are evidently reserve resources which have not yet been pressed into service.

Deutsche medizinische Wochenschrift.

October 27, 1910.

Treatment of Morphinism.—Weber warns against confounding the mere effects of morphinism with the degenerative substratum which paves the way for the habit. This is shown chiefly in anomalies of character, as bound up in mental and physical inefficiency. Such individuals may be trusted to pursue a vocation which is essentially tranquil. Prognosis must be guarded if patient is subject to neuralgia, biliary colic, etc. Such ailments should if possible be radically terminated by surgical operation. A successful cure is usually heralded by normal pupillary reaction, return of sleep and appetite, and gain in weight. The mind may, however, exhibit peculiarities for a much longer period, and hence an aftertreatment of from 4 to 6 weeks is advisable, especially as it tends to prevent a sudden relapse. There is a peculiar mental indifference which exists even after restoration of the physical functions. The patient must be made to feel that he is undergoing a new birth, and it is possible that psychoanalysis may be able to remove some lurking inimical influence to a complete regeneration.

Functional Tests of the Pancreas.—Hirschberg concludes that our diagnostic resources in this direction are extremely divergent, according to the nature of the disease actually present, all depending upon whether the gland is wholly or partly destroyed, and whether its secretion is wholly or partly cut off; and finally upon the physiological presuppositions which have been present in the minds of the investigators and which have led to the formulation of the tests. One cannot tell in general whether a given diagnostic resource is more trustworthy than some other. But if one combines the results of all tests one should have made essential progress in pancreatic diagnosis. In order to recognize acute inflammation of the pancreas, Wohlgemuth's test—the increased presence of diastase in the urine—should be of value. We now make a diagnosis by this means *in vivo* where formerly we had to await the autopsy. Next in value to this urinary test come the results of fecal investigation as judged by increase of fat and presence of a tryptic and diastasic action of the feces. Results of an oil breakfast for pancreatic action, the presence of undigested nuclei of meat, etc., and many other tests are mentioned, covering the whole of gastrointestinal digestion. Most striking to note is the complete omission of Cammidge's name.

Lordotic Albuminuria.—Pechowitsch takes up this clinical variety of orthostatic albuminuria, which becomes less in extent when the patient creeps on the floor. It is due entirely to lordosis in the lumbal region, which furnishes a mechanical obstacle to the passage of blood through the renal veins. The creeping exercises, as developed by Klapp, are not only of diagnostic but therapeutic value. The children who suffer from this condition are of a type predisposed to tuberculosis and are asthenics in general. The number of varieties of postural albuminuria is now known to be considerable, and the predominant influence in the production of all the varieties is obstruction of the venous circulation.

Book Reviews.

Fifty Years of Darwinism. Modern Aspects of Evolution. Centennial Addresses in Honor of Charles Darwin. Before the American Association for the Advancement of Science, Baltimore, Friday, January 1, 1909. New York: Henry Holt & Co., 1909.

It is hardly possible for the generation of to-day, for whom the heresies of only a comparatively short time ago have always been articles of faith, to realize the truly stupendous nature of the change in scientific thought and feeling occasioned by the first enunciation of Darwin's doctrines. Some echoes of the battlefield reach our ears when we read such books as "Huxley's Life and Letters," or the remarkable "Father and Son," written by Philip Gosse's son; but of the storm of opposition that greeted the appearance of "The Origin of Species," of the acrimony of the controversies it engendered, of the havoc among the intellectual leaders of the time that this bloodless revolution wrought, we can have but little idea. That more extensive research has sometimes failed to corroborate some of Darwin's dicta, and that it may be necessary to modify his theories in more or less important respects, in no way alter the greatness of his work, the value of which is not only intrinsic, but lies also in the momentum of the tremendous forces of research that he set in motion. In this collection of addresses, commemorating the centenary of Darwin's birth and also the fiftieth year since the appearance of the "Origin," a number of eminent scientists review the evolution of the doctrine during this period and discuss its application in the most varied fields of natural history. The growth of some of the modern conceptions, such as that of De Vries concerning the discontinuity of unit characters, Waagen's mutation, and rectigradations of Osborn, is fully outlined and the possibilities and probabilities of the next half century's research are suggested. It would hardly be possible to produce a more effective summary of the whole doctrine of evolution as at present taught, and the method of discussion adopted by the authors is sufficiently untechnical to be acceptable to any reader of average intelligence. The whole story, from its stormy beginnings to its present era of rapid amplification is one of absorbing interest, quite aside from the fact that familiarity with it is an essential in the mental equipment of every well-educated person, and we know of no better exposition of its essentials than is to be found in the present volume. The writers of the separate addresses are as follows: T. C. Chamberlin, University of Chicago; Edward B. Poulton, Oxford University; John M. Coulter, University of Chicago; David Starr Jordan, Stanford University; Edmund B. Wilson, Columbia University; D. T. MacDougall, Carnegie Institution of Washington; W. E. Castle, Harvard University; Charles B. Davenport, Carnegie Institution of Washington; Carl H. Practical Pathology. A Manual for Students and Practitioners. By G. Sims Woodhead, M.A. (Cantab.), M.D. (Edin.), Hon. LL.D. (Toronto), Fellow of the Royal Society, Edinburgh; Professor of Pathology in the University of Cambridge. With two hundred and seventy-five Colored Illustrations. Fourth edition. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1910.

It is twenty-five years since the first edition of this well-known book was issued, and yet, so thorough has been the work of rewriting and revision that it appears to-day as one of the most complete and modern manuals we have. The author was a pioneer in writing what was really a *practical* pathology; that is, a treatise in which every step and procedure necessary for the successful study of a given tissue are described in detail as part of the discussion of its pathology, and he has had many imitators, but none of these, certainly, has ever surpassed him in the application of this method of dealing with the subject. While the book is avowedly intended primarily for class-room use, its breadth of scope and unusual richness in technical information make it an invaluable work of reference as well, for both the laboratory and the library. The opening chapter deals with the technique of the post-mortem examination and describes a very satisfactory and systematic method. It might be suggested that the introduction of a few diagrams illustrating the position and direction of the various incisions in exposing the body cavities, opening the heart, etc., would be of great value here, and would make the description of the procedures much easier for the beginner to understand. The following hundred pages comprise an excellent treatise on section cutting, staining methods, etc., in which nearly every method of importance has been incorporated. Somewhat less attention is given to the preparation of frozen sections, however, than present-day practice, in this country at least, would seem to require. The use of compressed carbon dioxide gas in this connection is so great a step in advance as to justify more than the casual reference the author makes to it, and the value of thionin as a stain for frozen sections in rapid diagnostic work is not spoken of at all. In the description of the methods for paraffin embedding the recent carbon disulphide method, certainly the most useful and rapid of all, is not given, and under the celloidin technique Stepanow's very rapid and excellent clove oil method has been omitted. The succeeding chapters on inflammation, organization, and repair, and then on the various organs and systems of the body, are superlatively good. The descriptions are marvellously clear and complete and the unusually careful system of cross-referencing adds greatly to the value of the book. Criticism might be made of the chapter on the organs of generation in the female as being somewhat less full than is desirable, particularly as this is a subject that is usually treated in rather stepmotherly fashion in works in general pathology in spite of its exceedingly great importance; for example, out of two hundred and seventy-five illustrations, six seems rather a small number to allot to this topic. Bacteriology has now assumed such proportions, and is customarily so fully taught as a separate subject, that it might appear wiser to give up the nine pages devoted to it to a more ample discussion of some of the other subjects. The illustrations are unusually beautiful and the author's judgment in selecting for them sections showing lesions commonly seen rather than laboratory curiosities will meet with the approval of all teachers. The mechanical execution of the work is very fine, and only one typographical error has been encountered, a misspelling of "sporozoa" occurring twice on page 740. The author is to be highly congratulated on what is truly a work of remarkable excellence, and the industry with which he has kept it so fully abreast of the times without sacrificing any of its original virtues must command the admiration of all who have ever attempted a similar task.

A Practical Treatise of Organotherapy. By D. M. Ouspensky, M.D. St. Petersburg [Russian text], 1910.

The author of this monograph is an enthusiastic disciple of Brown-Séguard, and has collected a great number of data in reference to the internal secretions of various organs, their preparations for therapeutic use, and the results obtained. Not only such glands as the thyroid, the adrenals, the ovaries, etc., are considered, but also the lungs, the heart, the intestines, the prostate, etc., all of which are supposed to furnish specific secretions, which may prove useful in the treatment of conditions due to a supposed organic or functional deficiency of these structures. The wealth of data contained in the book should make it useful to such students of this phase of therapeutics as are able to read Russian or to obtain correct translations from this perhaps the least widely known European language.

Praktische Winke für die chlorarme Ernährung. Von Prof. Dr. H. Strauss, dirigierender Arzt der inneren Abteilung des Jüdischen Krankenhauses in Berlin. Berlin: Verlag von S. Karger, 1910.

This booklet consists of a number of tables giving the salt-content of various foodstuffs and of numerous "recipes" for the preparation of salt-free dishes. It should prove very useful in making up diets for chronic nephritic and cardiac patients.

Essentials of Laboratory Diagnosis. Designed for students and practitioners by Francis Ashley Faught, M. D. Director of the Laboratory of the Department of Clinical Medicine, and Assistant to the Professor of Clinical Medicine, Medico-Chirurgical College, etc., etc., Philadelphia, Pa. Containing an Indican Scale in Colors, Eight Full-Page Plates and Numerous Engravings in the Text. Second Revised Edition. Philadelphia: F. A. Davis Company, 1910.

In this little volume the author has supplied practically all the information on laboratory work that the general practitioner is likely to require. As its title implies, it contains the essentials (and nothing else) of what relates to clinical laboratory diagnosis. The arrangement of the material is good, the instructions are clear and concise, and all superfluous matter is omitted. The section on blood pressure is particularly valuable; the chapter on serodiagnosis includes the Wasserman and Noguchi reactions.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 24, 1910.

The President, Dr. John E. Weeks, in the Chair.

Nominations.—The nominations of officers, censors, and delegates to be elected at the one hundred and fifth annual meeting (November 28, 1910) preceded the scientific session.

The Relation of Experimental to Human Poliomyelitis.—Dr. Simon Flexner addressed the Society on this subject and said that it seemed to him that the experience of the last three years entirely justified a discussion on the subject of poliomyelitis before such a representative medical body. Many were doubtless familiar with the fact that within this period of time this disease had been introduced into the United States and had widely extended over the country. During the summer just past there were greater numbers of cases of poliomyelitis than had ever been known before and probably a greater number than had occurred in the previous two years during which this epidemic prevailed. The figures available, however, were not complete nor accurate; but from the official figures, as well as from those unofficial, Dr. Flexner thought it was reasonable to state that there occurred as many as 20,000 cases of epidemic poliomyelitis during the past summer in this country. The mortality from this disease varied from five to ten per cent. and the percentage of children crippled was probably 75 per cent. Doctors were not at all adequately informed regarding all the features of the disease, but what was more important was that the doctors were not alive to the fact that epidemic poliomyelitis was a contagious disease. It was not easy to establish in an individual case precisely how the disease was acquired; it was difficult to bring evidence that was at all convincing that this disease was contagious. However, the fact of the contagiousness of poliomyelitis had gradually been spreading. In many quarters the disease had been dealt with by the public authorities as was customary with other established contagious diseases. Such measures, however, were not generally undertaken. In the Greater City of New York not to report these cases he believed to be a flagrant omission. It was desirable that physicians who dealt with this disease should realize that they were dealing with a contagious disease, and also that it could be spread by healthy intermediaries. Since the disease was so terrific in its effects every precaution should be taken in preventing its spread. Three years ago epidemic poliomyelitis appeared on the Atlantic seaboard; this year it had prevailed along the Pacific coast, in Mexico, and had spread over this country to an alarming extent. The disease had been looked upon as something mysterious; they had but little knowledge of its agency and of its pathology. However, since the epidemic of three years ago an opportunity had been afforded for a study of the disease by experimental methods. It had been found that it could be transmitted among the lower animals, but only those that were closely allied to the human species, namely the monkey. A very large number of experiments had been conducted with success upon the lower animals, and particularly upon the so-called lower monkey. It had been found that poliomyelitis could be transmitted to the lower monkey and with regularity. It was necessary to bring the infected material from the human source from the central nervous system and spinal cord in direct relationship with the central nervous system of the monkey. He knew of no disease that was so rapidly reproduced in the monkey as was poliomyelitis, and it probably took in 100 per cent. of the animals inoculated. It resembled the disease which appeared spontaneously in the human being. Monkeys did not spontaneously take the disease, and the question naturally arose why a disease which was so fatal in this species should not occur naturally or spontaneously in that species. This might seem to indicate that the disease was not so contagious as he had suggested. Dr. Flexner called attention to the defenses set up against the infection. There were external as well as internal measures of prevention against microorganisms; when one came to the question of the experimental or artificial protection, he must take into account the natural defenses of the organism against diseases. The virus of epidemic poliomyelitis must come into intimate association with the central nervous system before the disease developed. The experimental study of the disease had established the fact that this particular virus belonged to that class of infectious agents which were described as filtrates, the kind that were beyond the observation of the human eye. At the present time he had a virus which had been under observation since last September, which developed the disease in a severe form, producing death in animals in 90 per cent. of the cases, and this virus had been transmitted in from 38 to 40 generations. Whether the virus belonged to the bacteria or to the protozoa he could not tell. However, it was a living organism; of this there could be no doubt. Epidemic poliomyelitis was a disease infectious in character as well as contagious in nature. The virus could not be seen by the naked eye, and it was not likely that it could ever be seen directly or photographed by the ultra violet rays.

In speaking of the pathogenesis of epidemic poliomyelitis, Dr. Flexner said that the indications were that the virus of this disease did not act directly upon the gray matter of the cord or ganglion cells of the anterior portion of the cord. The paralysis which resulted was not due to the immediate effects or results of destruction of these cells. The disease began as an infection of the meninges, especially in the tissues near the blood-vessels. The paralysis was produced partly by a functional disturbance of innervation, because of an interruption of the blood supply. The vessels became narrowed. What he thought very important to bear in mind in studying the pathogenesis of epidemic poliomyelitis was that the restoration of function occurred so remarkably that one should know that he was not dealing with actually destroyed ganglion cells, but that he was dealing with some functional disturbance. There was no therapy in this disease which could be regarded in any way as specific; the treatment was purely symptomatic. Since there was such a great variation in the appearance of the disease and because there was so much to learn regarding its pathogenesis, it developed upon the laboratory workers to do something which would tend to mitigate the ravages of epidemic poliomyelitis. It had been proven that one attack of the disease when experimentally produced protected against a subsequent inoculation or infection. It was not improbable that one attack of the disease produced a permanent immunity. It was possible to inhibit the disease by inoculation. Up to the present time in their experiments with this disease it was possible by means of a serum secured from an animal recently recovered from the disease to bring about an interruption in the progress of the affection. Experimentally they had been able to control the disease. Dr. Flexner was very hopeful that when the disease was once acquired it might be controlled. He asked that the medical profession become more united in believing in the contagiousness of the disease; much more then could be accomplished toward the elimination of this distressing disease.

Dr. L. Emmett Holt said that even five years ago if anyone had suggested that the disease under discussion was an infectious or a contagious one, it would have been

looked upon as a joke. The opportunity for studying the disease during the past few years had been so great that it was now a settled question that the disease was spread from patient to patient. All were brought face to face continually in practice with the question "What shall we say about the disease?" The public now was wide awake upon this subject, and Dr. Holt recalled a case in which the father made the diagnosis of poliomyelitis when the doctor in attendance had failed to do so. This disease had had an enormous spread during the past four or five years and he urged the necessity of a rigid quarantine in every case. Poliomyelitis promised to become one of the great scourges of the country. There was a hopeful outlook for a specific therapy. The profession generally should be made aware of the great prevalence of the disease and should be constantly on the lookout for these cases. There was but little doubt regarding the nature of the disease, whether it existed epidemically or sporadically; it was the same disease.

Dr. B. Sachs did not believe that this disease was entirely out of the hands of the clinician, and he called attention to the fact that while they owed much regarding the knowledge of its contagiousness to the work of Dr. Flexner, fully fifteen years ago they knew that this disease was infectious, if not contagious. Years ago they also know the seasonal influence on the character of the disease. With regard to the prognosis, Dr. Sachs believed that a great deal could be done particularly if they bore in mind certain observations made in Scandinavia that school houses seemed to play an important rôle in the spread of the disease. Many of the cases could be traced to the school houses. To prevent the spread of the disease, when a case appeared in a child attending school, that school should be closed; in fact, all schools should be closed that were within a radius of that disease. So far as the contagiousness of poliomyelitis was concerned, it was a curious fact that in the hospitals where the cases were not thoroughly isolated, other cases had not appeared. He did not know of one family in which there was one case that infected another member of the family. However, Dr. Sachs thought it was well to maintain a strict rule in regard to the isolation of such patients. It was a mistake, in his opinion, to be frightened regarding this disease; the mortality in Greater New York was not greater than 10 per cent. and probably not more than 5. He was surprised at the large number of mild cases and the large number that ended in complete recovery without any paralysis. He had made a study of the epidemics and he had before no conception that so many people had been affected and recovered without any residue of paralysis. There was no reason for a panic regarding epidemic poliomyelitis. With regard to the treatment, as a matter of fact little could be accomplished by the use of drugs. But everything was to be done by the use of electricity, gymnastic exercises, and massage. The keynote in the therapeutic situation was the exercise of the muscles, actively or passively.

Dr. Israel Strauss said that poliomyelitis was not a very infectious disease when compared with such diseases as scarlet fever and measles; the infections with poliomyelitis fell very low when compared with the epidemics in these other two diseases. The child normally seemed to have a great resistance to the virus of poliomyelitis. The probabilities were that in a few years, rather than increasing, the sporadic form of this scourge would be on the decrease. One thing he thought should be impressed upon all, that was that when a man was called in to see a case of this nature in which there had occurred paralysis, he should at once call in a skilled orthopedist. If any quarantine was needed, it should be a strict one.

Dr. Virgil Gibney said that in 1907 when they realized that they had a terrific epidemic of poliomyelitis to deal with Dr. Flexner was communicated with because they all felt the need of a preventive serum. He was willing to admit that the orthopedic surgeon could do much against the resulting deformities of poliomyelitis. But the cases were not gotten by them until the deformities had occurred as a rule. He emphasized the importance of immobilization; the lower limbs should be completely immobilized from the toes to the free ribs. He said he was panic stricken in the face of these epidemics. The orthopedic surgeon must make rapid strides in work on the disease if he expected to cure the cases, but he must look to the laboratory for prevention. Dr. Gibney thought the best plan during the first ten days of the attack was to immobilize the parts and keep the feet at right angles to the leg. To prevent much deformity, as much counter-irritation as the patient could stand should be employed. Keep the legs and toes extended.

Dr. Le Grand Kerr of Brooklyn (by invitation) said there was no reason in the face of the facts that they had at the present time both from a study as to its epidemicity and the studies from the laboratory why they should sit idly by and allow themselves to be parties to the further spread of this infection. The cases should always be isolated and especially during the acute stage. It was a difficult matter, however, for a doctor to go into a home and insist upon strict isolation when the Department of Health in that city or town took no recognition of the disease and its possible infectiousness or contagiosity. The Department of Health of every city and town should make this a reportable disease. Closing the public schools simply added to the hysteria of the public and made matters worse; such a course, he believed, to be impracticable.

Nitrous Oxide-Oxygen Anesthesia.—Dr. R. C. Coburn read this paper. He said that until recent years the dangers of the anesthetic were considered solely those occurring upon the operating table, but laboratory investigation had established, beyond a doubt, that a percentage of surgical mortality, hitherto considered to be due to the patient's condition, effects of the operation, etc., was sometimes directly due to the effects of the anesthetic, even though death occurred remotely from the time of the operation. Clinical observation had completely corroborated this scientific conclusion. Since the discovery of nitrous oxide-oxygen anesthesia, this agent had slowly, intermittently, but very persistently gained recognition, until to-day it occupied the meritorious position of being endorsed by one of the largest and greatest scientific societies in the world, as being, all effects considered, the best means for producing anesthesia that was known. The prevalent idea that nitrous oxide-oxygen was better adapted for minor surgery and for short operations than for major work was erroneous, for the longer this form of anesthesia was maintained the better it became in every way. The writer had administered it without deleterious effects in several operations lasting three and one-half hours, and in one case for over four hours, the longest period, he believed, wherein this agent had been continuously used. Dr. Frederick Hewitt, the leading authority of Europe on anesthetics, had said that there was no form of anesthesia at present known which was so devoid of danger as that which resulted from nitrous oxide when administered with a sufficient percentage of oxygen to prevent all asphyxial complications. The Anesthesia Commission of the American Medical Association reported at its recent session in St. Louis that "As a routine anesthetic nitrous oxide-oxygen has a peculiar value, and in the hands of highly skilled anesthetists is the best method yet devised." These statements had been corroborated by such surgeons as Crile, Bevan, Beck, Kelley, and Halstead. There was much less surgical shock and postanesthetic nausea and depression with nitrous oxide than with ether or chloroform: the patient regained consciousness

very quickly, and, being less depressed, recovered from the operation sooner and better. The quicker recovery and consequent shorter stay in the hospital counterbalanced the increased cost of the anesthesia. Hamburger and Ewing, in investigating the effects of different kinds of anesthetics upon the blood, found that ether caused the color index to show a rather constant drop, starting immediately after anesthesia and reaching its lowest point on the fifth to the seventh day. This indicated a relative loss of hemoglobin per cell; the volume index likewise showed an immediate loss, which was most marked in 24 hours, and again on the fifth to the seventh day. In nitrous oxide the percentage volume remained unchanged throughout and the only sign of low color index was found immediately after removing the mask and this was entirely absent two hours later. Chloroform produced even more destructive changes in the blood than did ether. These facts in critical cases might be the determining factor in producing a fatal termination. Ether increased the toxemia arising from infection, whereas nitrous oxide exerted no injurious effects upon the leucocytes and consequently did not lower the patient's immunity. In serious cases the difference in recovery was strikingly shown. Ether was an irritant to the respiratory mucous membrane and to the kidneys, whereas nitrous oxide was without deleterious effect upon these tissues; it was, therefore, strongly indicated as the anesthetic agent whenever these structures were involved, no matter what might be the operation. Very sick patients with a rapid pulse and quick shallow respiration actually seemed to be benefited by this form of anesthesia; some such patients would undergo this anesthetic for three-quarters of an hour to an hour and manifest a distinct improvement in the rate and quality of both circulation and respiration, both during and subsequent to the operation. The lessened discomfort to the patient was an added factor in favor of this anesthetic. Before administering nitrous oxide-oxygen it was advisable to use a preliminary hypodermic injection of morphine and atropine about one-half hour before the operation, as this medication aided very materially in securing muscular relaxation. The patient recovered from this anesthesia so quickly that this measure was indicated for the postoperative pain alone. In that class of patients in which it was difficult to overcome muscular rigidity the addition of a very small amount of ether, not sufficient to give the ether after-effects, would secure the necessary relaxation. Used in this way, the speaker said, nitrous oxide-oxygen amply fulfilled the requirements of both minor and major surgery, and produced not only the lightest but also the least toxic general anesthesia yet discovered.

Dr. Joseph E. Lumbard said he was very glad that Dr. Coburn had brought this safe and very valuable anesthesia sequence to the notice of the Society; the medical profession were in the main ignorant of the possibilities and limitations and proper mode of using nitrous oxide with or without oxygen. He said he could not recommend it for a general routine anesthesia, for it would not work well unless ether was added in many cases. In well-selected cases, however, and in the hands of an experienced anesthetist, it was almost ideal; surely it was the safest and pleasantest anesthesia for all parties concerned. For an anesthesia, short or long, where absolute immobility and complete muscular relaxation were not essential, and where there was some special reason for not using ether or chloroform, this anesthesia sequence was well indicated. So far as the simple maintenance of unconsciousness was concerned, this system was practical, but the surgeon usually wanted more; then this sequence would not always meet the requirements. Ether was often used in this sequence, but was seldom mentioned in discussion on the method.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held October 17, 1910.

The President, Dr. Reynold Webb Wilcox, in the Chair.

Nasal Diphtheria in Infants.—This paper was by Dr. George Dow Scott, who said that nasal diphtheria was not uncommon, but was often overlooked, and the condition illy diagnosed. The cause was the Klebs-Loeffler bacillus; the predisposing factors, rachitis and malnutrition. Crowded tenement houses, badly ventilated rooms, adenoids, congestion of the epipharynx, articles placed in the nose, and deflected septa aided materially in producing a fertile soil for the bacillus. The absolute diagnosis was possible only by a microscopical examination. Nasal diphtheria, in his experience, was never absolutely of a pure character. Even the simplest forms showed a larger or smaller number of other bacteria. The condition was both primary and secondary, and passed through three stages: a catarrhal rhinitis, a fibrinous rhinitis, and a diphtheritic catarrhal rhinitis. The characteristics of each of these were described. The first, he said, was often overlooked and not treated; passing away in a few days and leaving the mucous membrane sound as before infection. Of the bacilli present in this primary form, the Klebs-Loeffler predominated. In the second stage the membrane disappeared in eight to ten days if untreated (earlier if treated), leaving a moderate diphtheritic catarrh, or the third stage of the disease. The latter might last for weeks, and Fränkel's bacillus, the pneumococcus, the pseudo-diphtheritic, and the staphylococcus or streptococcus might implant themselves upon this fertile soil. The persistency of this stage was undoubtedly due to the implantation of the specific organism of the disease in the accessory sinuses. The infection might extend also through the lachrymal duct, with the effect of closing it and causing an overflow of tears. In infants the cervical adenitis incident to nasal diphtheria rarely terminated in sloughing or abscess. The above classification as to the three stages of the disease Dr. Scott believed to be the best. On the other hand, some authors, as Fränkel, Hoffmann, and Beck, regarded the second stage, that of fibrinous rhinitis, as an independent disease, since few Klebs-Loeffler bacilli were apparently found, and these due to their implantation on the surrounding membranes. Baginsky, however, considered fibrinous rhinitis diphtheritic unless bacterial examination showed this not to be the case, while Bretonneau stated that one or two enlarged glands, combined with redness of the upper lip on the same side as the pathological lesions, were pathognomonic symptoms of nasal diphtheria. The nasal type of diphtheria might be remarkably contagious. Hence the prophylaxis of the patient and his surroundings was almost as necessary as the treatment. Conscientiously done, it meant no further contagion. At the outset an immunizing doze of antitoxin should be given to each member of the family, 500 to 2,000 units as the ages warranted, subcutaneously or by the mouth, and they should be instructed not to mingle with others. Having described the other prophylactic measures required, he said that swab cultures from the nose ought to be taken every three days until no bacilli were found to be present, care being used in pushing the swab gently toward the posterior nares. In speaking of the treatment he said that a nursling should have its regular feedings from the mother, the latter carefully cleansing the nipple immediately after nursing. She should, moreover, receive a larger immunizing dose of antitoxin than other members of the family. In the bottle-fed infant, if the ordinary modification of milk was not taken well, the proteids might be reduced. During the intervals between feedings Dr. Scott gave 1 to 3 drachms of fruit soups or raw pineapple or

orange juice, warmed and slightly sweetened. He was strongly opposed to the use of nasal douches, on the ground that they are liable to carry infected material into the surrounding sinuses. Pledgets of cotton, moistened with warm raw pineapple juice, inserted alternately into both nares, softened and probably digested the crusts, and might be followed with pledgets containing carbolic acid, 2 per cent., or warm sweet oil, hydrogen peroxide, one-quarter strength, or argyrol, 5 per cent. Broths, bouillons, peptonized milk, and wine whey are at times of service. For the prostration, strychnine, caffeine, or camphor might be given, while castor oil, in small but frequent doses, served to relieve constipation. Enough antitoxin should be administered to neutralize the poison and lessen its invasion; the amount required depending on the age of the child, the severity of the intoxication, and the extent of the nasal membrane. It was well never to wait for a bacterial examination in a suspected case, but to give the antitoxin immediately. Fifteen hundred units injected deeply into the buttocks once, and followed by 2,000 units by the mouth, once or twice (after an interval of six hours), usually sufficed. In the second stage he follows up the initial injection with a second, and perhaps a third, at five-hour intervals. As the membrane disappeared, 2,000 units were again given by the mouth once, twice, or three times, as might be required. In Dr. Scott's hands this mouth administration of antitoxin had always worked well. At each visit a study of the condition of the membrane and of the intoxication present is of paramount importance.

Psychotherapy: Its Uses and Abuses.—Dr. Edward D. Fisher said that the various discussions on this subject had attained the purpose of removing much of its mystery, while the many failures in effecting cures had made the public less credulous and rendered those practising this form of therapy less boastful in their claims. We had possibly, therefore, arrived at a time when the chaff could be sifted from the wheat in this field. That there was something of value in psychotherapy should be accepted, because many persons showed by restored mental health that something had wrought a change in them, and because, while many individuals having no knowledge whatever of disease had assumed to treat disease by this method, many others, thoroughly trained in the study and treatment of disease, had seriously employed it. It could readily be seen, however, that such a so-called school of medicine, when it assumed for itself a special entity, apart from the realm of general medicine, instead of remaining only a subsidiary branch of the latter, became a danger to any community by its very specialism, since its practitioners were entirely ignorant of the vast field of scientific medicine. As regards the Emmanuel movement, it was hardly an answer to these objections to contend that the patient must first be examined and passed on by a physician. Practically, when the patient once came under the care of the Emmanuel operator he remained there indefinitely. If there was need of special mental therapy, the physician should be the one to send the patient to the religious adviser; not, however, giving him up as a patient, but treating him from a physical standpoint until in his opinion no further treatment was required. This, in fact, had always been the course pursued by every intelligent physician. It was almost trite to say that only in functional, temporary disturbance of the body was it possible for psychotherapy to have any position as a curative agent, and it was a sad commentary on what we would expect from the advanced general teaching of the present time that we found so many anxious to flock to the exponents of these various schools of irregular methods of cure. The speaker next considered the trained teacher and expositor of psychotherapy as a science founded on psychology; taking up the two methods most prominent in this kind of treatment. Dubois' work on "The Psychic Treatment of Disease" had been of great value to the physician. His method was that of suggestion, and he did not in any way discount medical treatment. Its danger was its positivism. Dubois was opposed to the psychoanalysis plant of Freud. He kept constantly asserting to his patient that his trouble was psychic and therefore curable, and his talk took the form of repeatedly saying, "You will be cured." Freud, in his work "Psychotherapy of Hysteria," maintained that all hysteria is due to a psychic *trauma*, some unhappy experience or shock in the past, or to some immoral act, especially, in his experience, of a sexual nature. He taught that if the patient could be made to reproduce this original trauma, and circumstantially discuss it, the hysterical or nervous symptoms would disappear. Often it was only when the patient was questioned while in the hypnotic state that these memories appeared with the unlimited vividness of first occurrence. In this method of treatment much depended on the physician and the exhaustion and submission of the patient. Education and training, leading to self-control in habits of life and processes of thought or reasoning, had always been the means of making men moral, hopeful, and energetic. What more did suggestion do, and why should it be more effective when urged only on the subconscious self, a lower, automatic part of our consciousness, than when presented to the individual when his higher consciousness was at its full capacity of activity and receptivity? As to there really being such a condition as functional disease, Dr. Fisher expressed the opinion that it was rather a confession of our ignorance as to the etiology and especially the pathology of so-called functional affections. It was the very absence of function of its consciousness which made a hallucination, illusion, or delusion possible. It was a loss of the powers of association and coordination, either in the field of memory itself, its association tracts, or in the highest region of intellectual association or coordination. It was difficult to think of such conditions of mental impairment without a physical change having taken place in these cell areas. How limited, then, was the field of practical psychotherapy! Obsessions of the condemnatory type, delusions of the paranoid type, persistent phobias, which the patent prayed to be delivered from and from which he tried to deliver himself, were supposed to be the especial field in which the psychotherapeutist was eminently successful. That improvement often took place in this class of cases could not be denied, but this might possibly be explained by the attention given to the patient and the evident interest in and desire to help his case. In conclusion the speaker said that psychotherapy seemed an unnecessary and labored process, and one open to much error and fraud, as well as liable to have permanent evil results.

Dr. Smith Ely Jelliffe said that if he were to ask someone how he treated diphtheria or syphilis or tuberculosis, and the reply made was, "by pharmacotherapy," further questions would be necessary in order to find out the particular kind of pharmacotherapy employed in each instance. The same was true in regard to psychotherapy, which was just as diverse as pharmacotherapy in its aims and methods, although, naturally, the variety here was not so great. In psychotherapy to prescribe the same kind of measures in every case would be just as sensible as to treat all kinds of disease with one prescription. Psychotherapy, in plain English, was simply a group term for a large variety of mental modes of treatment. These measures were among the very oldest forms of medical treatment, but, because they were so ancient, it did not follow that distinct advances had not been made in our knowledge of the methods and their various applications. Such drugs as opium and belladonna had been employed for a very long time, yet no one would pretend to say that we did not know more about them than our forefathers. Very little

had been said in reference to the subdivisions of psychotherapy. Psychotherapy was an extremely complex matter. To be able to get at a knowledge of mental facts and the effects of these required an amount of acumen which was scarcely called for in any other department of medicine. The absurdity of the claims of many modern pretenders, various sects of mental healers, etc., was strikingly shown in their attitude toward functional disease, which alone they claimed to be able to treat. Now, the only difference in this connection between organic and functional disease was that in the former the causes and the mode of development were known and could be worked with, whereas the term functional was a confession of ignorance on the part even of those best informed about these very facts. Thus the reasoning reduced itself to absurdity. The mental healers, with no knowledge whatever, stated that they did not pretend to understand those diseases which medical science really knows much about, but, in their simplicity and guilelessness, they pretended to be able to do the much more difficult thing of treating these diseases, the key for the understanding of which medical science, after long research, had not yet been able to find. Glancing at the gross classification of therapeutic measures, we found four prominent methods of treatment: hypnotism, suggestion, reeducation, and psychoanalysis. Hypnotism, it might be stated, applied to primitive minds alone, the type of mind which received everything unconditionally. The operator simply piled mere facts on the mind of the hypnotized subject. As to suggestion, it was not as simple a matter as many supposed. In order to get a mental fact in, one often had to be very careful, and it was necessary to employ what might be called subterranean methods. The Dubois method, the speaker said, he believed to be fundamentally sound. It was a kind of reeducation, and the ways of accomplishing this differed in different classes of patients. Psychoanalysis had a limited yet very important application, and could usually be employed with success only in the case of individuals of a particular kind of mentality. There were some persons, psychoneurotics, who carried about with them, buried down deeply, sore spots in the soul. These buried and incompletely adjusted complexes were not clearly recognized by the individual, and hence they had to be dug out by the various methods of psychoanalysis. The three chief modes of approach to these hidden sources of disturbance were free association, as originally outlined by Freud and now expanded, the system of word association, as elaborated by the Zurich school, and the analysis of dreams, as suggested by Freud. In actual practice we used all three methods, and others in addition. The disentombment of the complex, turning it over to the light of free consciousness, caused its catharsis and cured the patient.

Dr. Graeme M. Hammond said that the question which concerned most physicians was, What has psychotherapy done for medicine? Has it added anything to our ability to shorten the time in treating disease? This method of treatment was nothing new. Long ago Charcot had adopted the practice of pressing a disk of gold on the nape of the patient's neck, afterwards substituting rubber for this. In this procedure he simply made use of the influence of suggestion. There was a good deal in psychotherapy, and one of the first organizations to realize this was the so-called Christian Science Church. Eddyism had been established on the ignorance of doctors. Suggestion had an immense influence in neurasthenic females, and it remained for a woman to make practical use of this. There would be no objection to Christian Science if it were called by its proper name, suggestion. Its success showed that we had at our disposal a means which was very useful in appropriate cases. We now knew more about psychotherapy than formerly. As to Freud's method, it was a fact that everyone liked to talk about his own case, and the mind was relieved by discussing its troubles. The idea of a *trauma* was ridiculous and absurd. These mental diseases were caused by worry, grief, etc. The Weir Mitchell rest cure was itself suggestive therapeutics. Dr. Hammond said that in his own practice he used suggestion constantly. There was no one who was not more or less influenced by suggestion, and certainly no one more powerfully than the neurasthenic. By this means hope could be instilled into the mind of the despairing patient, and the dread from which he had been suffering became dissipated. He was often in a state of fright, fearing some catastrophe, as suicide or the onset of insanity, or believing that he had contracted some incurable disease, such as organic heart trouble. When the actual condition of affairs was explained to him he would get well, his mind being relieved by the removal of his fear and doubt. This was the part which suggestion played, and it was a *bona fide* and efficacious mode of treatment in such cases. We could, however, easily overdo it, and it was therefore essential to treat each patient in accordance with his characteristics. When you had won the intelligence of the patient, and thus secured his confidence, you had accomplished much. When we came to analyze the Freud and the Dubois methods, suggestion and Christian Science, it would be found that they all came down to the same thing, the influence of the physician or operator on the patient's personality.

Dr. George W. Jacoby said that in all scientific questions, and especially medical ones, it was a good plan to stop now and then and, so to speak, take an account of stock. In times long past all psychic trouble was looked upon as a result of moral turpitude, with the effect that the treatment, so-called, consisted in an endeavor to drive out the bad spirits which had taken possession of the sufferer. The advance in the natural sciences then created a complete reversal of ideas. The dualistic conception of the separation of body and soul was overthrown and replaced by the concept of the interdependence of brain and mind. Then science laid special stress upon the dependence of the *psyche* upon the brain, and psychology gave place to a study of brain physiology. With this materialistic conception, our treatment of psychic disturbances naturally also became materialistic, and of late years, he regretted to say, one-sidedly materialistic. Hydrotherapy, electrotherapy, rest cures, and medicinal treatment were carried on with the sole thought of their action upon the anatomical structures of the body. More recently the pendulum had swung backward, and much thought had been given to the psychic action of all our remedies. Psychotherapy to-day rested upon a psychological and physiological basis. This had brought with it much clearness in our concepts and much good to our patients; but the exaggerations of modern psychotherapy were also noticeable. In all psychotherapy the temptation was strong to give attention only to the mental symptoms. This, of course, was wrong, since psychotherapy could and must constitute but one part of our treatment in any given case. Knowing, as we did, that all mental action is quite as dependent upon physical processes as the latter are dependent upon mental action, we could not imagine any psychotherapy *per se*, but only a psychotherapy as a part of the general medical treatment of the individual. To what extremes this error of unilateral bias might lead was shown not only by the vagaries of Schlatterism, Eddyism, and Emmanuelism, but also by the edicts of a Dubois, who absolutely condemned the use of all aperients in chronic constipation and of hypnotics in any form of insomnia. Even not free from exaggeration was the system which of late years had attracted more attention than any other, that of Freud. While his psychological studies were undoubtedly of great scientific value, his method was open to much serious criticism. Thus, in the first place, his peculiar views as to

the origin of obsessions, it being stated by him that almost all have their origin in some sexual act committed in childhood. There could be no doubt that he exaggerated and overestimated this factor, and no doubt that he had by his method sometimes suggested memories of sexual occurrences where no such occurrences had taken place. Furthermore, by his method he produced a state of auto-suggestion, and with it an added hysterical state. The advantages which Freud himself claimed must to the practical man seem doubtful, since the length of time required to effect what he called a cure was from six months to three years, with daily sittings of one or more hours. Now, what he designated as a cure was freeing the patient from his false concepts; but if psychotherapy merely relieved a patient of his false concepts, and could not give him something positive and beneficial to replace them, the method must be looked upon as a failure. Therefore, practically, we had to have adjuvants. Here electricity, hydrotherapy, massage, etc., would have their place; but what we still required most for our patients was work of some kind, occupation, persistent and absorbing. This brought us to the question why psychotherapy might not be carried out by anyone but a physician. There could be no doubt that this, like all other medicinal, surgical, or mechanical therapy, belonged to the physician, and to no one else, not even the clergyman. Any remedy which was health-giving might also be disease-producing; and so it was with suggestion, the basis of all psychotherapy. Much hysteria might have been relieved by suggestion in the hands of clergymen and other unqualified persons, but certainly much hysteria had thereby been produced. The ill effects of any and every remedy could be avoided or relieved only by the schooled physician. In this there was no middle road; so that even the association of physician and clergyman was a partnership which could not be condoned. Having referred briefly to the subject of auto-suggestion, so-called, the speaker said that we must ask ourselves what was to be done in order to protect our patients against the craze of spurious psychotherapy which had taken possession of the public and which quacks and charlatans of all kinds were utilizing to enrich themselves. There was, he thought, but one answer to this question, and that was, the public must be educated, and we are the ones to do it. We were in possession of the proper facts, and we were the ones who should appeal directly to the public by means of popular lectures and books, and who should instruct them in the principles of psychology and give them a knowledge of true psychotherapeutics.

Dr. William M. Leszynsky said that this discussion was timely and valuable, as many members of the profession had an inadequate or erroneous conception of the prevailing views regarding practical psychotherapy. Again, others had given the subject no attention at all, or it received unjust condemnation or adverse criticism. On the other hand, there was an increasing majority who deemed it worthy of careful consideration. The viewpoints of the general practitioner and of the neurologist upon this topic were essentially different, and often more or less antagonistic. Psychotherapy should not be characterized as a method confined to special forms of psychological analysis, persuasion and hypnotic suggestion. Within its sphere we must include isolation, educational methods (physical, moral, and intellectual), healthful occupation and diversion, encouragement, etc. An idea might be pathogenic or therapeutic. According to circumstances it might prove beneficial or malign. One did not always realize the immediate or remote effect upon the patient of some inadvertent or discouraging remark. Many susceptible and sensitive persons were thus unfavorably influenced, and their subsequent brooding was not satisfactorily neutralized by the accompanying prescription. The man who thoughtlessly told his patient there was no hope for him, or implied as much by his manner or remarks, was, to say the least, an undesirable representative of intelligent psychotherapy. Special methods of psychotherapy in nervous diseases, such as the reeducation method of Dubois, Freud's analytic method, and hypnotic suggestion, all had their limited fields of usefulness, and should be selected with careful discrimination. But any form of psychotherapy alone, in the vast majority of instances, could not successfully supplant a rational plan of modern medical treatment adapted to the individual and based upon the regulation of diet, habits and occupation, hydrotherapy, physical exercise, the judicious use of drugs, etc.

As an adjuvant to customary forms of treatment unsystematized psychotherapy was unconsciously or deliberately utilized by all physicians in their daily work; but its practice as a special or exclusive method presupposed special skill and training and was applicable only in suitable cases of hysteria, impulsive or irrepressible ideas, obsessions, hypochondriasis, etc. It required much time, patience, and perseverance, and its successful utilization depended, in a large measure, upon the personal influence of the physician and the receptivity, intelligence, credulity, and faith of the patient. It was more effective and permanent in its result under radical change of environment. In some psychasthenic cases a favorable opinion of the patient's condition, emphatically expressed in writing and presented to the patient, often proved more impressive and beneficial than repeated and, at times, almost interminable verbal assurances and reassurances. A number of his patients, the speaker said, had carried such letters about with them for several years, with the most satisfactory results. However, psychotherapy was by no means a panacea in the psychoneuroses, its usefulness being limited. The recent wave of public opinion, fostered by a superabundance of psychopathic literature, ranging from that based upon sound psychological principles to that of blatant self-advertising, had, naturally, resulted in overestimation and exaggeration of its importance. In an overzealous and, apparently, irrepressible activity in this direction the fundamental element of preliminary diagnosis had often been ignored, to the detriment of the patient and the ridicule of the medical profession. The profession and the public would, in due time, realize that attempts at the indiscriminate use of exclusive psychotherapy by untrained operators would inevitably result in a rapid increase in the ranks of the psychopaths. Whatever form of medical treatment was instituted, were it psychical, physical, or medicinal, it was the prerogative of the educated and specially trained physician, and should not be relegated to others.

Dr. Edward Wallace Lee said that he had studied psychotherapy for the last twenty-five years and he could not sanction it in any way. It might have been of some benefit in certain instances, but in many others it did harm. Foolish people were influenced by the Eddyites, who affected to consider all disease as an "error in human mind." The medical profession could not afford to countenance Christian Science in any way, and it seemed to him that the remarks of one of the speakers in reference to it were calculated to have a bad effect. It was to our shame that we were not in a better position to-day as regards such fraudulent practices. When he had made a correct diagnosis, and then only, the physician was competent to say whether such and such a treatment would prove of benefit or not. The medical profession had a great deal to contend with now, and from a selfish point of view, if for no other consideration, we had a difficult task to maintain ourselves.

The President, Dr. Wilcox, said that the presentation of the subject in these papers, each with its own line of thought, had been an illuminating one. It was noticeable that there was a great diversity of opinion in them, and not one of the four neurologists who had taken part in the

discussion was willing to express his entire confidence in either the Dubois or the Freud method. The case in its various aspects, it might be said, was now before the jury for its verdict; the jury being the great body of general practitioners. He would like to hear from one or more of these. It would appear that the proper field of psychotherapy was an exceedingly limited one and that its practice would be most successful when under the direction and absolute control of the educated physician, while its reputation as a remedial method would suffer from the unwarranted exploitation of its more or less ill-informed lay advocates.

Dr. Fisher, closing, said that the general idea in his paper was to take up the question of psychotherapy and to protest against its employment as a separate entity, a special school of treatment. There was unquestionably in it a great deal that was excellent. The important thing to decide was who should practise it. However much benefit there might be in mental suggestion we should not lose sight of the danger of depending upon that alone, or of the very limited field in which psychotherapy was applicable. There might in any given case be some grave physical condition upon which this kind of treatment could have no effect, and there was presented, therefore, the danger of failing to recognize this until it was too late for treatment of any kind to be of service. In the last twenty years nothing very novel had been promulgated in the department of psychotherapeutics, although we were now better qualified than formerly to discriminate in the matter. Dubois' book was filled with beautiful thoughts and no one could read it appreciatively without an inclination to lead a better life. But in it we did not find any definite line of treatment. There was simply the kind of advice which all of us on occasion would give to some friend in trouble. In Freud's work, on the other hand, there was a definite method of treatment, which any one, after a proper study of the subject, could carry out. But the question arose, Is the Freud treatment, after all, of any real benefit? If we failed to get results from the method in any given instance the disciple of Freud would be sure to say to us, "But you did not treat the case properly." The difficulty about the system was that it was not generally practicable, requiring too much time. Dr. Fisher said his own position was that the practice of psychotherapy should always be associated with proper medical treatment, as commonly understood. He had not taken up the matter of Christian Science because, this being a religious cult and not simply a method of treatment, it involved a wider field than we were now considering. But he did think that we could make use of psychotherapy as an adjuvant to the ordinary forms of treatment, and that we ought by all means to discourage any attempt to establish it as a separate school of therapeutics.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 13, 1910.

Dr. Eli Long in the Chair.

Report on the Use of Ehrlich-Hata Preparation for the Cure of Syphilis.—Dr. Herbert Budington Wilcox presented a girl, twelve years old, who was first seen at the Bellevue clinic suffering from periostitis and muscle pains of syphilis in November, 1909. After some weeks' treatment in the children's ward she returned to the clinic and was under weekly observation until August, when she developed a keratitis with severe inflammation of the entire eye, considerable hemorrhage, and marked photophobia. Under the usual treatment there had been no improvement at the end of two weeks; then Dr. M. S. Kakels injected 3 decigrams of Ehrlich's 606. In twenty-four hours the evidences of acute inflammation had almost subsided. The photophobia was correspondingly diminished. In the six days following the exudate and hemorrhage were rapidly absorbed and now the cornea was nearly clear. There was considerable pain and swelling at the site of the injection for forty-eight hours. The temperature rose to 101° F. on the second day, and was normal on the fourth day. The urine was examined daily and was negative throughout. There was a leucocytosis of 20,000 on the second day; this dropped to 12,000 on the fourth day. The Wassermann reaction showed a gradual reduction in intensity, being very weak at present. This patient illustrated the remarkable effect of the preparation of Ehrlich's on an acute inflammation due to the syphilitic poison. As illustrative of the action of the drug in clearing up products of inflammation, Dr. Wilcox reported the case of a boy, nine years old, who had a double keratitis which left him with barely light perception. He was sent to Bellevue for treatment. He was given 3 decigrams of Ehrlich's 606 and had no local reaction. The urine remained normal. The temperature rose to 101° F. on the second day. There was a leucocytosis of 15,000 for two days. On each of the six days following the injection there was noticeable lessening of the opacity in both eyes and at the end of ten days he was able to distinguish small objects at a distance of five feet. The first patient gained eight pounds in two weeks following the injection. No record was kept of the weight of the boy.

A Case of Hereditary Syphilis.—Dr. Charles Herrman reported this case. The mother had been injected with Ehrlich's 606. The patient was a baby at the breast and received the supposedly curative substance in the mother's milk. He said that several cases had been treated successfully in this way by German physicians. Thus far, six days after the injection, the patient had not shown any distinct signs of improvement. It was extremely important that cases of hereditary syphilis should have breast milk. It had been suggested that in cases in which the mother was unable to give the breast a syphilitic wet nurse should be injected with 606 and the baby nursed at her breast.

Dr. Alfred F. Hess reported three cases of hereditary syphilis treated with Ehrlich's preparation: in all disagreeable local symptoms developed after the injection into the buttocks. In one instance, a miserable marantic child developed necrosis six weeks after the injection. The children all had temperatures. The syphilitic symptoms disappeared. The injections were made by an experienced man and the solutions were neutralized.

A Case of Congenital Cardiac Disease without Cyanosis.—Dr. F. L. Wachenheim presented a child, six years old. When examined six months ago there were positive signs of an open intraventricular septum and ductus arteriosus, with stenosis of the pulmonary conus. There was a loud murmur over the pulmonary site. In spite of the cardiac lesions there was no cyanosis. The relative frequency of this condition was referred to.

Dr. William P. Northrup said that the question of the noise heard in the child's chest depended upon the relation of the pressure on the two sides and the size of the openings. He made a diagnosis of congenital pulmonary lesion. He said he had made a number of autopsies on these cases and he had verified about eight of them.

Dr. L. E. La Fetra said that at the Vanderbilt Clinic he probably saw one instance every month of these congenital cardiac cases without cyanosis. It should be kept in mind, on the one hand, that marked congenital murmurs with no cyanosis were not at all uncommon; and that, on the other hand, there might be extreme cyanosis and clubbing of the fingers with absolutely no murmur to indicate the congenital heart deformity. In all doubtful cases examination of the blood might be of value since a high

hemoglobin and a red cell count of over five million would indicate congenital heart disease.

A Case of Hysterical Singultus.—Dr. Sara Welt-Kakels presented a girl, twelve and a half years old, who had hysterical singultus lasting four and a half weeks. During the past six months she had occasional hiccough, lasting but a few minutes at a time. Six weeks ago she received a sudden fright and two weeks later her present condition appeared which had persisted. The hiccoughs ceased during the night but started immediately upon awakening. She complained of pain in the epigastrium. The singultus occurred about twenty-four times to the minute and appeared to be worse when she was being examined. In making a differential diagnosis of these cases it was important to remember that persistent singultus occurred in diseases of the gastrointestinal tract and of the peritoneum; it also might depend upon direct lesions of the phrenic nerve. It might occur also in myelitis (cervical portion of the cord). The treatment consisted in rhythmic traction of the tongue, compression of the lower half of the thorax, and insertion of the esophageal tube. Electricity, hydrotherapy, opium, and chloroform were productive of good results. Hysteria was found more frequently in boys during childhood than at a later period of life, and was characterized by the absence of stigmata. The prognosis was better among children than in adults because it was easier to influence the child's mind. The treatment was solely psychic.

Dr. William P. Northrup said he was struck by the suggestion of placing such children in a hospital and recalled the case of a girl who was said to have epilepsy. When she was brought to the hospital she had twenty-seven epileptiform convulsions on the first day and the same number of fits on the second day. She was placed in a ward and her convulsions dropped shortly to twelve a day. After three weeks the number was reduced to six a day and soon ceased entirely. She remained in the hospital three months and the fits did not return. She went home and again the epileptiform convulsions appeared. Here entered the question of the home life. The parents talked about fits before the child. The people smoked and pow-wowed up to midnight when the child was present. At home the attacks kept up. She was returned to the hospital, placed on ward diet and ward regulations with the same effect as before; the epileptiform convulsions ceased. Her seeming entire recovery was the only reason Dr. Northrup gave for thinking these attacks might have been hysterical rather than epileptic.

Purpura Hemorrhagica in a Boy Five Years of Age Successfully Treated with Human Blood Serum.—Dr. Charles Gilmore Kerley reported this case which he had seen in consultation. The family history of the patient was negative. His tonsils and adenoids had been removed six months before his present illness with no more than the usual bleeding. On June 15th he was taken ill and for a week his temperature ranged between 100° and 102° and numerous subcutaneous hemorrhages occurred at various sites over the body, but more particularly on the legs. A large hematoma developed in the abdominal wall and there was some bleeding of the gums. There was also moderate bleeding from the bicuspid tooth. The child was given calcium lactate, three grains every three hours. The hemorrhage from the gums ceased and the subcutaneous hemorrhages began to show signs of absorption. On July 7th there was a hemorrhage from the nose which lasted one hour and on the following day another which lasted five hours and resisted all ordinary efforts at control. The calcium lactate was resumed in ten grain doses every two hours. Normal salt solution was given into the colon by the drop method. The stools consisted largely of coagulated blood. On July 10th a nasal hemorrhage began again and lasted five hours. The child was in an extreme condition and 30 c.c. of human blood serum were injected hypodermically by Dr. Welsh. During the remainder of the day from 45 to 60 c.c. of human blood were injected at two-hour intervals, the entire amount injected being 290 c.c. On July 11th there was a moderate nasal hemorrhage, after which 167 c.c. human blood was injected in three doses. On July 12th there was no visible hemorrhage from any portion of the body. Four hypodermics of human blood serum were administered, the total amount being about 191 c.c. During the following three days three injections of serum were given daily, then two injections were given daily for two days. From this time the child made a slow but steady improvement and eventually a perfect recovery. The hemorrhage, which had continued intermittently for three weeks, ceased within fifteen hours after the first injection of the human serum, and it seemed beyond a possibility of doubt that the serum had saved the life of the child.

Mechanical Injuries (Blows, Falls) of the Head in Infants and Children; the Necessity for Immediate Treatment; What This Should Be.—Dr. H. Illoway said that children fell against tables, chairs, rocks, etc., or were struck upon the head in the course of play; they cried for a while, were often soothed to quietness and soon all was forgotten until sooner or later some one or other of the symptoms of cerebral concussion manifested itself. Though it was true that in a great number of the instances the traumatism had been of a trivial character, so slight that the brain was not at all affected thereby, it was equally true that it was the cause of serious and, not infrequently, fatal disease. It had been said by eminent pediatrists that only traumatisms of such great violence as to cause fracture of the skull were followed by cerebral disease; Dr. Illoway's experience contradicted this statement. No one could tell whether a fall or a blow upon the head would engender cerebral disease; in a certain proportion of such cases such injuries were followed by grave cerebral disease and, therefore, it was the physician's duty to prevent, if possible, the grave consequences. Tumors of the brain and its coverings were not of rare occurrence in childhood. Though it was true that a very large percentage, 50 per cent. according to Read, was said to have been of a tuberculous nature, there still remained a large percentage the etiology of which was as yet in total obscurity. It was not improbable that in many of these cases the first impulse to the development of a growth was a fall upon the head or a blow received in the course of play, an accident quickly forgotten in the rapidly moving life of childhood. In all traumatisms of the head there was, if nothing more, a cerebral concussion. The brain cells might be injured and an inflammatory condition develop with a tendency to pus formation or abnormal cell growth. The treatment that was imperatively indicated was to allay all irritation as quickly as possible and to further the restoration of the injured brain structures to the normal. Any child who had suffered such a traumatism should be kept in bed. Two very important effects of calomel, not clearly set forth in the books of to-day, he called attention to, namely, (1) calomel was a most potent remedy to allay vomiting; (2) it had a decided antiphlogistic action on the brain and its coverings, as well as on the spinal cord. It was, under the circumstances here treated of, the opium of the brain. By means of its antiphlogistic action one could effect what could not be accomplished with bromides and the various hypnotics.

Nitrogen Metabolism in Normal (Artificially Fed) Infants.—Dr. B. Raymond Hoobler read this paper in which he called attention to the fact that metabolism work thus far had been done mostly on sick babies and that until normal metabolism could be defined through the study of a sufficient number of normal infants it was rather dif-

ficult to draw conclusions from the study of abnormal cases. The study presented was a portion of a metabolism problem which involved the determination of the nitrogen, fat, sulphur, magnesium, and calcium in the food, urine and feces covering a nine days' period, divided into three periods of three days each. The child used for the study was a robust infant, nine months of age, who was fed on three different cow's milk mixtures, involving the use of certified whole milk, fat free milk, and 16 per cent. cream, which, when modified, represented a low fat, medium fat, and high fat formula. The child was kept on a definite formula for two days before being put in the frame for three days and was given a ten days' rest between the three-day periods. The urine was collected daily and the total nitrogen, urea, ammonia, and kreatinin determinations were made the same day, and also the tests for acetone, diacetic acid and beta oxybutric acid and total acidity. The feces were also collected in daily quantities except on two occasions when forty-eight-hour specimens were collected. Throughout the experiments the results were compared with those obtained by Keller and by Rubner and Heubner, who were the only other investigators who had published similar experiments—their children being three and seven and one-half months of age, respectively. The subject of the present study gained in weight while those of the other investigators lost, which seems to indicate that the others were underfed. The percentage of fat and proteid used in the present study was as follows: In the first period, called the "low fat" period, the fats were 2.1 and proteid 4.1; in the second period, called "medium fat," fats were 4.0 per cent. and proteids 3.5 per cent.; and in the period called "high fat" the fats were 5.5 per cent. and proteids 3.34. In the "low fat" period the child took 53.1 grams in 24 hours, in the "medium fat" period 44.8 and in the "high fat" period 43.4 grams. The study included the determination of the amount of nitrogen excreted by both the feces and urine during the three periods, both daily and average amounts, and the absorption of nitrogen in percentages and in grams per kilo of weight. The author thought that one case did not warrant any definite conclusions, but he made the following observations. 1. Nitrogen was absorbed exceedingly well by healthy children. 2. The percentage of absorption at varying ages was about the same, even though the intake of nitrogen per kilo differed greatly. 3. Nitrogen absorption was carried on equally well under low, medium, and high fat feeding. 4. The per cent. absorption varied little from day to day. 5. Nitrogen absorption was not affected by a condition of mild acidosis. In regard to retention of nitrogen the author observed: 1. The proportion of food nitrogen which was retained was about one-third. 2. The per cent. retained was about the same for the three ages under discussion. 3. Retention took place in about the same per cent. whether the infant was fed on low, medium, or high fat. 4. Percentage of nitrogen retained remained about the same whether fed on low, medium, or high protein. 5. In high proteid feeding a large amount of nitrogen was absorbed and eliminated, thus causing more work to be performed by the infant than when on a lower proteid feeding. 6. Body weight might diminish on a fair nitrogen retention. In regard to nitrogen elimination it might be observed that: 1. Nitrogen was largely eliminated through the urine. Considerably more than half of the nitrogen ingested was excreted in the urine. 2. A very small quantity was found in the feces. 3. The increasing per cent. of ammonia nitrogen in the urine is an index of acidosis.

Dr. Herbert Budington Wilcox said that the question of nitrogen metabolism was particularly applicable in the use of Finkelstein's Eiweiss-Milch in infant feeding. This had been the routine diet in Bellevue for the last three months. The average child in the ward weighed less than nine pounds and took daily from his food, which contained 2.8 per cent. proteid, about 6 grams nitrogen. Apparently all the nitrogen ingested must be absorbed and excreted. The digestion had no means of avoiding the nitrogen task set it by the diet, and the working over of so large an amount for a considerable space of time must represent a metabolic strain. After from two to three weeks of such feeding every one of these children began to have too frequent and large, although perfectly normal, stools and, at this point, were likely to lose in weight. It was an interesting question how much bearing the excessive nitrogen metabolism had on this intestinal condition; and whether it evidenced an attempt on the part of the body to aid in the elimination of the large amount of nitrogen ingested.

Dr. L. E. La Fetra said that the figures presented were very interesting and there were two practical conclusions which might be drawn from even this single case which Dr. Hoobler had so thoroughly worked out. In the first place he would emphasize that while the nitrogen feeding had its advantages it had also certain disadvantages. For instance in cases of diarrhea the use of Eiweiss Milch, as indeed of fat-free buttermilk, permitted giving food much earlier and food of a higher caloric value than had been found possible heretofore. This treatment prevented the severe loss of weight in such cases. On the other hand there was the disadvantage of high proteid feeding that so little of the increased nitrogen was retained, only about one-third in the case of cow's milk preparations. This was in great contrast to the much larger quantity retained when breast milk was given. The retention of so little nitrogen meant that high proteid feeding necessitated a great amount of work on the part of the organism to eliminate the two-thirds of the increased nitrogen, a process which was presumably a strain on the metabolic energy of the child. If breast milk was given, of course very much less nitrogen elimination would be necessary. Notwithstanding that breast milk had a lower proteid than cow's milk, it was necessary, on account of the smaller retention of nitrogen in artificial feeding, to use a higher quantity of protcid; but extremely high proteid undoubtedly placed a strain on the organism. The second conclusion to be drawn from the tables was that there was danger of acidosis from the use of high fats. Notwithstanding that the patient showed no nervous symptoms, the urine contained evidences of acidosis, and therefore the child was in danger of a nervous explosion. This must always be remembered when high fats were prescribed.

Dr. Henry Dwight Chapin said that he had often observed the diarrheal stools to improve in character, but the babies did not seem to gain in weight on the Finkelstein feeding. One should give the babies a high proteid diet, but apparently this did no good for they could not take care of it.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Virginia State Board of Medical Examiners.

June, 1910.

ANATOMY.

1. Describe the spine and give the general characters of vertebra.
2. Name and describe the muscles of the orbit.
3. Name the branches of the axillary artery and give its relation in its third portion.
4. What is the lymphatic system? Describe the thoracic and right lymphatic ducts.
5. Name the nine regions into which the abdomen is divided, giving their boundaries and contents.
6. Describe the superior radio-ulnar articulation.

HISTOLOGY.

1. (*a*) Name the elementary tissues of the body and give the morphological constituents of each. (*b*) Describe a cell.

2. Name the varieties of muscle tissue and give general distribution of each variety.

3. Give the two principal component parts of the nervous system. Briefly describe and give function of each.

4. Give the histological structure of the stomach.

EMBRYOLOGY.

1. What relation do the Wolffian ducts and the ducts of Muller bear to the sex of the fetus?

2. What is the difference between the human ovum and the ovum of the fowl as regards the nourishment of the embryo?

PHYSIOLOGY.

1. Give distribution and chief functions of vagus.

2. What is meant by an afferent impulse; an efferent impulse; by reflex act?

3. Give names and locations of the three salivary glands, with the manner of communicating with the mouth.

4. What part does saliva play in digestion?

5. Give composition of bile and its function in digestion.

6. What channels does the blood pass through in the systemic circulation, from leaving the heart till return to same? What changes take place in blood in each channel?

7. Describe the pulmonary circulation, giving changes in blood in same.

8. What is the lymphatic system?

9. How is heat dissipated from the body?

10. What organs eliminate soluble systemic poisons from the body?

CHEMISTRY.

1. Give preparation, properties, and uses of N_2O.

2. Give preparation, properties, and uses of (1) chloroform, (2) iodoform.

3. Name salts of K, and give preparation and medical uses of any two.

4. Give preparation of (1) ether, (2) chloral hydrate.

5. What is the periodic law?

6. Name three organic acids, and give description of two compounds of such acids used in medicine.

7. Name three sorts of sugars.

8. What changes occur in sugar solutions exposed to air?

9. What are the ordinary chemical substances used to produce soap?

10. Name four vegetable active principles used in medicine.

11. Name three mineral acids, with formula for any two.

12. Name following, any two:

(1) $C_2H_4O_2$ (3) $KMnO_4$ (5) C_6H_6O
(2) C_2H_2 (4) $Ca(ClO_3)_2$ (6) HNO_3

MATERIA MEDICA.

1. Define the following terms, giving an example of each: Alteratives, narcotics, diuretics, emmenagogues, mydriatics.

2. Define and classify anesthetics, naming the more prominent of each class, and state which you regard the safest general anesthetic, giving the main reason why you so regard it.

3. Give doses of the following: Hydrochloric acid dilute, hydrocyanic acid dilute, oxalate of cerium, chloral hydrate, codeine sulphate, creosote, strychnia sulphate, tincture strophanthus, and atropia sulphate.

4. Give sources from which cinchona is obtained and mention its main salt and alkaloid.

5. From what is the alkaloid hyoscine obtained, what is the dose and how best administered?

6. Classify astringents, with reference to the sources from which they are obtained and give one or more examples of each class.

7. Name several leading antipyretics and state in general how they reduce temperature.

THERAPEUTICS.

1. Give modes of administering drugs, and a good rule for dosage to children.

2. Give four general indications for diuretics.

3. What three ill effects sometimes develop during administration of digitalis, and what is its best substitute?

4. Write a prescription for four doses, containing four drugs, having active cholagogue properties.

5. Give indications and contraindications for use of ergot.

6. What are the general indications in the treatment of poisoning by drugs?

7. Give symptoms and treatment for poisoning by carbolic acid.

8. Differentiate the coma resulting from opium, uremia and alcohol.

THEORY AND PRACTICE OF MEDICINE.

1. Give treatment and management, in general, of typhoid patient, during and immediately following profuse intestinal hemorrhage.

2. Give period of incubation and symptoms of smallpox.

3. Differentiate lobar from bronchopneumonia.

4. Give symptoms of acute uremia.

5. Give gross pathology of hypertrophic cirrhosis of liver.

6. Give treatment of acute nephritis.

7. Define (*a*) hydronephrosis; (*b*) empyema; (*c*) chlorosis; (*d*) Graves' disease; (*e*) sciatica.

8. Name the important complaints of acute articular rheumatism.

9. Name five important symptoms of tabes.

10. Give causes of arteriosclerosis.

OBSTETRICS AND PEDIATRICS.

1. Give relative diameters of inlet and outlet of the true pelvis and fetal skull.

2. Give preparation of patient, solutions, dressings, room and bed during labor.

3. Describe an up-to-date obstetrical bag and its contents.

4. Technique of applying and delivering by forceps a R. O. P. position, the head being through the cervix, but not on the perineum.

5. Course and treatment of (*a*) primary uterine inertia; (*b*) secondary uterine inertia.

6. Causes, symptoms and treatment of phlegmasia alba dolens.

7. Diagnosis and treatment of early hereditary syphilis in infants.

8. Give the handling and care of cow's milk in order to be able to dispense with pasteurization of the same for infant feeding during the summer months.

9. Give clinical manifestations of acute infantile paralysis.

10. Give causes and treatment of acute ileocolitis.

SURGERY.

1. What is surgical shock? How managed?

2. What is the difference between an acute abscess and a purulent infiltration?

3. Describe the appearance, symptoms, and management of a syphilitic leg-ulcer.

4. Differentiate fractures and dislocations.

5. To what are hemorrhoids due? How many forms, and how treated?

6. Differentiate an incarcerated from a strangulated hernia. What other conditions may be mistaken for them?

7. Give detailed description of an amputation at midforearm. Include technique (preparatory and operative), describe each step in regular order, until dressing is complete.

GYNECOLOGY.

1. What conditions may produce leucorrhea?

2. To what may dysmenorrhea be due, and how best remedied?

3. To what symptoms would a medium perineal laceration give rise?

4. Differentiate pregnancy, retained menses, and uterine fibroid.

5. What are the evidences and manifestations of approaching puberty?

PATHOLOGY AND BACTERIOLOGY.

1. Define the terms thrombus and embolus, giving the causes and results of each.

2. Explain the occurrence of the metastatic abscesses characteristic of certain infectious diseases.

3. Name the diseases in which intestinal ulceration is an essential feature. Name the portion (or portions) of the intestinal tract in which the ulceration is found in each of these diseases.

4. Describe the phenomena, or signs, of inflammation, illustrating the subject by describing the formation of a common boil (furuncle).

5. Name the variety of degeneration termed cloudy swelling. Name the class of diseases in which it commonly occurs.

6. Name the class of tumors under which the carcinomata are grouped histologically. Name the subvarieties of carcinomata.

7. Give the bacteriology of erysipelas, syphilis, puerperal infections, and basilar meningitis.

8. Explain the mode of infection in the malarial fevers, typhoid fever, tuberculosis, and tetanus.

9. Define the term protozoa. Name two pathogenic protozoa and the disease which each causes.

10. Give a typical example of an obligate parasite, and of a facultative parasite. Does the colon bacillus ever become parasite in nature?

MEDICAL JURISPRUDENCE.

1. Name six signs of death.

2. How soon after death does rigor mortis set in, and to what is it due?

3. How can you determine that a body has been burned during life or after death?

4. What is infanticide?

5. Define illusion.

TOXICOLOGY.

1. What is the first thing you would do in being called to a case of poisoning?

2. Name two reliable emetics with dosage.

3. Give the best general antidote for (*a*) arsenical preparations; (*b*) mineral acids.

4. Give symptoms of acute phosphorus poisoning.

5. Give treatment of carbonic acid gas poisoning.

HYGIENE AND PREVENTIVE MEDICINE.

1. How does standing water purify itself?

2. Give an efficient method of rendering river water suitable for town consumption.

3. In the disposal of sewage, which is the more effective: the intermittent or the continuous flow, and why?

4. Give a cheap and effective formula for disinfecting privies and water closets.

5. How would you manage an epidemic of scarlet fever, and how would you disinfect clothing and rooms?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

VIRGINIA STATE BOARD OF MEDICAL EXAMINERS.

June, 1910.

ANATOMY.

1. For *Spine*, see Cunningham's "Anatomy" (1909), page 88; or Gray's "Anatomy" (1908), page 67. The *general characters of a vertebre* are: Body or centrum, arch, two pedicles, two laminæ, four articular processes, two transverse processes, and one spinal process.

2. See Cunningham's "Anatomy" (1909), page 399; or Gray's "Anatomy (1908), page 374.

3. The *branches of the axillary artery* are: Superior thoracic, acromial thoracic, long thoracic, alar thoracic, subscapular, anterior circumflex, and posterior circumflex. *Relations of third part of axillary artery: In front:* Skin, fascia, pectoralis major, and inner head of median nerve. *Behind:* Subscapularis, latissimus dorsi, teres major, circumflex and musculospiral nerves. *Outer side:* Median and musculocutaneous nerves and coracobrachialis. *Inner side:* Axillary vein, ulnar nerve, and lesser internal cutaneous nerve.

4. See Cunningham's "Anatomy" (1909), pages 904 and 906; or Gray's "Anatomy" (1908), pages 772 and 775.

5. The regions of the abdomen and their contents are shown in the following table. It is to be remembered that the contents will vary according to the position of the lines drawn; these are arbitrary, and nearly every writer differs from every other. In the following table the superior horizontal line extends between the cartilaginous ends of the tenth ribs, the inferior between the anterior superior iliac spines. The vertical lines pass upward from the iliopectineal eminences, at right angles to the upper horizontal line.

The viscera situated in each region are as follows:

RIGHT HYPOCHONDRIAC.	EPIGASTRIC.	LEFT HYPOCHONDRIAC.
Liver.	Liver.	Stomach.
Right Kidney.	Stomach.	Spleen.
Hepatic flexure of the colon.	Gall-bladder.	Left kidney.
	Duodenum.	Splenic flexure of the colon.
	Pancreas.	
RIGHT LUMBAR.	UMBILICAL.	LEFT LUMBAR.
Right kidney.	Transverse colon.	Small part of left kidney.
Ascending colon.	Duodenum and small intestines.	Descending colon.
Ileum.	Great omentum.	Small intestines.
RIGHT ILIAC.	HYPOGASTRIC.	LEFT ILIAC.
Cetum.	Small intestines.	Sigmoid colon.
Appendix.	Bladder in children.	Small intestines.
Last coil of ileum.	Distended bladder in adults.	
	Pregnant uterus.	
	Sigmoid colon.	

6. See Cunningham's "Anatomy" (1909), page 281; or Gray's "Anatomy" (1908), page 316.

HISTOLOGY.

1. The *elementary tissues of the body* are: Epithelial, connective, muscle, and nerve. They are all made up of cells and intercellular substance.

A typical cell is the ultimate element of structure; it enters into the formation of all tissues. It consists of a tiny mass of protoplasm, and contains a nucleus and an attraction sphere, but as a rule no cell wall. Cells vary in shape and size (from about 1-3000 to 1-300 of an inch in diameter), and are characterized by power of movement, assimilation, growth, excretion, and reproduction.

2. *Varieties of muscle tissue:* (1) Voluntary striated muscle; (2) involuntary, non-striated muscle; (3) involuntary striated or cardiac muscle. (1) is found in skeletal muscles, pharynx, diaphragm, larynx, external ear and eye. (2) is found in the alimentary tract, trachea, bronchi, arteries, ureter, bladder, uterus. (3) is found in the heart.

3. See Cunningham's "Anatomy" (1909), page 443; or Gray's "Anatomy" (1908), page 815.

4. See Cunningham's "Anatomy" (1909), page 1058; or Gray's "Anatomy" (1908), page 1281.

EMBRYOLOGY.

1. At an early stage the fetus contains an indifferent sexual gland, together with duct of Muller and the Wolffian duct. Later the gland becomes either testis or ovary; and in the male, the duct of Muller atrophies, and disappears (except at its extremities); while in the female the Wolffian duct atrophies or degenerates.

2. In the *human ovum* the protoplasm and deutoplasm are uniformly distributed; in the *ovum of the fowl* the deutoplasm accumulates to one side of the ovum.

PHYSIOLOGY.

1. *Distribution of vagus:* To dura, external ear, pharynx, larynx, heart, lungs, esophagus, and stomach. *Functions:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs: (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc." (Kirkes' *Physiology.*)

2. An *efferent impulse* is one that is conveyed away from the nerve centers; an *affrent impulse* is one that is conveyed toward the nerve centers. A *reflex act* is an involuntary or unconscious act due to a suitable stimulus. It depends upon the integrity of the *reflex arc,* which is a complex made up of (1) A surface capable of receiving an impression; (2) an efferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

3. *Parotid gland* is situated on the side of the face below and in front of the ear; it communicates with the mouth by Stenson's duct. *Submaxillary gland* is situated below the mandible, in the submaxillary triangle; it communicates with the mouth by Wharton's duct. *Sublingual gland* is in the floor of the mouth, at the side of the frenum of the tongue; it communicates with the mouth by the ducts of Rivinus.

4. Saliva by the ptyalin, aids in digestion of starches; the ptyalin converts them into dextrin and sugar.

5. *Bile* is composed of water and solids; these latter are sodium glycocholate, sodium taurocholate, mucin and pigments, cholesterin, lecithin, fats, salts (both soluble and insoluble).

The *functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis; and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in

converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

6. The blood passes through arteries, capillaries and veins. The changes occur in the capillaries, where the blood gives up nourishing material to the tissues and receives from them waste matter; in this way the blood is changed in character from arterial to venous.

7. For pulmonary circulation, see Cunningham's "Anatomy" (1909), page 991; or Gray's "Anatomy" (1908), page 1404.

(*b*) In its passage through the lungs, the blood in the pulmonary artery: (1) becomes cooled; 2; becomes a brighter red color; (3) gains oxygen (about 10 or 12 volumes); (4) loses carbon dioxide (about 7 volumes).

8. See above, ANATOMY, question 4.

9. *Heat is given off from the body* by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

10. The liver, lungs, kidneys, skin, and intestines.

CHEMISTRY.

1. PREPARATION OF N_2O. By heating ammonium nitrate: $NH_4NO_3 + \text{heat} = 2H_2O + N_2O$.

Properties: It is a colorless, odorless gas, with a sweetish taste, heavier than air, slightly soluble in water, is a supporter of combustion. It has (when inhaled) anesthetic properties. *Uses:* As an anesthetic, chiefly for short operations.

2. CHLOROFORM. *Preparation:* By heating chloral hydrate with potassium hydroxide: $C_2HCl_3(OH)_2 + KOH = HCOOK + H_2O + CHCl_3$.

Properties: It is a colorless, volatile liquid, with a sweetish taste and a strong, peculiar odor. It is a good solvent for many substances not soluble in water. *Uses:* As an anesthetic and a solvent.

IODOFORM. *Preparation:* By heating alcohol, iodine, and potassium bicarbonate: $C_2H_5OH + 2I_2 + 2KHCO_3 = 2KI + 3H_2O + 2CO_2 + 2CHI_3$.

Properties: A yellow, crystalline solid with a peculiar penetrating odor; insoluble in water. It contains nearly 97 per cent of iodine. *Uses:* Treatment of wounds, sores, and ulcers; as a surgical dressing.

3. *Salts of K:* Chloride, bromide, iodide, nitrate, hypochlorite, chlorate, sulphates, dichromate, permanganate, acetate, carbonates, oxalate, tartrates, cyanide, ferrocyanide, ferricyanide:

POTASSIUM IODIDE is *made* by dissolving iodine in solution of potassium hydroxide. $3I_2 + 6KOH = KIO_3 + 3H_2O + 5KI$.

Medical uses: In syphilis, rheumatism, pleurisy, synovitis, arteriosclerosis, nephritis, lead and mercury poisoning, goiter.

POTASSIUM ACETATE is *made* by treating acetic acid with potassium carbonate: $2C_2H_4O_2 + K_2CO_3 = CO_2 + H_2O + 2KC_2H_3O_2$.

Medical uses: As a diuretic, diaphoretic, in rheumatism, gravel, irritation of the urinary tract, and in fevers generally.

4. *Ether* is prepared by the action of sulphuric acid on alcohol:

$C_2H_5OH + H_2SO_4 = H_2O + C_2H_5HSO_4$

$C_2H_5HSO_4 + C_2H_5OH = H_2SO_4 + (C_2H_5)_2O$.

Chloral hydrate is prepared by the action of water on chloral: $CCl_3CHO + H_2O = CCl_3CH(OH)_2$.

5. The periodic law of Mendelejeff states that "The properties of elements, the constitution of their compounds, and the properties of these latter are periodic functions of the atomic weights of the elements."

6. *Three organic acids:* Oxalic, tartaric, and citric acids.

Cerium oxalate is a white granular powder, odorless and tasteless, insoluble in water.

Lithium citrate is an odorless, white powder or colorless crystalline substance, deliquescent.

7. *Three sorts of sugars:* Monosaccharids, disaccharids, and trisaccharids.

8. Fermentation occurs.

9. Soaps are generally the sodium, or potassium salt of oleic, palmitic, or stearic acid.

10. Strychnine, morphine, aconitine, and digitalin.

11. Hydrochloric acid, HCl; sulphuric acid H_2SO_4; nitric acid, HNO_3.

12. (1) Acetic acid; (2) acetylene; (3) potassium permanganate; (4) calcium chlorate; (5) phenol; (6) nitric acid.

MATERIA MEDICA.

1. *Alteratives* are substances which in some unknown way modify the course of disease; *Ex.* mercury.

Narcotics are agents which produce, or tend to produce, deep sleep, and to relieve pain; *Ex.* opium.

Diuretics are agents which promote the secretion of urine; *Ex.* alcohol.

Emmenagogues are agents which promote the menstrual flow; *Ex.* apiol.

Mydriatics are agents which cause the pupil of the eye to dilate; *Ex.* atropine.

2. *Anesthetics* are agents which temporarily abolish sensation. *Local anesthesia* is the condition in which there is loss of sensibility of the tissues over a limited area, due to the application of certain agents, such as cold, ethylene chloride, ether, cocaine, eucaine, or the infiltration of water, or a solution of salt, or of salt, cocaine, and morphine. *General anesthesia* is a condition in which there is unconsciousness as well as abolition of sensation; it may be induced by the inhalation of ether, chloroform, nitrous oxide gas, chloride of ethyl, or a combination of certain of these agents. The safest general anesthetic is nitrous oxide; the mortality with this anesthetic is very much less than that with the other general anesthetics.

3. Dilute hydrochloric acid, ♏x-xx; dilute hydrocyanic acid, ♏ij-v; oxalate of cerium, gr. v; chloral hydrate, gr. x-xv; codeine sulphate, gr. j; creosote, ♏j-iij; strychnine sulphate, gr. 1/40; tincture strophanthus, ♏v; atropine sulphate, gr. 1/80.

4. Cinchona is obtained from several varieties of cinchona tree (cinchona calisaya, ledgeriana, officinalis, succirubra, condaminea, pitayensis, micrantha). Its main alkaloid is quinine; its chief salt the sulphate.

5. Hyoscine is an alkaloid of hyoscyamus; the dose of hyoscine hydrobromide is gr. 1/125; best given hypodermically.

6. *Astringents are:* (1) *Vegetable* (as tannic acid, catechu, rhus glabra); and (2) *Mineral* (as alum, lead, silver nitrate).

7. The following table (from Potter's "Materia Medica") gives the chief antipyretics with their manner of action. Temperature depression may be done by five different actions working upon two principal lines, viz., by—

(*a*) *Lessening heat production, by*
- (1) diminishing tissue change.
- (2) reducing the circulation.

(*b*) *Promoting heat loss, by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration—its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above-named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Antipyrin, 1, 4.
Phenol, 1.	Alcohol, 1, 3.	Antimony, 2, 4.
Salicin, 1.	Nitrous ether, 3, 4.	Cold bath, 5.
Digitalis, 2.	Acetanilid, 1, 4.	Cold drinks, 5.
	Phenacetin, 1, 4.	Wet-pack, 5.

THERAPEUTICS.

1. *Medicine can be administered:* (1) By the mouth; (2) by the rectum; (3) by inhalation; (4) by inunction; (5) hypodermically; (6) by intravenous injection; (7) by fumigation; (8) by cataphoresis.

To determine the proper dosage for a child: Let $x =$ the age of a patient; then $\frac{x}{x+12} =$ the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

2. Diuretics are employed: (1) To remove excess of fluid from the tissues, as in dropsy; (2) to dilute the urine; (3) to promote the elimination of waste products or poisonous material from the blood, and (4) to maintain the action of the kidneys.

3. *Three ill effects:* Nausea, indigestion, and syncope. The best substitute is strophanthus.

4. ℞ Extracti colocynthidis, gr. j.
Hydrargyri chloridi mitis, gr. viij.
Jalapæ resinæ, gr. iv.
Extracti colchici, gr. ij. Misce.
Fiat massa in pilulas no. iv. dividenda.
Signa: Take one at bedtime.

5. ERGOT. *Indications:*—To promote uterine contractions during third stage of labor; fibroids, menorrhagia,

post-partum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

Contraindications:—In labor if the birth canal is not free, and the os uteri is not dilated.

6. *General principles of treatment in poisoning:* "(1) Lose no time. (2) Use the best remedy obtainable at once. (3) Get rid of the poison. (4) Stop its action. (5) Remedy the mischief already done. (6) Fight against the tendency to death (Tanner). In the treatment of poisoning, whether by mineral or vegetable substances, if the poison is known the first indication is to administer the proper chemical *antidote*, so as to render it harmless or comparatively so. Next, the stomach should be emptied and washed out, lest the newly formed compound be absorbed after a time, also to remove any poison which may have escaped the action of the antidote. Next, the appropriate *antagonist* should be administered to counteract the effects of such portion of the poison as may have been absorbed. Lastly, such *antagonistic measures* should be employed as may sustain the action of any organic function showing signs of failure. In most cases of alkaloid poisoning absorption has proceeded so far before professional assistance is obtained that antidotes are of no value, hence reliance can be placed only upon the physiological antagonist and such supporting measures as will tend to maintain vitality until the poison can be eliminated by the natural channels."—(Potter's *Materia Medica*, etc.)

7. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The *treatment* consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal.

UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.

—(From Eisendrath's *Surgical Diagnosis.*)

THEORY AND PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1907), page 117; or Osler's "Practice of Medicine" (1909), page 103.

2. See French's "Practice of Medicine" (1907), page 301; or Osler's "Practice of Medicine" (1909), page 115.

3.

LOBAR PNEUMONIA	BRONCHOPNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

4. See French's "Practice of Medicine" (1907), page 888; or Osler's "Practice of Medicine" (1909), page 683.

5. See French's "Practice of Medicine" (1907), page 831; or Osler's "Practice of Medicine" (1909), page 501.

6. See French's "Practice of Medicine" (1907), page 895; or Osler's "Practice of Medicine" (1909), page 600.

7. See French's "Practice of Medicine" (1907), pages 513, 547, 909, and 996; or Osler's "Practice of Medicine" (1909), pages 707, 721, 765, and 1039.

Empyema is a collection of pus in the pleural cavity.

8. See French's "Practice of Medicine" (1907, page 226; or Osler's "Practice of Medicine" (1909), page 223.

9. *Five important symptoms of tabes:* Loss of patellar reflex, lightning pains, Argyll-Robertson pupil, incoordination, and loss of muscular sense.

10. See French's "Practice of Medicine" (1907), page 623; or Osler's "Practice of Medicine" (1909), page 848.

OBSTETRICS AND PEDIATRICS.

1. The pelvic diameters:

	Antero-posterior.	Oblique.	Transverse.
Inlet	4 inches.	4½ inches.	5 inches.
Outlet	5 inches.	4½ inches.	4 inches.

The fetal head has the following diameters: Occipito-frontal, occipito-mental, bitemporal, biparietal, suboccipito-bregmatic, trachelo-bregmatic, and mento-bregmatic. Of these, the occipito-frontal is 4½ inches, the occipito-mental is 5½ inches, and all the others are approximately 3½ inches.

2. See Williams' "Obstetrics" (1909), page 303; or Hirst's "Obstetrics" (1909), page 778.

3. The contents of the obstetrical bag will vary with the requirements and experience of its owner, and the preparations already made by the patient. In any case the following articles should be taken by the accoucheur to a confinement: Tablets of bichloride of mercury, or some other material for making antiseptic solution; forceps; ether or chloroform, with inhaler or mask; fluid extract of ergot; hypodermic syringe, with tablets of strychnine, morphine, etc.; needles, sutures, and needle holder; nail brush and nail cleaner; umbilical scissors; carbolized vaseline; stethoscope; male catheter (rubber); a 1 per cent. solution of nitrate of silver, with eye dropper.

In addition to the above some would also include: A sterile apron or suit; a Kelly pad; solution of cocaine; soap, boric acid, and gauze, all sterilized; absorbent cotton, iodoform gauze, chloral hydrate; dilators, and other instruments.

A bag or grip made of canvas, or a metal case covered with canvas, is better than a leather bag, as the former can be sterilized.

5. See Williams' "Obstetrics" (1909), page 659; or Hirst's "Obstetrics" (1909), page 439.

6. See Williams' "Obstetrics" (1909), pages 489, 865, 878, and 898; or Hirst's "Obstetrics" (1909), page 761.

7. See French's "Practice of Medicine" (1907), pages 426 and 429; or Osler's "Practice of Medicine" (1909), pages 269 and 280.

8. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered during the summer in refrigerated cars or in bottles about which ice is packed during transportation. (8) when received by the consumer it must be kept in a clean place, and at a temperature some degrees below 60° F."

9. See French's "Practice of Medicine" (1907), page 1083; or Osler's "Practice of Medicine" (1909), page 915.

10. See French's "Practice of Medicine" (1907), page 771; or Osler's "Practice of Medicine" (1909), page 508.

SURGERY.

1. Shock is the name given to a sudden and general depression of the vital powers due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis.

Treatment of shock: place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermatically, may be necessary for the relief of pain.

2. In the abscess the pus is circumscribed; in the purulent infiltration it is diffuse and not circumscribed.

3. See Rose and Carless' "Surgery" (1908), page 97; or Da Costa's "Surgery" (1908), page 150.

4.

FRACTURE.	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

5. See Rose and Carless' "Surgery" (1908), page 1148; or Da Costa's "Surgery" (1908), page 1012.

	STRANGULATED COMPLETE HERNIA.	OBSTRUCTED OR INCARCERATED HERNIA.
Swelling	Larger than before and firmer.	Larger than before.
Impulse	None.	Present on coughing, but less marked.
Reducibility	Irreducible.	Irreducible.
Other local signs	Dull pain over swelling, later signs of peritonitis.	
Signs of obstruction	Colicky pains, absolute constipation; vomiting; later fecal.	Gradual onset; vomiting slight; bowels can be moved. Occurs in aged.
General disturbances	Marked and early intoxication.	Slight, no collapse.

—(From Eisendrath's *Surgical Diagnosis.*)

Reducible, simple, irreducible, or inflamed hernia, tumor or hydrocele may be mistaken for them.

7. See Rose and Carless' "Surgery" (1908), pages 1307 and 268; or Da Costa's "Surgery" (1908), pages 1211 and 52.

GYNECOLOGY.

1. *Leucorrhea may be produced by:* Pelvic congestion, endometritis, retroversion of uterus, vulvitis, vaginitis, gonorrhea, benign and malignant growths.

2. DYSMENORRHEA. *Causes:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis, or obstruction of the cervix, prolapse, or displacement of the uterus. *Treatment:* If possible remove cause; attend to the general condition, hygiene, tonics, regular habits, etc.; curettage may be necessary, and may have to be repeated (perhaps more than once).

3. Hemorrhoids, cystocele, rectocele, bearing down pain, frequent urination.

4. *Differential diagnosis.—Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Retained menses: Absence of other signs of pregnancy, cramp-like pains about once a month; the condition may be of longer duration than an early pregnancy, and the cause of the retained menses is generally demonstrable.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

5. Development of the reproductive organs, enlargement of the breasts, hair on pubis and axilla; the form becomes rounded, the hips widen, menstruation occurs; there are certain mental and emotional changes, and "the development of those womanly beauties physiologically designed to attract the male."

PATHOLOGY AND BACTERIOLOGY.

1. A THROMBUS is a blood clot formed in the blood-vessels during life. *Causes:* Changes in the blood current; changes in the vessel wall; anything within the blood current not covered with endothelium. Generally more than one of these conditions are present. *Results:* Formation of emboli; infarction; heart clot, and sudden death; cerebral softening; the thrombi may become organized, liquefy, soften, become calcified, putrefy, become discolored, or may resolve.

AN EMBOLUS is a plug in the circulation. *Causes:* Thrombi, detached pieces from the heart valves, microorganisms, oil, fat, parasites, pieces of new growths. *Results:* Obstruction to the circulation; infarction, inflammation of blood-vessel; dilatation of blood-vessel.

2. Small pieces of infected tissue are carried by the blood or lymph to distant parts; there they are lodged in the capillaries and proliferate and establish metastasis.

3. *Intestinal ulceration* is found: In the duodenum, in burns, in chronic nephritis and in enteritis; in the *ileum,* in typhoid and tuberculous enteritis; in the *large intestine,* in enteritis and dysentery.

See also French's "Practice of Medicine" (1907), page 776; and Osler's "Practice of Medicine" (1909), page 501.

4. See Rose and Carless' "Surgery" (1908), page 62; or Da Costa's "Surgery" (1908), page 132.

5. Cloudy swelling is known as parenchymatous or granular degeneration, also as albuminous infiltration. It commonly occurs in fevers, toxic infections, and some poisonings (such as phosphorus, arsenic).

6. Histologically, the carcinomata are grouped under the epithelial tissue tumors. *Subvarieties:* Squamous celled; cylindrical celled or columbar celled; glandular (scirrhus and encephaloid).

7. *Erysipelas* is caused by the *Streptococcus erysipelatis;* it appears in chains of varying lengths or in tangled masses, the presence or absence of oxygen does not seem to be of much importance, it grows at room temperature, and has the cultural characteristics of the *Streptococcus pyogenes.*

Syphilis is caused by the *Treponema pallidum;* this is a flexible spiral organism, with several turns, and a flagellum at each pole.

Puerperal infections: See Williams' "Obstetrics" (1909), page 852.

Basilar meningitis is tubercular. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length, and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella; it has no spores, is non-liquefying, non-chromogenic, erobic, and acid-resisting.

8. In *Malaria,* the infection is due to the bite of an anopheles mosquito which is already infected. In *typhoid* the typhoid bacillus is swallowed with food or drink which has become contaminated in some way. In *tuberculosis,* the tubercle bacillus is usually inhaled, but may be taken in with food and drink, or through wounded skin or mucous membrane. In *tetanus,* the tetanus bacillus generally gets into wounds (penetrating, or dirty, or gunshot, or "cracker," with earth).

9. *Protozoa* are unicellular animal organisms, of variable size (from that of bacteria to many centimeters in length), and of complex and little understood life cycle. *Examples:* Trypanosome, which causes sleeping sickness; and *Plasmodium malariæ,* which causes malaria.

10. The tape worm is an obligatory parasite; the bedbug is a facultative parasite. Yes, the colon bacillus may be a parasite.

MEDICAL JURISPRUDENCE.

1. *Six signs of death:* (1) The permanent cessation of circulation; (2) the permanent cessation of respiration; (3) rigor mortis; (4) loss of body heat, so that the body has the temperature of the room in which it is placed; (5) adipocere formation; (6) putrefaction.

2. Rigor mortis begins at a period varying from about fifteen minutes to eight hours. It is said to be due to the coagulation of the muscle plasma.

3. In *burns* produced *before death:* There is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous; occasionally there will be no blister if there has been excessive shock; also, there will be a red line of demarcation between the injured and the uninjured parts, and this, being a vital process, is only de-

veloped during life. In *burns* produced *after death* there is no true blister, no red base, and gas only is present in place of the serous fluid.

4. *Infanticide in a medicolegal sense* is the murder of a newborn child, which has a separate existence from its mother. In a *physiological sense* it would include the destruction of the life of a fetus or child before it was separated from its mother.

5. An *illusion* is a false or perverted impression received through one of the senses. *Example:* The whistling of the wind being mistaken for a voice telling a person to do a certain thing.

TOXICOLOGY.

1. See above, THERAPEUTICS, 6.

2. *Two reliable emetics:* Apomorphine hydrochloride, dose gr. 1/10 by hypodermic; and wine of ipecac, dose ℥xx.

3. (*a*) For *arsenical preparations*, give freshly prepared solution of ferric hydroxide; (*b*) for *mineral acids*, give magnesia, or soap and water, or milk.

4. *Symptoms of acute phosphorus poisoning:* "Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours, pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies." (From Witthaus' *Essentials of Chemistry and Toxicology.*)

5. Strictly speaking, carbonic acid gas is not a poison; it suffocates. Treatment, therefore, consists in removing the patient immediately to pure air, and instituting artificial respiration. After respiration is established, stimulation will be necessary.

HYGIENE AND PREVENTIVE MEDICINE.

1. The standing of water aids in the subsidence of foreign particles, and also (slightly) of organisms. It can be increased by the addition of precipitating agents (lime, alum, iron, etc.). Most of these substances have been suspended mechanically in the water, and the standing causes them to settle; but some have been in solution, and have become insoluble because the water is deprived of carbon dioxide by being exposed to the air.

2. River water may be rendered suitable for town consumption by filtration. Ordinary filter beds for the purification of water are tanks of varying size, shape, and construction; the walls may be vertical or sloping; upon the paved bottom are pipes to carry off the filtered water. Above these pipes are successive layers of coarse gravel, fine gravel, coarse sand, and at the top fine sand about four feet deep. Through these layers the water passes.

3. The intermittent system is the better, because it allows of aeration of the soil.

4. *Disinfection of privies and water closets:* "In the disinfection of these nothing is more convenient and effective than lime chloride, which is a mixture of various chlorine compounds, or milk of lime, freely used; the latter is made by adding one pound of freshly slaked lime to two or three quarts of water. Lime chloride should be purchased in sealed packages only, otherwise its efficacy as a disinfectant is slight. Air-slaked lime is of no use as a disinfecting agent."—(Wilcox's *Fever Nursing.*)

5. See French's "Practice of Medicine" (1907), pages 324 and 309; or Osler's "Practice of Medicine" (1909), page 139.

The Pathogenesis of Tetany in Childhood.—V. Pexa found that dogs fed on a calcium free diet presented a clinical picture in which the most conspicuous symptom was a passive condition toward external influences. There was no increased electrical irritability in the peripheral nervous system. The calcium content in the central nervous system was diminished, but there was an abundant increase in the amount of glycogen contained in the parathyroids, which were otherwise unchanged. It is concluded that the origin of tetany and spasmophilia can not be attributed alone to a deficiency of calcium in the various organs, which deficiency is not associated with a diminution of electrical irritability in the peripheral nervous system. Even if the poverty of calcium in the various tissues plays a rôle in tetany, at any rate the latter would be prevented by the antitoxic power of the parathyroids.—*Archiv für Kinderheilkunde.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of November 12, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	573	163
Diphtheria	312	30
Measles	106	5
Scarlet Fever	134	3
Smallpox	—	—
Varicella	69	—
Typhoid Fever	133	26
Whooping Cough	54	3
Cerebrospinal Meningitis	2	2
Malarial Fever	—	—
Totals	1,383	232

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended November 11, 1910.

PLACE	DATE	CASES	DEATHS
CHLOERA			
China: Amony	Sept. 18–24		1
Hankow	Sept. 24	2	..
Germany: Marienburg	Oct. 3–9	6	2

THE U. S. NAVAL MEDICAL SCHOOL.*

BY HENRY G. BEYER,

MEDICAL INSPECTOR, U. S. N., PRESIDENT OF THE SCHOOL.

GENTLEMEN: It may be taken for granted that all those of us most deeply interested in the work of the Naval Medical School consider it eminently fit and proper to open the sessions with an informal introductory address, if even for no other purpose than that of giving those of you who enter as students of the school, first, a hearty welcome; second, a brief description of the aims and objects of the school and, third, a short account of the requirements which students are expected to conform and live up to during its sessions.

Those of you, gentlemen, who have successfully passed the Naval Medical Examining Board have caused to be placed on file at the Navy Department not only a written record of your professional qualifications, but also and at the same time a record of a mental endurance test. It is conceivable and has indeed happened more than once in my experience in the service that persons, otherwise well qualified professionally to pass the examination, have, nevertheless, withdrawn on account of a lack of enduring moral force. Military hardihood and a disciplined mind, kept well under the control of a strong will and guided by a noble purpose, are characteristics as desirable in a naval medical officer as they are in an officer of the line. The successful candidates are therefore to be congratulated as having proved themselves physically, mentally, and morally equal to an accepted standard in an examination for one of the Government services.

An Examining Board, indeed, with its requirements and its functions, is not unlike a standard toxin, by means of which we standardize our antitoxins coming into our laboratories from the different manufacturing establishments. At least one difference, however, we must admit exists between these two standardizing agencies, and that is that we cannot keep the members of an Examining Board in a water and air-tight compartment and at a uniform temperature during the intervals of their functional activity. On the contrary, we must admit that the more air and the more light this standardizing board receives during such intervals the more perfect, the more to be feared, it is bound to become. This, gentlemen, with all due apology to the distinguished members of that board present on this occasion.

The results of your examination having thus clearly been obtained by scientific methods, they certainly ought to be reliable, and the congratulations which I have the pleasure of extending to you are consequently also not merely matters of empty form and rhetoric, but they rest on sound principles and logical reasoning. Still, in order to make you not unduly or prematurely proud and to continue the figure, it is your practical value to the service to be shown in your future work that must be allowed to confirm the promises which you have so far given us and to convert the probability values of your examination marks into actual and undisputable values.

Function of the Naval Medical School.—The objects and purposes of this school, like those of any other school, are, of course, educational, but the educational completeness that we must ever aim at, the special ideal that we should never for a moment lose sight of and which forms the very foundation of our existence, is that we should lay special stress in teaching those branches that alone are calculated to make of us and of our services more valuable instruments in the service of the Navy of the United States than we would be without such instruction, and especially with reference to service in the fleet and at sea. At present we are still working on the foundations of this ideal structure. It will be for you to carry on the work after we have gone.

Regarded in the light of a preparation for service, the course which you are about to begin signifies one more of those rare opportunities knocking at the door of your young lives and at the beginning of your professional career, clamoring for admission, and which it is of the greatest importance for you to embrace with all your might and to utilize to the full extent of your ability; an opportunity which never can be made to come back after once it is gone. Let there be no wobbling uncertainty about that. I am merely stating a plain and serious truth when I say that if I, who stand at the end of my professional career in the Naval Medical Service, possessed the ability of conveying to you, who stand at the beginning of it, the true sense of appreciation that I feel of the value of the instruction you are about to receive at this school, and which experience alone can duly appreciate, you would enter upon your work here with an attachment for all your instructors little short of reverence.

The instruction at this school, so far as it has been possible to perfect it up to the present time, falls into three main functionally different groups or branches, namely, (1) the biological branch, (2) the professional branch, (3) the military branch.

The Biological Branch.—To the biological group of subjects I would refer bacteriology, pathology, and medical zoology. Chemistry, as far as it is taught in this course, is auxiliary to both the biological and the professional branches of study. All these studies may be termed the fundamental sciences upon which medicine depends.

*An address delivered at the opening of the U. S. Naval Medical School, Washington, D. C., on Monday, October 3, 1910. Published by permission of the Surgeon-General of the Navy.

In reading the syllabi submitted by Drs. Butler, Mink, and Garrison you will notice that the laboratory work is all done by the students themselves, that no important detail of work is omitted, the intention on the part of the instructors being that of making the student an independent worker is everywhere apparent. In bacteriology none of the practical laboratory procedures are omitted. In pathology I was glad to note that due attention will be given the collection, preservation, hardening, and embedding of pathological specimens, as well as to the study of the microscopic characters of the various lesions. In medical zoology, besides a thorough study of the protozoa, vermes, and anthropoda, from which three classes of the animal kingdom most of the animal parasites are derived, you will receive some further useful instruction with regard to the collection and the systematic recording of museum specimens and the necessary information of their habitat that must go with such specimens.

The biological laboratories have furnished the physician and surgeon alike new means for diagnosing and combating disease, and the education of the medical practitioner under the present changed conditions makes entirely new demands on both his preliminary and his professional training. Since the large majority of the medical schools in this country do not require a knowledge in the fundamental branches before admitting the students to professional studies and since the highest standards of professional efficiency cannot be attained without it, the necessity for the creation of special service schools for the supply of that knowledge became apparent. The brief history of these schools and the excellent work done by the students and instructors has more than justified their existence.

The Professional Group.—Hygiene (Dr. Fiske), tropical medicine (Dr. Butler), surgery (Dr. Spear), ophthalmology (Dr. Shipp), and psychiatry (Dr. Butts) together form the professional subjects in which you will receive advanced and practical instruction. The very essential importance of a practical knowledge on these subjects will at once appeal to you without any further comment on my part. I may therefore omit the reading of the syllabi submitted by the instructors in these departments. From the service point of view, however, I might mention that their relative importance should be interpreted as following the order in which they are here enumerated.

The Military Group.—The various military exercises and drills that are so essential and so necessary to make you a homogeneous part of the corps of officers of the naval service are of great practical and of still greater personal importance to you. This branch of instruction is practically a school of application intending to point out the way in which your professional accomplishments must be applied to the naval service. This branch of instruction is under the sole charge of Commander Wilson, a gentleman who combines a rare quality of kindliness with a sincerity of purpose which must appeal to all of you and whom you will all respect and appreciate and, I am sure, remember long after you are well launched on your career as naval medical officers. I herewith admonish you to give him the respect he deserves.

Laws, Regulations, and Orders.—With the laws, regulations which you will most frequently come in contact with, it will take but a short time of practical naval life to make you acquainted. But, in order that this first acquaintance may be a pleasant one and not be followed by disagreeable consequences, it behooves you to get a knowledge of the regulations as soon as practicable, and to get yourselves into the habit of obeying orders. Any lawful order, whether good, bad, or indifferent, must be obeyed without hesitation and mental reservation. The sooner you will understand that a military order is not an insult or an attempt at any interference with your personal right or liberty but constitutes for you a simple call for duty, the smoother also will be your introduction into the service. Respect for and obedience to the orders of your superiors must be insisted upon wherever you may hereafter be on duty. This is necessary in order that not only shall the machinery run smoothly and without friction, but it constitutes a training for your daily life in the service if this is expected to be a happy one.

With regard to local orders, orders to which you will be expected to conform while attached to this school, the necessary information may be obtained from the various bulletin boards. Whenever in doubt as regards your military conduct, Commander Wilson will, I am sure, be your ever willing and ever present friend and guide.

In conclusion, I charge you to hold high your professional aims and I beg of you to remember that from now on you have assumed a serious and lasting responsibility, both personal and professional, for the honor and efficiency of the naval medical service. While every man owes that duty to his profession, and while in no profession this obligation is clearer than in that of the physician, in no association of physicians is this duty more compelling than in that of the medical corps of the military services.

THE PHILOSOPHIC ANATOMY OF THE LIVER.

By EDMOND SOUCHON, M.D.,

NEW ORLEANS, LA.

PROFESSOR EMERITUS OF ANATOMY, TULANE UNIVERSITY.

It is remarkable that the liver is the organ which the common people mention most often in telling of their ailments. In warm climates especially they are all the time saying that they are bilious, that their liver is not acting, that they have cooked bile on their liver. They often say of people of a sallow complexion that they are bilious. In fact, we are told that in very hot climates people greet each other not by asking "how are you?" but "how is your liver?" Physiologists tell us that the liver is the lungs of hot climates.

It is noticeable that the word liver in Greek means fat, so says the dictionary. It is truly the only organ that will accumulate fat most rapidly. It is particularly so in the lower animals. All epicures know how luscious is the famous "Paté de foie gras," due to the hyperfattening of geese from overfeeding or gavage, particularly with nuts. It is probably due to the fine taste of young fat livers that the birds of prey instinctively selected the liver to pick in the case of the legendary Prometheus while chained to the rock. It is astounding how rapidly the liver undergoes total fatty degeneration, in some cases of yellow fever, the whole organ being converted into a hard mass of tallow in some forty-eight hours.

We should note that there is only one liver in the human subject, but in some of the lower animals there are a number of lobes and lobules inde-

pendent of each other. However, the common people from their observation of rabbits and other animals speak of the liver in the plural—the livers, "les foies," in French.

We must lay stress on the fact that the liver is the largest organ in the human body, except perhaps the lungs separately. This is in keeping with its manifold and most important functions. It is noteworthy that it is beyond question the heaviest of all the organs. No other organ presents such variations in weight, however, within the boundaries of health.

The liver is a single organ, but is not on the median line like the heart, brain, and bladder. The other single organs are the brain, the heart, the pancreas, the bladder, the prostate, the womb, the penis. It is to be noticed that it is an asymmetrical median organ. The heart and the pancreas are the only other such organs. The liver is unique in the large extent it occupies in the abdominal cavity, extending through three regions, right hypochondrium, epigastrium, and left hypochrondrium.

We must call attention to the several directions it presents; its axis is horizontal, its anterior surface is vertical, the posterior is oblique; the upper border is longitudinal, the lower is oblique. The manner in which the organ is held in place is most worthy of notice. Like the heart it is suspended from its broad upper border by the large hepatic veins as they open into the inferior cava, itself so firmly adherent to the fibrous opening presented by the aponeurotic diaphragm for its passage. The so-called suspensory ligament, the coronary ligament, the triangular ligaments have but little to do in holding the liver in place. We must note also that the liver is supported or rather rests on the stomach and intestines as on a soft bed, such as the heart lies cosily on the diaphragm and the spleen on the left of the colon.

We must bear in mind that in its situation the organ is entirely passive. It moves up and down with the movements of the diaphragm and the lungs, but it has no motion of its own. It is to be remembered that whatever be the means of fixity of the liver it will sometimes stretch them to the extent of comparative excessive mobility. We all know of floating livers, though the organ never roams about the abdomen as the spleen and especially the kidneys do. These organs are the only ones that "float." The liver is the one organ whose shape is truly hard to define so as to convey a correct idea. The comparison to the longitudinal half of an ovoid is about the best.

It is notable that for many years the anterior or convex surface of the liver was the only one that interested the surgeon, but now there is no part of the organ that he will not reach. It should arrest attention that it is the largest surface, that it gives insertion to the so-called suspensory ligament, that this ligament corresponds to the median line, that it divides that surface into a right and left lobe; that the part of the surface which corresponds to the right hypochrondrium is covered by the ribs and intercostal muscles, the pleura, the diaphragm, the peritoneum. It is of importance to remember that the portion of the anterior surface that corresponds to the epigastrium is the only superficial portion of the liver, reached as soon as the skin, muscles and peritoneum have been incised. We must note that that portion of the organ extending into the left hypochondrium is very small, thin, and comparatively of little pathological or surgical interest.

The posterior surface is most remarkable for its many irregularities. It presents more of these than the surface of any organ in the body. These irregularities are due to the several organs with which this surface is in relation, the stomach, colon, suprarenal capsule, kidney. It is concave because the largest of all these organs are convex. That surface is smaller by one-third than the anterior or convex surface, but how many most remarkable and unique things are seen there! It is striking that the most important peculiarities are all centered in the middle of the surface, to the right of the median line, in a space not more than four inches square. The first that should arrest attention is that these peculiarities are represented by three grooves, two vertical or oblique and one horizontal or transverse, the whole representing the letter H. Of these grooves or fissures the transverse one is the one to be dwelt upon above all others. It is the hilum, a model hilum. The liver and kidneys alone present such a model hilum. This hilum, however, has a special interest over any of the others because it presents the portal vein, which in this hilum becomes an artery by penetrating and breaking up into capillaries in the liver. This is unique and truly wonderful. In the hilum we must observe particularly the reflections into the organ of the capsule of Glisson as it is here more developed than in any other structure. Surgeons should bear in mind that the hilum is in the right of the epigastrium and comparatively superficial, so that in exploring deeply with a large aspirator needle the portal vein and the hepatic artery might be wounded with possible serious consequences. We should not forget the relative position which the artery, the portal vein and the common bile duct occupy on their way to the hilum in the right border of the gastrohepatic omentum. The artery is on the inside of the duct, on the same plane, and the vein is behind them. Our attention must be arrested by the fact that these structures form the anterior boundary of the famous foramen of Winslow.

It is interesting to note that the suspensory ligament, the obliterated umbilical vein correspond to the median line, the vein being deeply seated; the obliterated venous duct corresponds also to the median line, but higher up and still more deeply seated. Also that the fundus of the gall bladder corresponds to the lower border of the liver and to the junction of the edge of the abdominal straight muscle and the chondral border; higher up and very deep we find the inferior cava on the same line.

We must insist on the fact that no other organ presents such lobes as the spigelian, the square, the caudate. It is of particular interest to the pathologist and to physicians to remember that these lobes are in relation with the stomach, so that abscesses of the liver may, and do, discharge into that organ. This applies also to the right lobe, which partly rests on the colon, into which abscesses of the liver are thus enabled to discharge.

The upper border of the liver is most interesting because it is through it that the inferior cava passes to go through the diaphragm and that it is just at that point that the hepatic veins discharge into the cava. The adhesions of that border to the diaphragm and through the diaphragm its relation with the base of the right lung offers a possible issue to hepatic abscesses into the bronchi.

It is worthy of more than passing notice that the inferior border is long, thin and oblique, quite in contrast to the upper border. We must lay pe-

culiar stress on the fact that it is truly the surgical border of the liver because of its accessibility, because it never projects beyond the ribs unless the organ is enlarged or is pressed down by accumulations or by tumors above. A point of special interest to operators is that it presents the notch for the fundus of the gall gladder corresponding to the junction of the edge of the costal cartilages and the border of the abdominal sraight muscle. That border is also of interest because it crosses the epigastrium longitudinally, a surgical landmark of some value. We find nowhere else an organ presenting such a large and solid lobe as the right lobe and extremity of the liver. We should admire its bulk, filling all the right hypochondrium. It is, in fact, the liver.

The smallness and flatness of the left lobe and extremity is comparatively insignificant both from a pathologic and a surgical aspect. However, it sometimes has surprises in store for the diagnostician.

It should be noted that the liver, the spleen, and the kidneys are the only dark colored organs, the liver and the kidneys being very much of the same color. When a man is known to be of strong sexual temperament and happens to lose a couple of wives in rather close succession the common people say that he has a white liver. The liver and kidneys also present pretty much the same consistency. They are also remarkably friable, though less so than the spleen. For that reason they are often lacerated in falls and blows and ordinary sutures will tear through the tissue. Mattress sutures are the best to use. It is noticeable that, like the kidneys, the liver has no elasticity, no retractility. It is unyielding, hence the great pain in all lesions that tend to increase the interior pressure. We must observe that, on tearing, the liver presents a granular appearance due to the projection of the innumerable small acini. No other structure, except the kidney, presents this.

The liver presents the most wonderful structure of all the organs. It has more unique and peculiar features than are found in any one organ. It has more folds of the peritoneum connected with it than any other, the falciform ligament, the coronary, the triangular, the gastrohepatic. The falciform is unique, and is due to the presence and course of the obliterated umbilical vein.

The thinness of the fibrous coat on its surface is to be noticed. It is more delicate than in any other organ, is so much so that it cannot be peeled off as can be done with the fibrous coat of the kidney, although this one is quite thin also, but it is more resistant. We should here admire how it thickens in the hilum and how it is there reflected into the organ to form a sheath for the vessels, veins, and the bile ducts. Thus they have an easy and protected course through the dense tissue of the organ, like electric wires in conduits. Nowhere is the interior reflection of the external fibrous coat so well seen as here, although it is seen in all the organs presenting an external coat. Attention must be called to the fact that on a section of the liver the ramifications of this capsule collapse, whereas the sections of the hepatic veins remain gaping. Let us note that the ultimate divisions of the capsule become very delicate and cause the stroma of the liver to be barely visible with the naked eye, quite in contrast with the stroma of the spleen. Finally, we should not overlook the fact that the stroma is purely fibrous, presenting no elastic fibers, no muscular fibers such as we find in the spleen, hence the absence of normal expansion and retractility as we see again in the spleen.

It is indeed worthy of notice that the cells of the liver present no characteristics. Taken out of the organ they cannot be distinguished, and it is impossible to say with certainty that these cells come from the liver. But their radiated arrangement in the lobules is characteristic, unique, and most admirable. This arrangement with a linear space or track between the radii was imperative to have a way for the capillaries of the portal vein and hepatic artery on their course toward the center of the lobule, where they finally merge into the single small trunk of the central intralobular hepatic vein.

The vascular supply of the liver challenges admiration. It is dual. It presents two arterial vessels bringing the blood into the organ. The lungs are the only other organs presenting a dual circulation.

The hepatic artery is most remarkable for its small size compared to the bulk and density of the organ. That is because it is mostly the nutrient artery of the organ, and contributes comparatively little to the secretions.

The portal vein is the most wonderful of all veins. It is unique. No such vessel is to be seen anywhere else. It is the type of portal systems, *i.e.* a system of veins which originate like ordinary veins in a set of organs, which veins unite to form a single trunk which itself breaks into capillaries into another organ without passing through a propelling center. A portal vein is an ordinary vein at its initial end, but it is an artery at the other end. Such a special arrangement was rendered necessary by the fact that the veins of the stomach and intestines absorb indiscriminately all the soluble substances contained in the gastrointestinal canal, many of which substances would be injurious if discharged directly into the general circulation. By the portal arrangement these substances are carried into the liver, which eliminates or modifies them before allowing their penetration into the general circulation through the hepatic veins. We must note specially that the vessels do not anastomose in the liver, nor do they in the lungs or kidneys.

The efferent vessel from the corpuscle of Malpighi is considered also as a capillary portal system, but how infinitely insignificant compared to this gigantic hepatic portal system. Besides, it is an arterial portal system.

It is also unique that each hepatic lobule is surrounded by a dual set of capillaries, one formed by the hepatic artery and the other by the portal vein. It is beautiful to see arising from the concave surface of the dome the fine capillaries which descend into the radiated intercellular space. This sort of arrangement is seen nowhere else. It is truly admirable to behold on a fine penetrating injection the red colored arterial capillaries gradually merge into the blue colored radicles of origin of the central intralobular hepatic vein, and then the blue capillaries centering into a blue dot which is the section of the trunk of the capillary central hepatic and intralobular vein, the origin of the whole system of the large hepatic veins. We may look in vain for any similar arrangement in any of the other organs of the human body. I only saw this to my satisfaction once in my life, but I saw it then for all time, because I am the lucky and happy possessor of that beautiful slide. It was made

many years ago by one of the most skillful German technicians of that time, the celebrated Thiersch. I saw a number of pretty good slides of this kind, but not one could approach this peerless one.

To mention the star-shaped cells of the Kupffer is to challenge admiration. It is also unique and most worthy of wonder to note that the ultimate capillaries in the lobules have no endothelium, the walls of the vascular channels being formed by the walls of the hepatic cells themselves between the blood and the contents of the hepatic cells. We find such a condition in sarcomas, but I do not know of another instance in the normal tissues.

It is noteworthy that the hepatic veins form a system of their own, that they have a direction and course separate from the hepatic artery and portal vein. We must note that in their run out of the liver they have an independent course and that they do not come out where the arteries go in; that they converge toward the left part of the upper border; that there they form two large trunks discharging into the inferior cava as it passes through the aponeurotic diaphragm. We must observe that the vein from the right lobe is enormous, due to the very large size of the lobe. We again find in their course a peculiar condition, that their walls are adherent to the hepatic tissue so that when they are cut they remain gaping. Yet they are not sinuses because all the coats of ordinary veins are there present. Again we must be impressed with the direct venous connection between the right auricle and the farthest venous radicles of the liver through the inferior cava, the opening of the hepatic veins in the cava being so close to the auricle that that vast system of venous canals without valves, all the time gaping, presents an easy to and fro course from the liver to the heart and the heart to the liver. No wonder, therefore, of the great correlation between the affections of the two organs. In cases of obstruction through the heart the stasis of the blood into the hepatic veins dilates and stains the central hepatic intralobular vein so that on a section they appear like black dots, and cause the condition known as the nutmeg liver.

We must here consider the large size of the splenic vein compared to the size of the spleen, that it is one of the two large formative branches of the portal system; that it has such free communication with the liver that it is said that the spleen is the reservoir or safety valve of the liver; specially owing to its expansibility. It is also to be noticed that whereas all the other veins which form the portal vein come from the gastrointestinal canal the splenic vein is the only exception.

It is of importance to remember that the most distal capillaries of the portal system come from the anus. This explains how obstructions in the liver cause hemorrhoids and how inflammation and ulcerations of the anus cause hepatic abscesses. It is to be noted that the veins which form the portal system come from organs which receive a coat from the peritoneum, except the last portion of the rectum.

We must not lose sight of the fact that the hepatic or efferent veins carry a purer blood than the afferent vessel, because the liver has purified this blood. The pulmonary vein and the renal veins also carry purer blood than their corresponding arteries for the same reason; although veins by their direction and course they are truly arteries by their contents.

A noteworthy fact is the anatomosis of some of the veins of the liver with adjoining veins, a fact of which surgeons have tried to make use by performing operations to increase these anostomoses in order to relieve the circulation through the liver in case of intrahepatic impediment.

The liver is the only organ where, for a long time, it has been thought and taught that the lymphatics had any connection with the initial radicles of the excretory apparatus of the organ. This idea, however, is altogether abandoned nowadays. We must note in connection with the lymphatics the presence of the several glands in the gastrohepatic omentum which when enlarged have a detrimental action by the compression of the trunk of the portal vein. The vas aberrans of the liver is worthy of remembrance.

The nervous supply of the liver must arrest attention. That it has two great sources of supply should be noted. The fact is that almost all the terminal portion of the right pneumogastric nerve is lost into the liver. The only other large nerve that is distributed exclusively almost to one organ is the hypoglossal nerve to the tongue, barring the nerves of special sense. The second supply, it is to be remembered, is purely sympathetic, coming from the solar plexus and its divisions following the hepatic artery. This supply, let us note, is quite abundant owing to the large size of the artery presenting a large surface for support.

The excretory apparatus of the liver will fully repay close consideration. It is notable that the origin of the bile radicles is still, for some, a moot question. Not to speak of the theory expressed above, the relation of the hepatic cells to the beginning of the radicles have given rise to an altogether unanatomical conception. It is truly queer to place the cells around, on the outside, of the dilated extremities of the bile radicles instead of placing them in the interior of the dilations as we find the gland cells in all the glands. For the liver, it is to be borne in mind, is nothing less than a huge racemose gland.

That the color of the interior of the ducts is unique is readily understood. Another unique feature is the presence of microscopic racemose glands in their walls. This is seen nowhere else. It is remarkable that next to the kidneys the liver presents the most extensive excretory apparatus, presenting, however, more branching off than the kidneys in the form of the bile ducts, hepatic ducts, common bile ducts, and conjoined duct of this common bile duct with the main pancreatic duct or duct of Wirsung. It is also remarkable that the liver is the only organ the opening of whose duct on the surface of the mucous membrane presents such a large tubercle-like projection like the tubercle or ampulla of Vater. The accessory duct of the pancreas presents also a projection, but so small, the lesser tubercle. The only other gland that does present a projection is the opening of Wharton's duct. But how small and insignificant compared to the large tubercle of Vater presenting the opening of the dual ducts, the common bile duct, the duct of Wirsung. All the other ducts open by depressions, the salivary glands, the kidney, and the testicles.

We must here remind the surgeon of the special course of the common bile duct, on the outer side of the hepatic artery, in the right border of the gastrohepatic omentum; and further down, in the groove between the head of the pancreas and the middle portion of the duodenum. He should not forget that there it is in the posterior groove.

The gall-bladder comes in now for a share of many interesting remarks. We must first note that it is, next to the urinary bladder, the largest of the receptacles found in the course of the various excretory apparatuses. The spermatic duct is the only other organ presenting a storage reservoir in its course. But whereas the largest of these reservoirs, the urinary bladder, is on a straight line with the course of the ureters and the urethra, the gall-bladder is, as it were, on a side track, presenting a duct of its own, the cystic duct, which joins it to the main channel. The seminal vesicles are also on the side of the duct, but they are sessile, they have no duct similar to the cystic and are simply like dilatations or offshoots of the spermatic duct. It is notable that the other glands of the body, the salivary glands, pancreas, prostate, present no reservoirs. That is because their secretion is intermittent, taking place only when needed.

We should consider the peculiar shape of the gall bladder. It is unlike the urinary bladder and unlike the seminal vesicles. The neck is without a parallel, being manifestly twisted or spiral-shaped. The interior of the gall bladder is unique again, first by its color, yellow or green, due to the contact of the bile, then because it is reticulated and villous in the full acceptance of the two words. Why reticulated and villous? We must also remember that the walls of the gall-bladder present microscopic racemose glands like those found in the walls of the bile ducts. Now the neck of the gall-bladder is twisted inside as well as outside, so as to prevent the too rapid outflow of the bile. We should pause here to consider that, of all the glands, the liver, the kidneys, and the testicles are the only ones with reservoirs on their course. Of these the contents are excretory, whereas in the case of the gall-bladder it contains a secretion that has an ultimate action in the process of digestion. It does seem a small reservoir for such a large organ especially when we think of the kidneys and bladder. Maybe its contents are simply a reserve to come into use at once until the secretion of the gland has been well established under the stimulus of the presence of food in the stomach.

Let us remember that the liver, like so many other organs, is developel by separate parts which finally coalesce more or less completely. Thus we understand how the various lobes of the liver are formed. Sometimes the blending of the lobes fails, and then there are separate livers. I have a specimen where the left lobe is separate from the right, joined to it only by a fibrous band. But the most astonishing feature in the development of the organ is the presence and course of the umbilical vein on its under surface where it gives off a special branch to the left division of the portal vein. So that the left lobe of the liver equals the right lobe in size. After birth this branch obliterates and the left lobe generally becomes of the size we find in the adult. Why this special branch to the left lobe? We find nowhere else anything like this except, perhaps, the arterial duct of Arantius.

We must here mention some anomalies in the development of the liver represented by some two or three vertical grooves on the external surface of the liver. I have read several explanations of them but none satisfactory. The liver is one of the few organs that is liable to be deformed by habits. Very tight lacing long continued may develop a circular groove on some subjects, besides disfiguring and displacing the organ.

CHEMICAL PROBLEMS IN DIABETES.*

By ADOLF MAGNUS-LEVY, M.D.,

PROFESSOR OF MEDICINE IN THE UNIVERSITY OF BERLIN.

METABOLISM OF PROTEIN.

In former times an increased protein metabolism was generally attributed to diabetes. Especially with the French, azoturia played a great part in diabetes. But it is of course of no significance if an undieted diabetic patient consuming large quantities of meat yields thirty, forty, or fifty grams of nitrogen in the urine. Such azoturia is the result solely of the large protein intake in the food. But an abnormal protein metabolism was believed in quite apart from this form, mostly by reason of clinical phenomena, because it was so often observed that diabetic patients lost in weight. Physicians attributed a toxic destruction of the body protein to the disease itself. But in the older experiments no attention was paid to the calculation of the intake, nor to the loss of energy by the sugar output. If a diabetic patient be given sufficient quantities of fat and protein his protein metabolism behaves just the same as that of a healthy man on the same diet. Still diabetic patients, although being kept at a rational diet, lose weight in the course of years: but this by no means contradicts the statement that their proteid metabolism takes place as in healthy people. The loss of flesh is caused by the one fact, that for the length of time patients cannot command sufficient food for the conservation of equilibrium.

Diabetic patients may subsist even on small protein intake. Therapeutics at present tend to restrict not only the carbohydrates but also, as far as possible, the protein ingestion. Also with small protein rations nitrogen equilibrium is reached in most cases. I had a severely diabetic patient of sixty-four kilos, a remarkable fat eater, who for many weeks remained in nitrogen equilibrium on being given only sixty grams of protein.

Since the introduction of the oat diet, nitrogen equilibrium has been observed with still less protein, at least for short periods. The physiological economy in food, which your countryman Chittenden has studied so successfully with healthy subjects, is applicable also in diabetics. As a rule the general nitrogen metabolism is not disturbed in the ordinary course of diabetes and the presence of a toxic moment must be denied.

It is only in single cases and in certain periods of diabetes that a real disturbance in the protein metabolism occurs, that is to say, a toxic loss of body proteid, which cannot be explained by insufficient food. These are rare occurrences and their cause is still unknown. It was believed that diabetic coma was dependent on a loss of body protein. This was found true in some cases, but these are exceptions. I myself happened to study the nitrogen metabolism of three patients for from ten to twelve days before, during, and after the coma. If coma had produced any toxic disturbance of the protein economy it would surely have been observed on account of the long duration of the experiments. But in none of these most convincing experiments had a loss of body protein taken place.

The behavior of the protein metabolism in pancreas and phlorhizin diabetes of dogs is in

*The second of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, Columbia University, New York, for 1910.

striking opposition to its behavior in cases of human diabetes. The most convincing experiments are those made on fasting animals. In these the height of the protein decomposition is often four to five times the normal value. Hence, Falta has concluded that there is an *essential* difference between pancreas diabetes in dogs and human diabetes. I believe he is not right, the contrast between the two conditions being due to the different time of development of the metabolic disturbance. The sudden and complete suppression of sugar combustion which occurs in the experimental diabetes of dogs induces a radical and most serious damage to the organism. In human diabetes, on the contrary, the decrease of sugar utilization extends over a long time, during which the organism adapts itself partly to the new conditions of life. In pancreas diabetes no time is left for compensation. If phlorhizin experiments are conducted for a long time adaption seems to take place. In the observations of Hartogh and Schumm, indeed, the nitrogen elimination sank appreciably in the later weeks. If moderate quantities of meat were given, and even more so with large quantities, nitrogen equilibrium was almost reached in some animals.

As to the chemical decomposition of the protein molecule, only a few peculiarities are to be mentioned. Blumenthal, on applying the methods of Fischer and Bergell, found tyrosin in the urine. Also in regard to the combustion of inactive alanin irregularities have been observed. But it is unknown whether such occurrences are more common with diabetic patients and whether they do not also occur in other diseases. Before we know this it is useless to discuss this question.

As a general rule the decomposition of the protein molecule proceeds normally in diabetes. The same end products are found in the urine as in normal life; the amount of urea reaches from 80 to 90 per cent. of the total urine nitrogen, supposing that no excess of ammonia is present. Even if this is found it means no disturbance of the protein breakdown, for the normal end product of such destruction is *ammonia* and not *urea*. The formation of the latter is due to a synthetic process, and this synthesis, which is performed principally by the liver, is not itself disturbed in diabetes. The ammonia, however, combines with some of the organic acids, such as oxybutyric acid, and is thus withdrawn from the synthesis. If the ammonia be set free from this compound by replacing it by sufficient alkalies the ammonia content of the urine sinks and the urea rises accordingly.

I have now to make a few remarks as to the so called protein degeneration in diabetes which some years ago was widely discussed. The opinions were based on those experiments which should show a sugar formation from fat. As I have already mentioned in my last lecture, we calculate all the experiments on the assumption that the maximal sugar formation from protein never exceeds a certain value of forty-five or perhaps sixty grams from a hundred. Kraus, an opponent of the doctrine of sugar formation from fat, relied on the supposition that the protein breakdown might have been very much greater in the experiments in question than could be calculated from the urine nitrogen. He took for granted that a part of the protein involved in the metabolism had given up sugar, but the corresponding nitrogen had been retained in the body. A retention in the form of ammonia or of urea is out of the question considering the long duration of such experiments. The only question is whether the ordinary protein is transformed by giving up carbon for the sugar into a protein *poorer in carbon*. That was called a degeneration of the protein and this hypothesis was regarded as extraordinarily brilliant. But a closer consideration shows that this assumption is quite untenable, or at least absolutely improbable.

Let us look a little closer at this idea from the chemical standpoint. First of all, I would emphasize the fact that varieties of proteids with less than 50-53 per cent. of carbon have never been found in nature. A degeneration of a protein with 53 per cent. of carbon into a sort essentially poorer in carbon might for example occur in *this* manner, namely, that a lower amino acid takes the place of a higher one. For instance, a part of leucin, tyrosin, or histidin would be replaced by groups such as alanin or glycocoll. But a protein with its composition changed in this way will by no means possess the same chemical properties as the original protein. Even with the simplest chemical substance a certain change of its properties takes place if a butyl, propyl, or ethyl group be replaced by a methyl. Remember that we have defined protein as a polysubstituted polyglycocoll. For the formation of any quantity of sugar, innumerable phenyl, isobutyl, propyl, or ethyl groups must be split off from this protein, or be replaced by methyl groups, and so on. And if the chemical properties of a lifeless protein be so strikingly changed by varying the radicals, which are substituted in the glycocoll group, how much more shall we expect this to be the case in the complicated structure of the living protoplasm? There is no doubt that the fundamental differences of the different proteids which are obtained from various organs or from different animals depend chiefly on the different amount and on the different nature of the amino acids which they contain. A casein molecule certainly could yield no mechanical energy in the muscle, a brain albumin could furnish no hydrochloric acid in the stomach, etc. A degeneration or rather a transformation of the protein molecule has certainly taken place in the course of millions of years in the development of plant and animal life. But then it went hand in hand with a change in the life itself and with a modification of the functions. A transformation of this sort with a retention of the same functions in single individuals is for me unthinkable.

THE METABOLISM OF FAT IN DIABETES.

The extent of the metabolism of fat in diabetes must as a whole be considered together with the question of the metabolism of energy. This will be treated later. The chemical decomposition itself is in principle certainly quite undisturbed. It is only when the higher fatty acids have been broken down to butyric acid and this has been oxidized to oxybutyric acid that that remarkable disturbance of oxidation begins, which is known as acidosis and which is announced by the appearance of acetone bodies in the excreta. This question will also be treated separately.

We will here speak only of that remarkable disturbance of the fat metabolism which we call lipemia. This phenomenon is not peculiar to diabetes alone, but it is in this disease that it is most frequently met with and reaches the highest degree. As high as 30 per cent. of fat has been found in the blood serum.

Normal blood at all times contains fat, partly

combined and invisible, partly in the form of fine drops. If considerable quantities are visible to the naked eye in the form of an emulsion in the blood, then we speak of lipemia. All lipemia means a wandering of fat. Digestive lipemia after eating fat, and hunger lipemia are the visible expression of a *normal* transport of fat, either from the intestine or from the fat stores to the organs in need. This transport takes place partly in the same way as with the other foodstuffs, through the blood passages, but in opposition to protein and to sugar the fat betrays its presence on its way by its optical properties. The fat content of the blood varies with and depends upon the varying relation between the fat entering the blood and given up by it. Under conditions of normal life the fat content seldom exceeds 1-2 per cent. In severe diabetes this equilibrium between the fat entering the blood and given up by it is most extensively disturbed. However, it should be remembered that lipemia may be absent even in diabetic coma.

The reasons for this disturbance of the fat equilibrium are as yet unknown. It is immaterial also whether this fat, which is circulating in the blood, comes directly from the intestine or from the subcutaneous fatty tissue, etc. In no case, however, dare we, like earlier investigators, try to explain the lipemia by a diminution of the combustion of fat or by a decrease of the oxidative power of the organs. Neither in diabetes nor elsewhere is the oxidative power for fat, as such, deficient. And on the other hand no lipemia occurs in those rare cases in which a marked decrease in the total oxidation occurs, as for instance in myxedema.

With a fat content of from 20 to 30 per cent. in the serum, about 500 grams and more of fat circulate at the same time in the blood passages of a diabetic patient. Of course some time is necessary for the accumulation of such quantities, several weeks at least. So the disappearance of lipemia which can be observed in a non-diabetic patient requires a long time; in the case of an alcoholic patient of Gumprecht's with an amount of 7 per cent. of fat fully six weeks were required. In any case the disturbance is due to difficulties not met with by the fat in passing out from the capillaries. Perhaps in this passage we have to deal with a fermentative process or a vital property of the capillary cells, a process which is also of the highest interest for physiology. Still the normal process is not yet completely explained.

It is striking in diabetic lipemia, as Klemperer first emphatically brought to our notice, that the lipoids, cholesterin, and lecithin form a large part of this blood fat. Their amount in the blood can reach several parts per cent. and their percentage in the fat of the blood is far higher than is normal, and what is more, far higher than in the fat of the fat deposits. Accordingly Klemperer is right in stating that the fat in the blood of a lipemic patient is not simply wandering deposit fat. He though first of all of a deprivation of organs which are rich in cholesterin and lecithin. But neither the brain nor the kidneys show any diminution of these substances in diabetic patients with severe lipemia. I think that another explanation is possible, that the cholesterin and lecithin stored up in the blood are derived exclusively from the food and that at first only the exit of these substances from the blood is disturbed. In the second place, only a retention of the true fats would take place which are required to keep the lipoids suspended. As to the true fat itself its origin could be looked for in the fat stores of the body. This is proved by the severe lipemia occurring in fasting diabetic dogs.

DIABETIC ACIDOSIS.

In dealing with the problems of β-oxybutyric acid and of acidosis I do not venture to give you a full account of this doctrine, though it is that field of metabolism in which research has most widely enlarged the knowledge of biochemical occurrences.

In order to place the problem fully before you let us take for granted the following statements:

1. Oxybutyric acid yields acetoacetic acid;* the transformation of the latter to acetone occurs only in very slight degree within the body. Most of the acetone found in urine is split off from acetoacetic acid within the eliminated urine, but was not secreted as such by the kidneys. Probably also the exhaled acetone is split off by the capillary cells of the lungs. Instead of dealing with three different acetone bodies—a term which means oxybutyric acid, acetoacetic acid, and acetone—we have to deal actually only with the two acids, and a calculation of their amount as by the amount of oxybutyric acid alone is justifiable.

2. Oxybutyric acid is derived from fats and from certain amino acids, but not from alcohol and not from carbohydrates.

3. Acetone bodies appear in the urine and in the expired air only when carbohydrates are lacking in the food, or when they are not utilized in the normal way. There may be other factors which increase or diminish the height of acidosis, but the predominant cause of acidosis is the non-utilization of the sugar molecule.

4. Acetone bodies are found in minimal quantities in the excretions of healthy people. Thus they must be considered as normal intermediate products.

5. Besides carbohydrates other substances are known which diminish the output of the acetone bodies. They are called antiketonuric bodies. Their efficacy may depend on different reasons.

The problem to which I want to call your attention is as follows: What is the extent of the intermediate formation of acetone bodies in the human organism in normal life and in disease, and especially whether any difference exists in the amount of acetone bodies formed in health and in diabetic coma?

I shall attempt to support the doctrine that oxybutyric acid is formed to just *the same amount* in healthy persons living on meat and fat as in diabetes. In enunciating this hypothesis I own frankly that it has not been proved and that some facts might be considered as contradicting this view. But in my opinion all facts known about acetone bodies would be understood best and be appreciated in the most simple manner by the doctrine that oxybutyric acid is the *obligatory* product of intermediate metabolism of fatty acids and of certain amino acids.

Having just introduced the conception of an *obligatory* intermediate product of metabolism, please allow me to explain what is meant by this term. When in the sixties of the last century the idea of intermediate products was introduced no clear definition as to its quantitative side was given for many years. The term was applied to all products which not having been completely broken down have been found under any conditions in the excretions or in the body itself. But a sharp distinction has to be made between facultative and

*This transformation, however, is reversible.

obligatory intermediate metabolism. For instance, glycuronic acid is a facultative product; it appears in the urine only when substances are introduced or formed in the body which need neutralization by combination with glycuronic acid because of their toxic character. Thus glycuronic acid is a facultative product of the sugar decomposition. If once it were established that sugar is broken down by yielding at first lactic acid or another chain with three carbon atoms, then this substance would have to be designated as the obligatory intermediate product of sugar oxidation. As another example: One might say that amino acids were the obligatory products of proteid breakdown if the decomposition in the body cells were initiated by a fermentative splitting-up identical with that of trypsin and erepsin. I might mention, by the way, that the opinions of authors on this point are as yet contradictory.

The amount of intermediate obligatory products will, according to this definition, depend only on the amount of the mother substances broken down and may be estimated by stoichiometric calculation.

As to oxybutyric acid, its amount is easily calculated, as far as the fatty acids are concerned in its formation. Of the two components of fat only the fatty acids yield acetone bodies; glycerin, on the contrary, is an antiketonuric substance. By investigations performed either with living beings in the state of acidosis or with the transfused dog's liver, it has been established that fatty acids are broken down by a repeated splitting off of two carbon atoms. The first step is the formation of a β-oxy acid which is then transformed to a β-keto acid;* the prototype of such conversion and the best studied is the transformation of butyric acid into oxybutyric acid and acetoacetic acid. The transformation requires a twofold oxidation at the β-carbon atom. Contrary to what happens in the lungs with acetoacetic acid, a splitting off of the carboxyl group and a formation of a true ketone generally does not take place in the metabolism; instead we find a simultaneous splitting off of the carboxyl group and of the α-carbon atom, thus yielding a new fatty acid lower by two carbon atoms. This opinion has been proven by the admirable experiments of Embden. He found that in the transfused dog's liver only fatty acids with an even number of carbon atoms gave rise to an increased formation of acetoacetic acid, while the acids with an uneven number do not. And I might also mention in this connection the name of Dr. Dakin, who has made important contributions to our knowledge of the breakdown of fatty substances. In this way from stearic acid palmitic acid is formed; from this an acid with fourteen, twelve, ten, or eight carbon atoms is derived; then caproic acid and finally butyric acid and oxybutyric acid are formed. The relative figures are as follows:

	Molecular Weight	Relation of Mol. Weight	% Yield of Oxybutyric Acid from 100 gm.
C_{18}	284	100	36.5
C_{16}	256	90	40
C_{14}	228	80	46
C_{12}	200	70.5	52
C_{10}	172	61	60
C_8	144	51	72
C_6	116	41	90
C_4	88	31	118
Oxybutyric Acid	104	36.5	

*Now, however, some authors assume that at first a β-keto acid is formed, and that this is reduced to a β-oxy acid.

Thus from one hundred grams of *stearic* acid ninety grams of palmitic, eighty grams of myristic acid are formed, and so on. And finally, thirty-six grams of oxybutyric acid arise. The yield is somewhat higher from one hundred grams of palmitic acid. Thus from a triglycerid of average composition thirty-six grams of oxybutyric acid are formed, supposing that every molecule of fatty acid yields one molecule of oxybutyric acid.

A similar calculation of the quantity yielded by the decomposition of protein is far more difficult. Neither do we know all the components of the protein molecule, nor do we know the real percentage of the known amino acids in the different proteids, especially in the katabolized protein of the body. Moreover, the behavior of all the different amino acids in regard to the acetone body formation is not yet known. With some reserve we may accept the following statements: That leucin, tyrosin, phenylalanin are producers of acetone bodies, while valin, glutaminic acid, aspartic acid, alanin, and so on are not.

I cannot point out the chemical steps leading from amino acids to oxybutyric acid; by analogy we might exclude certain amino acids as not giving rise to oxybutyric acid, while we might assume such possibility with others in regard to their chemical structure. But I might emphasize the fact that at least two groups of amino acids are contained in the protein molecule whose behavior is entirely antagonistic. Those amino acids which yield oxybutyric acids like leucin and others are not converted into sugar and *vice versa*. Considering the fact that one hundred grams of protein may form fifty grams of sugar and even more, we might estimate a yield of 40 per cent. of oxybutyric acid from one hundred grams of protein as a maximum. This calculation probably is rather too high than too low.

For the simplification of reckoning we might assume that the percentage of oxybutyric acid yielded from protein was just as high as from fats, namely, 36 per cent., or a little more than the third part.

Furnished with these approximate figures we are now able to examine the quantitative side of the intermediate metabolism. The fundamentals of the doctrine that acetone bodies are the *obligatory* products of metabolism are to be found in the experiments carried out on patients who survived diabetic coma. I emphasize the fact that only in surviving patients can the formation of oxybutyric acid be exactly studied by analysis of urine because the elimination stops too early in the progressively fatal cases. In 1899 I observed in a boy of thirty-one kilos an average elimination of ninety-eight grams of acetone bodies during a period of three days. As to an approximate calculation the boy had decomposed 90 grams of protein and 200 grams of fat; from these 33 grams plus 72 grams or, as a total, 105 grams of oxybutyric acid could have been formed; that is almost the same figure as was found by analysis. The almost perfect identity of the two figures is merely accidental, since different factors of the calculation are not exactly determinable, but in spite of that the agreement of reality and of calculation is striking. *In this case no doubt every molecule of fatty acids and of those amino acids which can be converted into acetone bodies really had undergone this transformation*, and it has been possible to prove this because no destruction had taken place.

For a number of years after that time no similar observation was made by other scientists; then I had the great satisfaction of finding a full confirma-

tion of my figures in the work of one of your countrymen, Dr. Joslin from Boston, with whom I had the pleasure of working in the laboratory of Prof. Naunyn at Strassburg. Since that time other cases were reported in which the amount of acetone bodies during coma reached approximately the above value.

The hypothesis that the acetone bodies are an obligatory product means that in healthy persons living without carbohydrates just as much of them are formed as in the above cases of coma. A healthy man seventy kilos in weight can cover his loss of energy by the decomposition of 100 grams of protein and 200 to 220 grams of fat either derived from the food or from his own body. From these, 110 to 220 grams of oxybutyric acid could be formed in the course of twenty-four hours; that is, 1.75 grams per kilo. Such a surprising assumption would be refuted immediately if it was not shown that human beings are able to decompose the acetone bodies completely by the process of oxidation. The question has not been definitely decided in *man* because nobody has ventured to introduce such enormous quantities. Twenty grams, which was the maximum I gave to healthy men in Naunyn's clinic, were completely destroyed. But in feeding rabbits with 3.6 grams per kilo of oxybutyric acid or acetoacetic acid I found not more than traces of acetone bodies in the excreta. A dog of Schwarz's three kilos in weight on being given twelve grams of acid eliminated only two grams. Ten grams were burnt. Thus in dogs as well as in rabbits three grams of acetone bodies introduced per kilo were decomposed completely. Three grams per kilo in a small animal does not mean three grams per kilo in a man, whose metabolism of energy is only the half. On the other hand it is to be considered that when substances are administered in four or five subcutaneous doses they rapidly escape through the urine and are withdrawn from oxidation.

The conditions of decomposition are much more favorable when the substances in question are formed in minimal quantities within the body cells during the course of the whole day. You may remember the old example of alimentary glycosuria. Hence the combustion of 1.75 grams of oxybutyric acid per kilo in man seems to be within the limits of biological possibility.

In the normal state of health every molecule of oxybutyric acid is broken down immediately after formation; thus accumulation never takes place. It occurs only when the destruction becomes deficient. Accumulation of acids within the body, a state which was called *acidosis* by Naunyn, according to this opinion depends merely on deficient oxidation. We estimate the degree of acidosis with approximate accuracy by the amount of acids which pass into the urine.

The less fat is burnt in the organism the less acetone bodies are formed. Each gram of carbohydrate or of alcohol replacing fat and removing it from combustion will diminish the formation of acetone bodies. When the needs of the organism are covered by 100 grams of protein and 500 grams of carbohydrates, only 36 grams of oxybutyric acid will arise instead of 110 grams in the case of decomposition of 100 grams albumin and 200 grams of fat. But carbohydrates act not only in diminishing the amount of *formation*, but they are directly implicated in the destruction of the acetone bodies.

Rosenfeld's statement that fats are burnt only in the fire of carbohydrates is not quite right, inasmuch as *only* the breakdown of the lowest stages of fat decomposition, that is to say the acetone bodies, depends on the metabolism of the carbohydrates. Naunyn explains the decomposition of the acetone bodies by the simultaneous combustion of sugar as being a *secondary* oxidation. I should prefer to call it a secondary *splitting-up* due to the splitting-up of carbohydrates. However, this term is merely a paraphrase, since we do not know anything about its mechanism. But we can consider the problem as to its quantitative side.

It is a known fact that fifty to eighty grams of starch are sufficient to make the acidosis of a fasting man disappear within a few days. But even in the absence of any sugar in the food acidosis reaches only a slight degree; from ten to twenty grams of acetone bodies are the maximum found in urine outside diabetes, eighty to one hundred grams derived from fat and protein are decomposed, although no carbohydrate was ingested. The combustion in this case is due to the decomposition of sugar formed from protein, for the withdrawal of the new formed sugar by administering phlorhizin causes an immediate rise of the output of acetone bodies. The quantity of new sugar formed in men fasting or living on fat and meat does not exceed fifty grams. Fifty grams of sugar thus are sufficient for the combustion of almost 100 grams of oxybutyric acid. Between these figures there is no equality in the stoichiometric relation. Considering the different size of the molecules, eighty grams of oxybutyric acid represent more than three times as many molecules as fifty grams of sugar. Thus either one molecule of sugar causes simultaneous decomposition of several molecules of acids or the decomposition of the latter is not *exclusively* dependent on a simultaneous decomposition of sugar. We will come back to this point later on.

In every case utilization or non-utilization of sugar plays the preponderant part in the combustion of acetone bodies. As a rule acidosis, that is, the quantity of non-destroyed organic acids, runs parallel in diabetes to the loss of new formed sugar. There are, however, some exceptions to this rule which I intend to explain later on.

It may be safely assumed that a far larger amount of acids is formed in severe diabetes than is eliminated in the urine. Thus we understand the action of ingested sodium bicarbonate upon the output of acetone bodies. It is a well known fact that alkalies increase their elimination. For instance, in a diabetic girl weighing twenty kilos, on varying the amount of sodium bicarbonate given, the following figures were obtained:

$NaHCO_3$ given.	Acetone bodies in the urine.
9	31
18	37
36	47
50	60

The surplus of acetone bodies with the highest doses of alkali was almost thirty grams. The fact is easy to understand. Alkalies by neutralizing the acids circulating in the blood facilitate their elimination with the urine. Here the increased output of acetone bodies does not mean a diminution of the oxidizing powers of the cells, but merely a rapid withdrawal from oxidation. Generally an increased output of acids means an increased deficiency of metabolism and at the same time an increased danger to life, but in case alkali is given the higher rate of acids in the urine not only is not a harmful process but on the contrary it is beneficial, inasmuch as

the accumulation of acids within the body is lessened.

You may ask why in healthy fasting men, when taking alkalies, no similar increase in the output of acetone bodies is found. Indeed, only minimal quantities pass into the urine in the case of healthy persons. But in these, contrary to what happens in diabetes, only minimal quantities of acids enter the blood, and it is only the circulating acids which are carried away and eliminated by the sodium carbonate.

In opposition to the effect of the alkalies, hydrochloric acid tends to diminish somewhat the output of acetone bodies. In binding the alkalies or the ammonia which were used for the neutralization and for the elimination of the organic acids their elimination is rendered difficult. Thus they are retained in the body and their combustion is favored because they circulate a longer time in the blood. But the increased destruction in this case does not mean an advantage for the organism.

I shall now endeavor to explain some striking results of feeding experiments carried out in regard to acidosis. Butyric acid given to diabetic subjects was found to be the strongest producer of acetone bodies. This conversion requires only one atom of oxygen; it is performed rapidly and the organism is suddenly inundated by an excess of oxybutyric acid. Thus an important part of it escapes decomposition and is found to pass into the urine. On the other hand, on giving stearic acid a certain time will be needed before each molecule is broken down until it reaches the stage of butyric acid. The formation of oxybutyric acid from stearic acid extends possibly over many hours, no sudden inundation will occur and thus no appreciable rise in the output of acetone bodies will take place.

Remember also the fact that regarding the formation of oxybutyric acid three grams of stearic acid are equivalent to only one gram of butyric acid. In the second place we have to consider that on adding 100 grams of fat to the food no corresponding additional combustion of fat occurs, but only a replacing of 100 grams of body fat by food fat. In analyzing the results of all experiments on fat introduction I cannot accept the opinions of some authors that overfeeding with fat causes an increased output of acetone bodies.* Only in a very few experiments the output was increased after taking a great amount of fat, especially in comparison with fasting men, who decomposed body fat. But the difference was small and I do not think it was due to a different breakdown of body and food fat, but rather to secondary factors.

Some years ago the conclusion was reached by several physicians that it was necessary to restrict the fat in the food of a diabetic patient on account of its giving rise to acetone bodies. The above explanation will be sufficient to show the inconclusiveness of such postulation. And knowing as we do at present that the protein molecule also yields acetone bodies, you may easily appreciate that the above conclusion was erroneous.

As to the protein, its part in relation to acetone bodies is more complicated. Protein contains two different groups of amino acids, one group yielding oxybutyric acid, and the other increasing its destruction. In healthy men the efficacy of the latter group prevails. When a healthy man, living on eighty grams of protein and two hundred grams of fat, eliminates six grams of oxybutyric acid, and he is given a surplus of one hundred grams of albumin, acidosis will disappear within a few days. But the rôle of protein is different in severe diabetes. In such cases those amino acids which exert an antiketonuric effect, like alanin, glycocoll, etc., are converted into sugar and eliminated; thus they cannot help in splitting up oxybutyric acid, and the surplus of oxybutyric acid, formed from the other groups of amino acids, will be added to the amount present in the body, and thus acidosis may increase frequently.

Glycerin also is able to prevent acidosis in a *healthy* man. Its efficacy is due to its transformation into dextrose, just in the same way as is the case with glycocoll, alanin, etc. These amino acids also owe their effect to their conversion into sugar. In diabetic patients, however, glycerin fails to show its antiketonuric effect, because the sugar formed from glycerin is not available for the patient.

Besides protein and glycerin another substance is to be mentioned whose antiketonuric efficacy is available, not only in *healthy* men, but also in diabetics, namely, alcohol. Alcohol is not convertible into sugar, hence this food stuff, if we may call it so, is useful in severe diabetes, at least in moderate quantities, on account of its energy content, and of its possible efficacy against acidosis. I deem further experiments on this subject necessary, especially in coma, and I think it very likely that it might give us a little support in the struggle against coma. Its efficacy can be explained either exclusively by its replacing fat and thus diminishing the formation of oxybutyric acid, or by the assumption that it increases destruction, similarly to the efficacy of carbohydrates. Whether or not this be so is as yet unknown.

I will set aside many questions of great interest in the problem of acidosis and will confine myself to three questions only.

1. We know that as long as coma is not imminent, the oxybutyric acid output amounts to not more than fifty or sixty grams daily. In coma the amount rises to two or three times this amount. According to my conception this does not depend on increased formation, but merely on a decrease or even a total loss of the destructive powers. We may ask why oxidation ceases so rapidly, coma occurring sometimes in the course of a few hours? In some cases the coma seems to have accompanied a sudden decrease of the sugar combustion. Such a case was reported by Spitzer. Coma set in immediately after a strong physical shock combined with a physical emotion. From that moment the elimination of sugar, up to then rather slight, rose to abnormal height, and at the same time by increased loss of sugar the oxidation of acetone bodies was lessened to a minimum. Here no time was left for adaptation, which in the general course of diabetes prevents the rapid increase of acidosis. But it is unknown whether the sudden increase of acidosis in coma can always be explained in this way. It is necessary to look for other reasons which influence acidosis.

In connection with this problem I might refer you to a second question, namely, to the differences which are observed in different patients. Some of them, when kept on a strict diet and eliminating some grams of sugar, do not eliminate acetone bodies through long periods of their illness. Others on the contrary, although still decomposing thirty and forty grams of starch given in their food, will eliminate several grams of oxybutyric acid. This

*With the exception only of butter.

difference, which is rather remarkable, points to the conclusion that still other factors besides the carbohydrate breakdown come into play in acidosis; von Noorden especially has insisted upon the existence of such factors. At present we cannot determine them. But I might suggest that the above difference in the acetone body output may be explained by a different localization of the carbohydrate combustion. If the splitting up of oxybutyric acid depends on the simultaneous splitting up of carbohydrate, the decomposition of both substances ought to occur *simultaneously* and in the *same place*. If there was no coincidence of the two processes, neither in time nor in space, then acetone bodies would be eliminated although certain quantities of sugar were utilized.

Let us now return once more to the principal subject of acidosis. In asserting that acetone bodies were an obligatory intermediate product, I refer principally to Embden's experiments on the dog's liver. The yield of oxybutyric acid from the liver, on transfusion with butyric acid, amounted to not less than nine grams, if calculated for twenty-four hours. Considering the low weight of this organ, which is from 100 to 200 grams, this yield is extremely high. Considering further that in the isolated liver the conditions of formation are less favorable than in living beings, and considering moreover that other organs also might form acetone bodies, although we have no knowledge of such formation except in the liver, we might consider the formation of 100 grams in healthy men as being within the limits of biochemical possibilities.

But it was Embden himself who made an important objection to my doctrine. This skilful investigator found that dog's liver is capable also of *destroying* acetoacetic acid. And in comparing the rate of destruction in the liver of a normal and of a diabetic dog, he found that there was no difference. Hence he inferred that the destruction of acetone bodies was not diminished in depancreatized dogs, and he inferred that this was the case also in human diabetes. Thus he was obliged to explain the acidosis in diabetic patients by an increased formation of acetone bodies. His opinion is just the reverse of mine. But there is one error in Embden's conclusion, and that is the difference in the metabolism of diabetic dogs and of men. Contrary to what happens in human beings, severe acidosis is rather rare in depancreatized dogs, and it seldom reaches the height of the human acidosis. *The dog being a carnivorous animal is used to breaking down oxybutyric acid without the help of carbohydrates*, which are needed in human metabolism; thus in canine diabetes the destruction of acetone bodies is not as deficient as in men. It was erroneous to transfer the results of the experiments on the dog's liver to the metabolism of diabetic patients. Thus I deem that Embden's results by no means refute my hypothesis.

The doctrine which I have endeavored to present to you is to the effect that oxybutyric acid is an obligatory intermediate product of metabolism; second, that its amount is the same in healthy persons and in diabetics, supposing that only fat and albumin are decomposed. And, third, that acidosis and the elimination of acetone bodies depend *merely* on the deficiency of destruction. I own frankly that this hypothesis is not proved at all, and you are at liberty not to accept it. I myself do not fix my opinion absolutely. By the thorough calculation of the quantitative factors of the hypothesis in problems of this nature and careful consideration of the ultimate possibilities presented, valuable insight into the question may be obtained which may lead to the development of a well founded theory. In this way weak points in the doctrine may be discovered and new aspects of the problem would present themselves for further investigation. If the ideas that I have been putting before you should lead you to undertake new experiments and to obtain new results, I will be the first to accept them willingly, even if they are contradictory to the above hypothesis.

METABOLISM OF WATER IN DIABETES.

The large quantities of water which the diabetic patient eliminates are almost exclusively the result of his loss of sugar. There is a certain relation between the absolute and percentage quantity of sugar output and the volume of urine. Exceptions occur but are not very frequent. There are patients who on losing only a few grams of sugar eliminate three to four liters of urine. In this case the glycosuria is sometimes overlooked; it seems to be a case of *diabetes insipidus*. Also another variety sometimes deceives physician and patient, and has, therefore, been given the name *diabetes decipiens*. The patient is not troubled with an abnormal thirst; the volume of urine is within normal limits; the patient has also, as the loss of sugar often remains slight, no striking symptoms. Accordingly often only an accident leads to the discovery of the urine sugar, whose mass may then amount to many parts per cent.

In ordinary cases of diabetes the patient covers his increased water output by taking in large quantities of water, so that his organs do not lose water. They do not dry up. But in other cases the taking up of water does not keep step with the flow of urine, in spite of severe thirst and great drinking. The tissues of the body lose some water, whereupon of course a new equilibrium is set up between water introduced and eliminated. This occurs only in patients with a very high sugar output and on a completely unrestricted diet, and especially in wholly neglected cases. Such we find rather seldom at present in Germany. Diabetes has changed its clinical aspects, when compared with a period of thirty years ago, on account of early and careful treatment.

In such patients the loss of water from the skin has sunk to a minimum. Külz has seen diabetics in whom only 100 c.c. water are evaporated from the skin instead of 500 c.c. So much water is used for the sugar elimination that only a very little is left for the dried up skin. As soon as the water content of the organs becomes normal again the perspiration increases. It was also believed formerly that in such severe cases the skin would take up water from the surrounding air. Even Gaethgens has fallen a victim to this deception in spite of great care in his experiments. We know to-day that the skin by no means takes up water from the air. In a bath of warm water a swelling of the epidermal layers takes place and there is a transitory absorption of water. This water, however, does not penetrate into the general circulation. The loss of water from the lungs is usually fairly normal with diabetic patients. If the diet be regulated and the transition to strict diet carried out *quickly*, the weight of these patients sometimes rises several kilos in a few days. This increase is

caused most exclusively by regaining of the lost water of the body.

Also in periods of regulated diet the water equilibrium of a diabetic subject can vary to a certain extent from day to day, partly in connection with the change in the sugar output. To a smaller degree variations of this kind also occur with normal persons. We must be careful not to attribute every kilo of loss or increase in weight to a loss or increase of flesh and fat.

But at certain periods an excess of water may be stored up. True dropsy can appear, but also that condition which Widal has suitably called "preedema." Widal observed that the weight of patients suffering from parenchymatous nephritis on being fed on a diet rich in salt rose five to six kilos before dropsy became visible. In this period the water is uniformly distributed over the body. Both of these states, preedema and dropsy, may appear in diabetic patients, also when distinct nephritis is absent, and are found especially when the patient takes large quantities of sodium bicarbonate, thirty and forty grams daily.

This circumstance leads us to an important consideration. Widal, as you know, has referred the appearance and disappearance of nephritic dropsy to the retention and excretion of salt, and has put forward irrefutable proofs for this opinion. But we must no longer be content to ascribe certain properties to any salt as a whole, since it is known that all salts are split up into ions.

It has always been thought that in the retention of salt by the diseased kidneys it was the chlorine ions and not the sodium ions that played the decisive part. But experimental investigations of this sort had not been carried out when I drew attention to this question last year in Wiesbaden. I myself believe, like most clinicians, that the chlorine ions are responsible for the nephritic retention of common salt. Experiments on nephritic patients which I carried out last winter in this direction strengthen this assumption. But the conditions seem to be otherwise with diabetic patients. Here sodium carbonate often effects distinct retention of water. It appears to act similarly also in infants according to experiments of my friend, I. F. Meyer, on the idiopathic dropsy of young children. Whether the conditions are really different in nephritis and in diabetes I consider not yet decided. Perhaps the dropsy producing property of the sodium ion observed in diabetes is not a direct one. Further experiments in this direction promise to be of value for pathology and physiology.

METABOLISM OF INORGANIC SUBSTANCES.

Common salts, that is to say sodium chloride, also sodium bicarbonate, have such intimate relations to the water metabolism that investigations in this direction will for the most part go hand in hand. Nothing is yet known about peculiarities of the mineral metabolism in the course of common diabetes. Almost no experiments on mineral equilibrium have been carried out, but severe disturbances are scarcely to be expected. Quantities of from thirty to forty grams of common salt in the urine of certain diabetics are only an accidental symptom of the polyphagy. If nephritis appears perhaps the elimination of common salt might be interfered with. Still it is not yet known whether diabetic nephritis has not its own special peculiarities and is different from ordinary nephritis. That appears probable to me.

Disturbances of the lime and magnesia metabolism, also of phosphoric acid, occur in severe diabetes. Considerable losses of all three substances sometimes have been observed. The loss of lime can amount to several grams in the course of a week. It is clear that this lime is derived from the bones, for the total fleshy parts of the body contain hardly more than ten grams of lime and a marked diminution of the lime content of these parts scarcely occurs. The bones, on the other hand, can give up large quantities of lime together with phosphoric acid. Frerichs years ago found in autopsies that bones of diabetic subjects were extremely poor in mineral substances. This single result must be controlled by systematic investigations in diabetic cadavers, but also in other diseases. As in such cases of demineralization a strong acidosis is mostly present we can consider both phenomena to be in connection with one another. We might attribute the loss of lime and magnesia to the action of the oxybutyric acid.

But we must not regard this demineralization purely chemically as consisting of a simple solution of the bone ash in the same way as one formerly ascribed rachitis and osteomalacia to the dissolving power of lactic acid. The oxybutyric acid of the serum is not present in the state of the free acid but as the neutral salt, or as we should say to-day as the anion accompanied by the corresponding masses of cations. The alkalinity of the blood is not changed, at least not except in coma. The oxybutyric acid does not exert a specific action which attacks the bone tissue directly and leads to decomposition, as certainly is the case with oxalic acid. But we cannot quite doubt the influence of acidosis on the inorganic metabolism. I will bring to your notice two very instructive examples showing the influence of acids on the metabolism.

Zuntz and Tangl have shown that the passage of even small quantities of lactic acid from the working muscle into the blood by which the alkalinity is not appreciably diminished has an immediate and definite action on the respiratory centers. By this a more active aeration of the blood and ventilation of the lungs are called into play. Another instance: Loghem several years ago brought forward a particularly good experiment. Rabbits into which uric acid had been introduced subcutaneously transform this rapidly by means of the body alkali into sodium urate, which on account of its slight solubility remains for a time at the site of the injection.

In several experiments Loghem gave the rabbits half a gram of hydrochloric acid, corresponding to about one-fourth gram per day and per kilo. That is a quarter only of the dose which according to Walther is fatal, a quantity which does not interfere with the health of the animals. This small quantity, which is neutralized by three-tenths gram of sodium or by one gram of sodium carbonate, suffices to prevent the transformation of the uric acid into the sodium salt. Experiments of this and of similar sorts show that the influence of acid or of basic components on the metabolism is not to be underestimated, as was done by investigators who apply the modern physicochemical conception of acids and bases to the occurrences in the animal body. In experimental hydrochloric acid poisoning of a dog a moderate loss of sodium was found, and with rabbits this was very much more considerable. So we may assume that a loss of sodium and potassium could also occur in severe diabetic acidosis. But if compared to the large quantities of sodium which diabetic subjects pass through the body (twenty

grams of common salt contain eight grams of sodium), the loss of small quantities of body sodium will not distinctly enough be recognized in the analysis of the urine in the experiments on equilibrium. Probably on analyzing the organs more striking results could be obtained. I consider it possible that, while during a slowly developing acidosis the body loses some alkali, a new equilibrium between intake and output is shortly reached. This will then once more be disturbed in coma by the sudden increase of the acidosis.

TUBERCULIN TREATMENT IN ADVANCED STAGES OF TUBERCULOSIS;

A REPORT OF SEVENTEEN CASES TREATED WITH TUBERCULINUM PURUM IN HOSPITAL PRACTICE.

By FREDERICK A. DEAL, M.D.,
NEW YORK.
VISITING PHYSICIAN TO THE ST. JOSEPH'S HOSPITAL FOR CONSUMPTIVES.

Tuberculin treatment now stands upon a well founded clinical and experimental basis, thanks to the researches of the past decade, which have taught us how to secure its specific effects with a minimum of risk by avoiding improper methods of administration. Despite the numerous modifications, there now is a distinct general tendency to revert to the original product, Koch's "old" tuberculin, the simple gylcerin extract of a filtered culture of human bacilli. Why none of the multitude of modified forms has displaced it is not certain; but the possibility suggests itself that they do not exhibit a better relativity between efficacy and toxicity.

Although there is practical unanimity of opinion regarding the value of tuberculin in incipient and moderately advanced cases, specific treatment is generally regarded as contraindicated in the very adanced types of the disease, principally because the patient's organism is unable to withstand the successive shocks of those toxic reactions which are almost inevitable in the course of tuberculin treatment. Accordingly, tuberculin treatment has never seemed to promise much at St. Joseph's Hospital, where the cases for the most part are of the advanced type, patients whom the sanatoria have rejected or discharged as unimproved, cases which have become advanced amid the unsanitary surroundings of the tenement, the workshop, or the mill. The fate of these unfortunate subjects is certainly a sad one; during their rapid progress toward death their sufferings are but temporarily relieved by opiates and other symptomatic remedies. It seemed a pity to withhold from them the possible hope of benefit from tuberculin treatment, on account of their inability to bear the reactive tendencies of the remedy. While it was formerly thought that a systemic reaction is a necessary and desirable therapeutic effect of tuberculin, preponderance of modern opinion regards reactions as both undesirable and unnecessary. The rules of dosage laid down by present day authorities aim at the avoidance of reaction as the prime object. (Goetsch[1], Denys[2], Sahli[3].) Marked reactions are certainly injurious to the system as a whole as well as to the pulmonary tissues, where the toxic effect of tuberculin may lead to necrosis. For this reason I was interested in a communication of Gabrilowitch of Halila, Finland, to the International Congress on Tuberculosis held at Washington in 1908.[4] He announced that Koch's "old" tuberculin contains not only the beneficial principle which has the specific properties, but also certain albumose constituents which have no therapeutic value and which are the cause of the untoward reactions. He worked with a preparation of Koch's "old" tuberculin from which these toxic constituents had been eliminated by means of chemical reagents (alcohol, chloroform, xylol), and found that this purified tuberculin no longer produced general toxic reactions.

According to Gabrilowitch, this tuberculinum purum (T. P.) can be used in rapidly increasing doses, is not contraindicated in cases in which organs other than the lungs are involved, and produces no subjective or objective discomfort to the patients. What was particularly noteworthy was the fact that one-third of his cases were "of the severe type," although the significant phrase occurs in the full report of Gabrilowitch's work[5]: "But it should not be forgotten that the best results can be obtained only in patients in the first two stages of pulmonary tuberculosis." Gabrilowitch reported that the remedy gave him very satisfactory results, reducing fever, increasing weight, improving the local lesions, and lessening the number of tubercle bacilli in the sputum.

Gabrilowitch's contentions seemed to me sufficiently important to challenge investigation, and I therefore concluded to determine whether the purified product could be used without danger in the advanced cases in my hospital service at St. Joseph's. The treatment was applied in the rather unfavorable surroundings of a large hospital filled to capacity and situated within the city, where the refinements of the sanatorium system are lacking. I therefore felt at the outset that the test to which this purified Koch's O. T. would be put left nothing to be desired in rigorousness. Naturally I did not expect to produce absolute cures, but determined to be satisfied if the albumin free tuberculin did no harm, while prolonging life, ameliorating distressing symptoms, and improving the general condition.

The work was begun about two years ago, and included a study of seventeen cases which were treated with the purified tuberculin. No other medication was employed, but the usual dietetic and hygienic rules were, of course, enforced. For the sake of brevity I have condensed the histories and omitted six cases which contribute little in the way of defining the uses and limitations of the tuberculin.

Chronic Pulmonary Tuberculosis. Case I. *Advanced Catarrhal Tuberculosis.*—M. D., woman, Russian, 23 years old, domestic. She has been ill for several months and had been a patient at the Stony Wold Sanatorium, but was not improved at that institution and had returned to the city. There had been cough, fever, considerable expectoration, and marked loss of weight. The patient entered St. Joseph's Hospital on April 16, 1909. Her condition at entrance was very poor, so that she had to be confined to bed. There was considerable cough and expectoration, nausea, and anorexia. All food was almost immediately vomited. Temperature on admission was 102°F. The physical signs revealed consolidation of the upper half of both lungs, without any cavity formation, but numerous râles over the affected area. The heart and other organs were normal. Numerous tubercle bacilli in the sputum. The first injection of tuberculin was given on April 20, 1909, the dose being 0.02 mg. of T. P. Two

injections were then given each week, the doses progressing gradually, according to the scheme laid down by Gabrilowitch, until 100 mg. were reached. At no time were the injections followed by any reactive phenomena or any unpleasant symptoms, except that the fourth injection caused a constricted feeling in the chest, which lasted for about a week. After the second injection the patient's temperature dropped from 102° to 99°F. (See chart 1, April 26.) On that day she was allowed to get up and go about, and this resulted in a slight rise in temperature on the following evening to 100 F. The chart shows the variation in temperature from April 18 to May 30. She continued able to go about, and her temperature gradually became normal after exhibiting some fluctuations during these weeks. On June 1 the evening temperature was normal and continued so thereafter. The patient's general condition markedly improved during the treatment. At the end of the course of injections there were still some bacilli in the sputum. A noteworthy feature was the prompt improvement of the appetite and digestion after the second injection, when nausea and vomiting ceased and did not reappear. The patient was able to enjoy her meals and to digest her food, with the result that her weight increased slowly but steadily. On April 30 she weighed 120.7 lb. When she left the hospital her weight was 130 lb., a gain of about 10 lbs.

The changes in the lungs at the end of the period of treatment, that is about June 1, consisted in a disappearance of the catarrhal symptoms and a clearing of the affected area of all but occasional râles, although the signs of consolidation still remained. The process was evidently quiescent, and in a favorable condition for hearing. There were still slight cough and a few bacilli in the sputum. Two months after the completion of specific treatment, the patient left the hospital and went to Russia. A letter received from her about a week ago (June, 1910) by one of the Sisters states that she continues in good health and has had no relapse of pulmonary trouble.

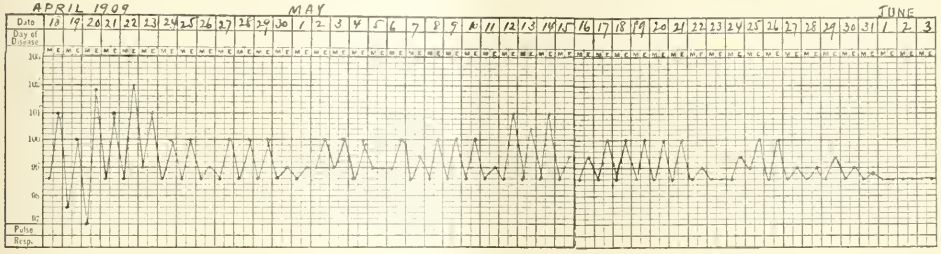

Chart 1. Case I.

Case II. *Catarrhal Tuberculosis.*—A. L., woman, Russian, 30 years old, domestic. The patient had been in the hospital for several months during which time she had shown a steady rise of temperature in the afternoon, in addition to cough, expectoration and at times nausea, vomiting, loss of appetite and general weakness. On May 7, 1909, the cough was annoying and frequent, with a rather moderate expectoration, and some dyspnea on exertion. The patient was able to be about and to do very light work, however. The physical signs revealed a consolidation of both lungs down to the third rib in front, and a corresponding point behind. There were no cavities, but numerous râles over both involved areas. Numerous tubercle bacilli were found in the sputum.

The first injection of 0.02 mg. tuberculinum purum was given on May 7; increasing gradually at each semi-weekly injection, the sixteenth dose amounted to 100 mg. None of the injections was followed by any unpleasant symptoms or any febrile reaction. On the contrary, there was steady betterment of the subjective condition. The temperature during the treatment gradually fell to normal, although a slight evening rise remained for some time after the last injection, and then disappeared.

The results in the lungs consisted in a disappearance of the râles and a quiescence of the catarrhal condition. The cough was markedly lessened and the expectoration decreased. Examination of the sputum showed at times a few tubercle bacilli and at other times none were found. The dyspnea on exertion was markedly improved as were also the appetite and the general condition. The temperature became normal night and morning and remained so. The weight, however, did not markedly increase, but remained practically the same with some fluctuation. The patient left the hospital two months ago and has had no trouble since the treatment.

Case III. *Fibroid Tuberculosis.*—J. K., man, Irish, 30 years old, laborer. The patient had been in the hospital for several months, during which time he had had several severe hemorrhages. A fairly well nourished patient. Cough and expectoration at times marked. Tubercle bacilli in the sputum. The appetite was good, but there was a slight febrile movement toward the evening. The physical signs showed chronic fibroid phthisis involving the upper half of the right lung. There was a moderate number of râles over the affected area, in addition to the other signs of fibrosis. The first injection was given on October 23, 1898, and the doses were repeated twice a week. The first course of injections, sixteen in number, reached the dose of 100 mg. After an interval of about three weeks a second course was begun, this time reaching a dose of 200 mg. At no times were unpleasant symptoms or febrile reactions noted. The slight evening rise spoken of disappeared gradually in the course of the first series. No further hemorrhages occurred after the injections were begun, nor was the sputum tinged red at any time thereafter. The catarrhal signs in the lung disappeared and the fibroid lesions which had previously tended to extend were arrested for the time being. The general condition at the conclusion of the treatment was good. The weight on entrance had been 135 pounds. On October 26, three days after the first injection, the weight was 148 pounds. On

November 16, 151 pounds; on February 16, 156 pounds. The patient became an orderly and remained in the hospital for several months, during which time occasional examinations showed that his good physical condition continued.

Case IV. *Fibroid Tuberculosis.*—C. F. M., American, 30 years old, porter. The patient entered the hospital on January 22, 1908, with a history of cough, expectoration, and a moderate evening rise of temperature. His general condition had been fair, his appetite normal. The physical examination showed chronic fibroid tuberculosis on both sides, reaching to about the fourth rib in front and a corresponding distance in the back. A considerable number of tubercle bacilli were present in the sputum. There were numerous râles over the affected region. Injections of T. P. were begun on October 23, 1908, two doses being given each week. Two courses were given in all as in Case III, the last injection reaching a dose of 200 mg. No unpleasant symptoms were noted, except a feeling of constriction in the chest during the first week of the treatment, which disappeared after about a week. As regards febrile reactions, these were either absent or very slight, leaving no subjective disturbances. The temperature gradually was reduced to normal and has remained so after the treatment until the present writing.

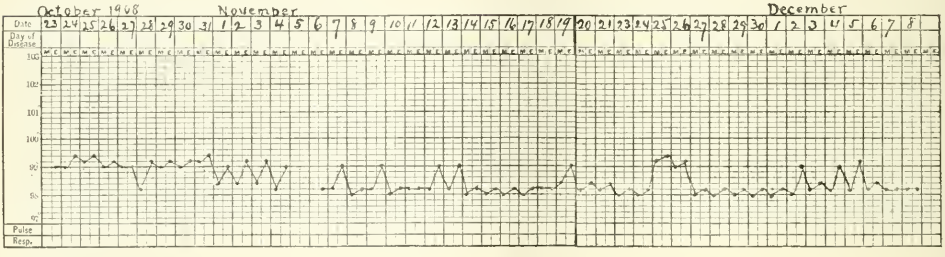

Chart 2. Case III.

The patient has just been reexamined (June, 1910). There has been an arrest of the active phase, disappearace of the catarrhal symptoms, clearing up of the involved area, return of the temperature to normal, considerable lessening of cough and expectoration, and marked reduction in number of tubercle bacilli in the sputum. To the present writing, almost a year later, the patient's condition has remained practically stationary.

Case V. *Ulcerative Tuberculosis.*—W. W., man, American, 52 years old, insurance agent. Patient entered the hospital on August 17, 1908, with cough and expectoration, poor general condition, anorexia, night sweats. There had been no improvement up to the present period of observation; in fact, he had been getting gradually worse. Physical examination revealed ulcerative tuberculosis, with consolidation of both apices, and a cavity in the right apex. The temperature on examination was 101°F. There were numerous tubercle bacilli in the sputum.

The first injection was given on October 23, 1908, and, like in the three preceding cases, two series of injections, 32 in all, were given. No unpleasant symptoms were noted after any of the injections. The weight had dropped from 128 to 120 pounds before the beginning of tuberculin treatment. During the treatment the appetite improved and the patient gained one pound, but his weight remained at this point practically stationary.

The results in this case were a general improvement, a lessening in the cough, dyspnea, and expectoration, and a reduction of the number of tubercle bacilli in the sputum. The patient's improvement, so far as the lung itself was concerned, was not marked, the process remaining stationary rather than receding. At the end of the treatment his general condition was good and remained so. Unfortunately this patient's mental condition was affected; he became melancholy, and committed suicide three months after the discontinuance of the treatment.

Case VI. *Ulcerative Tuberculosis.*—J. R., woman, American, 25 years old, clerk. Patient had been treated at Stony Wold Sanatorium. For several weeks she had been suffering from an acute exacerbation, with a small amount of blood in the sputum, nausea, vomiting, and fever reaching 102° F. Ulcerative tuberculosis was found on examination, with an extensive involvement of both lungs in their upper lobes and a cavity at the apex of the left lung. The first injection was given on April 21, 1909.

Sixteen injections were given in all, the tuberculin being administered twice a week. The maximum dose was 80 mg. After the third injection the nausea and vomiting disappeared, the appetite improved. The temperature gradually fell with fluctuations. The cough at first became looser and the expectoration increased. Later the cough became less frequent and the expectoration scantier. The weight increased from April 22, when it was 93 pounds, to 97 pounds on May 4. After the third injection I also noticed a peculiar change in the skin of this patient. The epidermis which in this girl had been harsh and leathery became pliable and normal in appearance. During the first few injections the patient complained also of a tight or constricted feeling in the chest which disappeared, however, after six or eight injections had been given.

In this case there was no lasting effect upon the temperature from the administration of T. P. I attribute this partly to the presence of a cavity and partly to the probable presence of a mixed injection which is so frequently seen in such cases.

Cases VII to XII were also chronic pulmonary processes of advanced types, but present no features of special interest and therefore their histories are here omitted.

Acute Miliary Tuberculosis.—With a view to ascertaining whether any reactive phenomena would appear, and whether some subjective relief would not occur, T. P. was given in two cases of acute miliary tuberculosis which were admitted in a dying condition. It is hardly fair to include these in

the mortality figures, since their death had been a foregone conclusion.

Case XIII. *Acute Miliary Tuberculosis.*—J. L., man, Italian, 30 years old, laborer. No previous history could be obtained with definiteness, as the patient spoke no English. He entered with nausea, vomiting and fever, and a good deal of prostration. Temperature was 102½°F. and the general condition very poor. On examination, both lungs were found involved in an acute miliary type of tuberculosis. The tuberculin was given with the hope of making the patient comfortable by lowering his temperature and arresting his nausea and vomiting, since it was evident that the case was hopeless. The patient remained in the hospital for about two weeks, during which time four injections were given, the first beginning with 0.02 mg., and the others increasing to 0.1 mg. After the second injection his gastric condition improved, as well as his appetite. The patient felt more comfortable, although no effect was produced upon the pulmonary process. The patient died a few days after the last injection. There were no untoward symptoms or febrile reactions following the injections, and I feel that the tuberculin made his last days comfortable, even if it did not succeed in prolonging his life.

Case XIV. *Acute Miliary Tuberculosis.*—M. F., woman, American, 23 years old, clerk. Patient had been ill for about two months when she entered the hospital on October 9, 1908. There was a cavity in the left lung, and at the time of entrance an acute miliary tuberculosis in both lungs. On admission the temperature was 104°F. At the request of her family physician T. P. was given, but after the seventh injection the treatment was discontinued, owing to the hopeless character of the case. There seemed to be no untoward effects from the tuberculin, but it did not produce any improvement. This case was totally unsuited for T. P., and it was only at the urgent request of both physician and patient that the injections were given. The case progressed rapidly toward its fatal termination, as all cases of this type do, death occurring within two months.

Tuberculosis of the Larynx: Case XV. *Laryngeal Tuberculosis.*—T. O'B., Irish, 33 years old, plumber. The patient had been in the hospital for eight months, during which time he gradually lost much weight, had occasional fever, and suffered from increasing aphonia. There was no history of pulmonary involvement, but repeated examinations of the larynx had shown progressive laryngeal tuberculosis. On October 23, 1908, careful examinations of the lungs showed no pulmonary signs of tuberculous disease. The larynx showed chronic tuberculosis. The patient could talk only in a whisper and was markedly emaciated. There was little dysphagia. At no time were there any tubercle bacilli in the scanty expectoration which accompanied the laryngeal cough.

The first injection of T. P. was given on October 23. There were two courses of injections given in this case, in the same manner as in Case III. At no time were any unpleasant symptoms noted. Improvement did not show itself to any extent in the laryngeal lesions; but rather in a steady gain in the general condition and the weight of the patient. The patient when admitted on April 2 weighed 165 pounds. On October 26, three days after the first injection, he weighed 138 pounds, having lost 27 pounds since admission. Until he began receiving the injections, therefore, he was rapidly losing weight. This was almost entirely checked by the T. P.

The patient is still in the hospital and doing fairly well, the process being apparently quiescent (June, 1910). The results in this case cannot be said to have been extraordinary, yet scarcely better could be expected in an advanced case of primary laryngeal tuberculosis.

Joint Tuberculosis.—Inasmuch as the tuberculinum purum had been well borne by patients with pulmonary and larynygeal phthisis, I employed the remedy in two cases of joint tuberculosis.

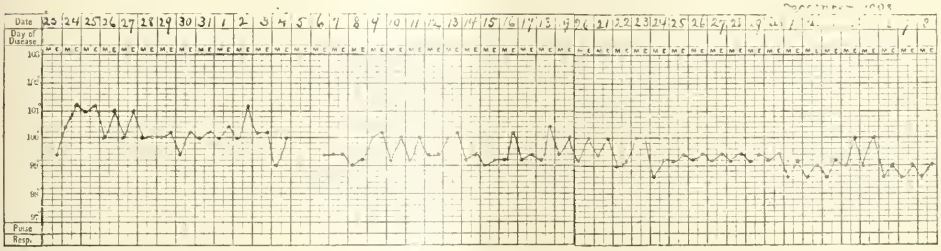

Chart 3. Case VI.

Case XVI. *Tuberculous Arthritis.*—J. G., American, 32 years old, saleswoman. In April, 1909, the patient was operated upon at St. Luke's Hospital for an abscess in the neighborhood of the knee joint. She was told at that time that the bone was not involved. A sinus persisted, however. On May 24 the patient had an attack of pleurisy and several pulmonary hemorrhages, with fever and delirium. In this condition she entered St. Joseph's Hospital. Here her pulmonary condition gradually improved, but the knee became swollen and painful, with limitation of motion and inability to extend. Upon diagnosis of tubercular process in the joint, the patient was put on tuberculinum purum, two injections being given each week. The initial dose was 0.02 mg., the maximum dose 100 mg. At first the pain in the knee increased, but after a few injections the swelling became less marked, the pain gradually disappeared, and range of motion increased. After the sixteenth injection the patient returned to her home with little or no pain in the knee joint, and was able to extend the limb fully, something she had been unable to do for months. The lung condition upon her discharge was in a quiescent state.

Case XVII. *Tuberculous Arthritis.*—B. C., Irish, 39 years old, houseworker. Three and a half years ago her right knee began to trouble her, giving the usual symptoms of tuberculous arthritis. Two years

ago her elbow also became involved. In October, 1909, injections of T. P. were begun. Both knee and elbow were markedly swollen, very painful, with considerably restricted motion. After the first injection of 0.02 mg. the patient complained of a "bound" or constricted feeling in both joints, a sensation which disappeared in about ten days. The injections were repeated twice a week, the doses gradually increasing. At no time were there any febrile reactions or other unpleasant symptoms. Gradually the motion increased in the elbow so that the patient could comb her hair, and in the knee so that she could freely extend that joint. The swelling and pain disappeared. Sixteen injections were given in all, the last amount being 100 mg. In this case not only was the disease arrested in both joints, but a considerable degree of motion was restored to the articulations, which with use will improve further. There was apparently no pulmonary lesion in this patient.

Dosage and Method of Injection.— In my work I followed the general scheme of dosage recommended by Gabrilowitch, and, while ready to make a modification of strength and frequency, did not see any need for so doing. The product was supplied to me in four series of each five sealed bulbs, the first series being a one-tenth of one per cent. solution of tuberculin and each of the following series being ten times as strong as the preceding one. The following table presents the progression of dosage in general, but it may of course be varied in individual cases by diluting the solutions with sterile water, or by repeating a dose without increase, or lessening it, or deferring its administration, if any sign that the limit of tolerance has for the moment been reached appears.

Number of Injection	Dose in Mgm.	Series Used	Volume of the Injection in 1–10 cc.
1st	0.02	A	2
2nd	0.04	A	4
3rd	0.08	A	8
4th	0.10	A	10 (or 1 cc.)
5th	0.20	B	2
6th	0.40	B	4
7th	0.80	B	8
8th	1.0	B	10 (or 1 cc.)
9th	2.0	C	2
10th	4.0	C	4
11th	8.0	C	8
12th	10.0	C	10 (or 1 cc.)
13th	20.0	D	2
14th	40.0	D	4
15th	80.0	D	8
16th	100.0	D	10 (or 1 cc.)

The injections were given not oftener than twice a week.

Conclusions.—Reviewing these cases, it appears that no untoward effect was produced by T. P., excepting occasionally a transient feeling of constriction in the chest. The temperature was not raised by the injections, save in some instances to the extent of a few tenths of a degree. This is in marked contrast to the severe reactions common with Koch's O. T.—fever, chills, dyspnea, prostration—whose occurrence means so sharp a set-back to the patients. In all but one of the acute miliary cases a specific effect on fever, lesions, bacteria in the sputum, expectoration, appetite, digestion, weight, general condition was evident. A distinct arrestive influence on the tubercular process must be conceded. These favorable effects were particularly striking on comparison of these cases with those which received only the regular treatment without tuberculin in the hospital. The results in tuberculous arthritis suggest the desirability of further trials of the product in surgical tuberculosis. My material, therefore, justifies the following conclusions:

1. The purified tuberculin, properly used, causes no reaction of any significance in advanced cases of tuberculosis, so that it may be safely used in stages in which tuberculin has heretofore been deemed contra-indicated.

2. The benefits which often follow the treatment with the purified tuberculin—reduction of fever, of the catarrhal symptoms, of the infiltrates, and of the subjective difficulties—certainly encourage its further use in combating the process and ameliorating the condition even in advanced stages of tuberculosis. I desire to acknowledge my indebtedness to Dr. C. M. Cauldwell for his interest, aid and counsel, which have been of such great value in this work.

ON PRELIMINARY EXAMINATION OF CHILDREN AT THE DISPENSARY, AS A MEANS OF PROTECTION AGAINST CONTAGIOUS DISEASES.*

By SARA WELT-KAKELS, M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE MOUNT SINAI HOSPITAL DISPENSARY.

Having been engaged for many years in active dispensary work, and impressed with the inadequate measures taken for the protection against contagious diseases, I took leave in April, 1907, to address a communication to the Dispensary Committee of the Mount Sinai Hospital, in which I suggested the introduction of a preliminary examination of children applying at the dispensary, with a view to early detection and exclusion of contagious cases. To the honor of the directors of the hospital, always anxious that the best should be done for the patient, it should be stated that the recommendation embodied in my communication was adopted and the matter was then referred to the superintendent, Dr. S. S. Goldwater.

According to the fifty-sixth annual report, issued January, 1909, the dispensary of the Mt. Sinai Hospital treats a larger number of patients than any other dispensary in the city; as many as the dispensaries of Bellevue, Gouverneur, Fordham, and the Harlem Hospitals combined. During the year 1908 12,214 children were treated in the medical classes, while the consultations numbered 21,316. From December 1, 1908, to July 20, 1909, on which date the dispensary was closed on account of extensive additions and alterations, which are at the present time nearing completion, the number of consultations in the children's department amounted to 14,583. The total daily average number of consultations, including children and adults, was 678.11, and the largest number of such consultations in one day was 941. Children are attended to

*Read before the Section on Pediatrics, New York Academy of Medicine, March 10, 1910.

daily in two afternoon and one morning class. Tickets are issued between 10 and 11 A. M. and 1 to 3 in the afternoon. Morning classes were established in 1907 to accommodate a constantly growing number of applicants and to receive the overflow of the afternoon classes. There is an average attendance of about forty-six children in both medical classes in the afternoon and about twenty-six in the forenoon, the number of cases being restricted to fifteen for each class. This plan was inaugurated by the superintendent of the hospital in 1907 and has proved to be an advantage as it permits the attending physician to devote more time and attention to each individual case. In addition to this, there is a like number of children treated in the other departments (nose, throat, skin, etc.), which brings the total daily attendance of children at the Mt. Sinai Dispensary to about 150.

Procedure of preliminary examination of children at the Mt. Sinai Dispensary.—Mothers and children enter the dispensary through the main entrance on Madison Avenue between 100th and 101st Streets; perambulators are left outside of the building; an orderly stationed at the door directs them to a spacious and light recess to the right, where the physician in charge is stationed; nearby is a desk containing necessary implements, as wooden tongue blades, culture tubes, antiseptic solutions, records for entry of contagious cases, etc. To avoid crowding, if the attendance be large, and to avert possible infection while waiting, visitors approach through a winding passageway between two railguards in single file; they are examined hastily, one after the other, for the presence of any infectious disease. The buccal cavity of each child is inspected and carefully searched for Koplik's spots, pharyngeal exudates, etc., while cultures are taken from throat and nose whenever necessary. The time from entering the dispensary to the conclusion of the preliminary inspection of each applicant shall not exceed three to five minutes.

A more complicated plan was proposed by Knoepfelmacher, who devised for that purpose a system of booths. Each visitor is admitted directly from the street to an empty booth and awaits there the arrival of the physician, who enters from the other side; after the preliminary examination the applicant leaves, without having been in contact with any other patient; in case of contagious disease the booth is closed and thoroughly disinfected. Knoepfelmacher's device seems to be almost perfect, an ideal method, but, I believe, rather difficult to carry out and hardly feasible in an institute with a large patronage.

While the advantage of a preliminary examination is evident, it would be erroneous to assume that by its establishment infectious diseases would be wholly barred from the waiting-room of the dispensary. Errors, often unavoidable, will occur; mistakes will be made, especially when the number of applicants is large; but, if not entirely eliminated, the danger of dissemination of contagious diseases is considerably lessened by it, an ample recompense for the trouble and financial outlay. To render preliminary inspection effective it is essential to examine each child, whether or not suspicious looking. Often children with diphtheritic sore throat present but few visible symptoms of the disease; and it will be easily understood that the exanthematous fevers are as a general rule seen in the dispensary in the early prodronal stage, when, with few external manifestations, the disease may be in the most active period of infection; it is of paramount importance to bar these early cases from the waiting-room, as a safeguard against the dissemination of contagious diseases.

During the precursory examinations it occurred that occasionally noncontagious diseases were detected requiring speedy medical intervention. On the entry slips of cases excluded from the waiting-room on June 17, 1907, I find: Varicella, two cases; tonsillitis exudativa (diphtheritica?), two cases; furthermore, one case of retropharyngeal abscess; and two days later, on June 19: Scarlet fever, one case; varicella, one case; and, again, a case of retropharyngeal abscess. Thus, the early detection of urgent cases requiring immediate medical attention appears to be another advantage of preliminary inspection. Only if found free from contagious disease children receive from the physician marked (O. K.) passes, which must be presented to the dispensary clerk before cards for the various departments are issued. They are then seated and wait for their turn to be called into the treatment room. After the consultation visitors leave the dispensary by a separate exit leading to 100th Street. The time the patient remains in the dispensary may average from two to three hours, and often longer. If, however, a child is found to suffer from a contagious disease, it is, with its attendant, immediately hurried off to one of the two isolation rooms in the basement; here they receive the necessary attention; in case of suspected diphtheria an antitoxin injection is given, and the patients are then sent home, if at walking distance from the dispensary; otherwise, they are detained, and the Health Department is notified to send an ambulance to convey them home, or, if possible, to the hospital for contagious diseases. This is very tedious, as the ambulance will often not arrive before three or four hours; occasionally mother and child will escape during that time, if not closely guarded, or, if waiting long, grow fearful and alarmed and thus give rise to great excitement among the other visitors.

Since April, 1907, preliminary examination of children applying for treatment has been conducted, as yet in the afternoon service only, when the bulk of the work is done, with the result that contagious cases are excluded immediately on entering the dispensary before being permitted to mingle with other applicants in the common waiting-room.*

Far superior to the method outlined here is the system in operation in some of the best European clinics. According to Escherich's description, children excluded from the ambulatorium (dispensary) are sent to the observation ward. This is an achievement of recent years only, though its idea was conceived by Rauchfuss in 1869. Of incalculable service to the hospital, it also serves to protect the individual from diagnostic errors. One part of the observation ward, set aside for the examination of patients and directly accessible from the ambulatorium, consists of separate cells, which are disinfected after each patient; there is also a

*Since the reopening of the dispensary last May two salaried physicians were appointed to conduct the preliminary examination of children in the morning as well as in the afternoon service. The importance of the work is shown by the number of excluded cases. To cite an instance I quote from the records kept by the physicians in charge: On May 17 the following contagious cases were detected among the applicants: Scarlatina, 2; rubella, 1; measles, 1; diphtheria, 1; and on May 26: Varicella, 3; scarlatina, 1; measles, 1; parotitis, 1; and diphtheria, 4. During sixteen consecutive days seventy-four cases were excluded.

room for microscopical examinations; children in whom the diagnosis is established are sent to the pavilions for infectious diseases, while "suspects," indeterminate cases, are detained in the observation ward proper. This has its prototype in the "Système cellulaire" first applied in the "Hôpital de l'Institut Pasteur," in 1900. It consists of cells constructed entirely of glass and iron. The patient remains in the "box" isolated from all others. Regulations to prevent contact infections are almost perfect. Patients are kept until the nature of the disease is determined, when they are transferred to the hospital, or are dismissed, in case of recovery.

The first dispensary in the City of New York, the second in America, was opened in 1791. According to "A Letter from Dr. John Bard, President of the Medical Society of the State of New York, 1791," its establishment was first suggested at a meeting of the Humane Society; the plan was then laid before the members of the Medical Society, who made an offer of their professional services. The necessary means were provided by the citizens of New York, who had long complained that there was no established resort for medical relief for the poor people, save the almshouse, which was the only medical charity in the City of New York at that time. This was the origin of the New York Dispensary, which was opened for patients on February 8, 1791; at first it was located at No. 24 King George Street, cor. William Street. It was incorporated by an act of legislature in April (8), 1795. The New York Dispensary was the only institution of its kind until 1828, a period of 37 years.

The economic and other advantages of the first dispensary were marked, and with the extension of the city limits, with the ever increasing number of its inhabitants, it became necessary to open other dispensaries in various parts of the city. According to the 40th Annual Report of the State Board of Charities for the year 1906, there were 60 licensed dispensaries in the Borough of Manhattan and a total of ninety-six in Greater New York.

During the year 1905, 869,866 persons were treated in Manhattan, and the number of treatments came to 2,452,814. As Manhattan had a population of 2,112,380, it would appear that in the year 1905 about two out of five inhabitants received medical aid in the dispensaries.

The ratio changes somewhat when we consider corresponding figures for the same year in Greater New York, including Manhattan, Brooklyn, Bronx, Queens, and Richmond, the total number of patients treated was 994,315 and the number of treatments amounted to 2,786,206, while the population was 4,013,781. This seems to indicate that approximately one in four of the population was ill and applied for medical relief at the dispensaries.

In the following two years the increase was not very great, possibly due to stricter rules on admission of new patients. According to the records of the State Board of Charities, the number of persons treated in 1907 in Manhattan was 910,380 and in Greater New York 1,042,887; during the year 1908 the number of treatments in Manhattan came to 2,800,170 and in Greater New York, 3,195,507.

But we can not place too much reliance on dispensary statistics; a good many of the gross number of patients have to be deducted as "repeaters," as with the present lack of a uniform system the same person may register in the course of one year at various dispensaries, or even at the same dispensary more than once.

The principles upon which dispensaries were founded were to afford medical relief to the sick poor; this still holds good. But concerned with the welfare of hundreds of thousands of sick people, it is bound to assume greater responsibilities. One of the most important and difficult problems of the modern dispensary is to prevent dissemination of contagious diseases in the common waiting-room.

To study the modus operandi, to learn personally of the prophylactic measures adopted, most of the large dispensaries in Manhattan were visited lately; the opportunity was kindly afforded me to make observations; with very few exceptions, data were given when asked for, and courtesy was shown alike by attending physicians and registrars, which I take pleasure in acknowledging here.

I shall not dwell long on facts well known to those interested in dispensary work; great progress has been made in the last decade. Since the exactment of the dispensary laws in 1899, sanitary and hygienic measures were adopted and a higher standard established, attempts were made to restrict medical charity to the sick poor and to prevent imposition. To Dr. Cabot in Boston belongs the credit of having inaugurated modern methods of hygienic and physical therapeutics, instead of superficial treatment and "wholesale drugging" of the dispensary patient. Following in the wake of the tuberculosis clinics, he introduced in 1905 the visiting nurse in the dispensary service, a useful ally to the physician, explaining and aiding to carry out instructions and insuring hygienic improvements in the houses of the sick poor. Two years later, in 1907, the Superintendent of the Mt. Sinai Hospital, Dr. S. S. Goldwater, proposed to further raise the standard of work in the outpatient department by the adoption of the principle of restricted numbers of patients. This plan has been carried out since in the Mt. Sinai Dispensary with excellent results.

While thus much was done to correct abuses, "dispensary evils" still exist. It is singular that the difficult problem of preventing "contact infection," in the common waiting-room, has up to the present time not attracted the attention it deserves, much less so than it has received in the best institutes in England and the Continent.

Professor Escherich was evidently much impressed by the prevalent lack of prophylaxis. He remarks in his "Pediatrische Reiseindruecke in America" that the fear of contracting acute infectious diseases must be much less in our country than it is in his own, as he had not found in our dispensaries any prophylactic arrangements whatsoever. Escherich, one of the foremost pediatrists of the time, believes that the prevention of contact-infection is of paramount importance. He does not hesitate to assert that the dispensaries, conducted as many are, contribute possibly to an even greater extent than the public schools to the spread of infectious diseases, especially the acute exanthemata. Escherich became convinced of this fact during his activity in Graz, a city with a small population, where it was possible to detect sources of infection which frequently could be traced to the dispensary, especially in cases of measles.

These conditions have long been known to exist, and led in the ambulatorium (dispensary) of Escherich and other pediatrists to the establishment of pertinent provisions for the exclusion of

children ill with infectious diseases and "suspects" before entering the common waiting-room; this is being done by a physician or a trained nurse, an arrangement that has proved satisfactory. Similar prophylactic regulations do not exist in any of the dispensaries I had the privilege to visit. Patients enter the dispensary promiscuously through the same door, through which they usually also depart; stating the nature of the disease, as well as they may, to the dispensary clerk, they receive numbered tickets and are then permitted to occupy seats on crowded, not always asceptically clean benches. Often when one child is ill, the mother is obliged to take the other healthy ones along, as there is no one at home to look after them. The reception hall receives them all, children ill with diphtheria and others in the early stages of the exanthematous fevers; most of them ill nourished, and all very susceptible to infection. It will be readily admitted that many children, even when exposed, will not be affected, either from a lesser susceptibility or because they are immune from a previous attack of the disease. But themselves immune, they occasionally may become "carriers" of the virus. Children within the first two years of age, toddling about and creeping on the floor, are exposed to a direct infection, which Escherich calls "Schmierinfection," by means of bacterial secretions which they smear over their little faces and hands. Already suffering from some form of disease, they thus become exposed to other infections, which may prove dangerous or even fatal, often waiting one or two hours or even longer for the arrival of the physician.

These conditions need to be remedied, not only from humanitarian motives or from consideration of the welfare and protection of the dispensary patient, but also for the sake of the well being of the community and on the ground of public policy.

As a practical illustration of the above I should like to mention an incident, witnessed some few weeks ago in the treatment room of a crowded dispensary on the lower East Side. The Chief of Clinic had just removed tonsils and adenoids in a little boy; one of the next patients was a child with a "sore throat," an inspection revealed the presence of exudates on the tonsils. Likely enough, the children mingled while waiting for their turn to be admitted. Similar instances of exposure are bound to occur under the prevailing system. In one or two of the dispensaries visited, I was informed that "suspicious looking" children are not required to wait their turn, but are picked out from the rest and attended by a physician as soon as possible.

In one of the best equipped dispensaries on the upper East Side, which has separate doors for entrance and exit of visitors, new patients are assigned to the different classes by a medical man, but there is no preliminary examination of children, and infectious cases are detected in this as practically in all other dispensaries, in the consulting room only, no attempt at separation being made in the waiting-room.

Isolation rooms are generally very primitive, and rarely made use of. In one large East Side dispensary with a daily attendance of 50 to 70 children in the medical classes, the attending pediatrist who is connected with the institution, for many years was not aware of the existence of an isolation room. The clerk assured the doctor and me, however, that there was one in the courtyard.

In conclusion I would respectfully submit:

1. There is at the present time an evident lack of prophylaxis in handling contagious cases at the dispensary.

2. As at present conducted, dispensaries contribute to the dissemination of infectious diseases among the poor by contact infection in the common waiting-room.

3. If not entirely eliminated, the danger of exposure is lessened by the preliminary inspection of children, a prophylactic measure which aims at an early detection and exclusion of contagious cases and "suspects" before entering the common waiting-room.

4. Preliminary examination of children has been conducted at the Mt. Sinai Dispensary since April, 1907, with satisfactory results.

5. Its establishment in similar institutes is required as a sanitary safeguard and on the ground of public economy.

THE PRACTICAL VALUE OF A POSITIVE COMPLEMENT FIXATION TEST IN SYPHILIS.*

By GEORGE W. VANDEGRIFT, M.A., M.D.,

NEW YORK.

ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY; PROFESSOR OF OPHTHALMOLOGY BROOKLYN POSTGRADUATE MEDICAL SCHOOL; ATTENDING OPHTHALMOLOGIST WILLIAMSBURG HOSPITAL, BROOKLYN.

I BEGIN by apologizing for trespassing from the limited field of ophthalmology into the boundless plains of general medicine. My excuses are those of the prospector rushing heedlessly into regions of new found gold; and though the soil I strive to overturn is not strictly virginal, it is at most primiparous, and promises further and exceeding fruitfulness.

We will linger for a few minutes over a study of the practical importance of a positive complement fixation test to the practitioner who handles syphilis in his office and in the clinic. At present it appears as if the serodiagnosis of syphilis has gained no strong foothold in general practice, being utilized more widely by the practitioners of the

*Read before the Williamsburg Hospital Staff Association, September 4, 1910.

various specialties. This may be because the test is looked upon by the majority of physicians as a corroborative symptom of syphilis of distinct value only in the presence of others. That this is far from the whole truth of the matter I hope to emphasize in this paper.

So great a mass of easily obtainable statistics already illuminates the literature of this subject I feel that pardon will be granted me cheerfully if I fail to embody any of them, old or new, into my discourse.

It has been proven that a positive reaction can be obtained in the vast majority of cases of syphilis as early as the appearance of the initial lesion. It is unnecessary therefore to wait for the skin rash before beginning specific treatment when a positive reaction is present. By this early start the patient may be saved from the misery of mucous patches, sore throat, and other secondaries. Nor need there be hesitation or delay if the chancre appears clinically doubtful; a positive blood test allows immediate antisyphilitic treatment. Once having a positive reaction, no matter how early in the history of the case, the physician may proceed assured of his diagnosis if the test has been made by a competent expert; for confusion cannot arise, as the nonspecific diseases that give a positive fixation test are clinically distinct from syphilis.

During the ordinary course of syphilis when the pathognomonic symptoms are present the positive reaction by being less paramount becomes corroborative only; but in the presence of symptoms that may or may not be luetic a positive reaction becomes vitally important. During the secondary stage no one doubts his diagnosis when confronted with the congeries of characteristic symptoms, but when one or two only of these are present, and perhaps atypical, one hesitates to deposit the syphilitic millstone around the victim's neck unless aided and abetted by a positive fixation test. A positive reaction also is paramount in the diagnosis of diseases or rather symptoms that are not typical secondaries and may not be luetic in origin at all. Among such conditions are afternoon headaches, neuralgia, pains referred to the calves of the legs, skin rashes, iritis, keratitis, etc. A positive reaction settles our doubt while a negative one invites further scrutiny.

We know, often to our chagrin, that our ability to diagnosticate correctly the protean manifestations of syphilis in its tertiary stage is measured by the limits of our clinical experience. Every branch of medicine has needed its expert in syphilis. With the complement fixation test at hand each practitioner may be his own syphilographer.

It is hardly necessary to detail the importance of the serodiagnosis of syphilis to the various specialties. It has become indispensable to the genitourinary practitioner. The dermatologist, hitherto needing somewhat of the qualities of the race track devotee of being a good guesser, now finds himself in the midst of an exact science—almost. The pediatrist has learned instructive and unexpected facts, notably concerning congenital and hereditary lues. The view that a healthy mother may bear a syphilitic child and escape infection must be modified, for it has been found that a very large number of such mothers (65 per cent.) give a positive fixation test, proving the presense of latent syphilis. Also we must change our belief that apparently healthy children of syphilic mothers are immune to the disease. Here again a high percentage of positive tests shows that these children have a luetic infection that is dormant. The internist finds the reaction of importance in manifold conditions, as in arteriosclerosis and certain heart lesions such as aortic insufficiency. In the practice of ophthalmology it has been my custom to prescribe antisyphilitic remedies on the least provocation, as a matter of good business to my patients, to my friends as a matter of kindness. Since I have been making use of the blood test I find that my custom is not unwise. It has become a habit with me to have a blood test made in every case of ocular disease in which the etiology was not absolutely certain. Frequently the test has been positive in cases hitherto looked upon as non-syphilitic, and in cases in which the etiology is unknown or guessed at. While the possibility of syphilis being concomitant and not genetic has not been overlooked, yet many of each of these classes of cases have improved under antisyphilitic treatment.

In no specialty has the serodiagnosis of syphilis been of more value than in neurology. Paresis gives almost 100 per cent. of positive reactions, while tabes over sixty. In cerebral and spinal sclerosis, brain tumor, cerebral endarteritis, and various muscular paralyses the positive reaction is of inestimable etiological and therapeutic import.

Thanks to the complement fixation test our failures due to etiological ignorance are growing less in number. And so it will continue if every case that comes into our practice the cause of which is not absolutely assured is subjected to the test. The practice of using the test only when suspicion of syphilis is aroused or when it is clinically certain is reprehensible, for it is along the ways of doubt and ignorance that the serum reaction carries its light most beneficently. One case I desire to report because it displays well the value of a positive fixation test:

Mr. X., forty years of age, three years ago began to lose the sight of both eyes from a descending optic atrophy of unknown origin. The history of the patient's life from a physician's viewpoint was most unsatisfactory. Every organ outside of his eyes was apparently normal. After a time a mild gastritis developed which was seized upon ravenously as the cause of his optic atrophy. The patient continued to lose flesh and strength. About six months ago he was referred to me and I found both optic nerves in a condition of primary atrophy and the vision reduced about one-half. Pupils were unequal and reacted only to intense light. Of the left eye there was a drooping of the upper lid, and of the right eye a paresis of the external rectus muscle. Knee jerks were absent. He is the father of several healthy children, and oral as well as physical examination failed to elicit the slightest trace or vestige to corroborate the suspicion I entertained of syphilitic infection. However, the Wassermann, the Noguchi, and the Weil tests were distinctly positive. Immediate energetic antisyphilitic treatment was begun consisting of gluteal injections of the salicylate of mercury (two grains a week) and increasing large doses of a saturated solution of potassium iodide. At the end of two months the vision and fields had improved slightly, the muscular pareses had disappeared, and the patient's general condition had improved markedly.

Here we have a case of syphilis in a man of intelligence who appreciates, at least in this exigency, the value of the truth. He says he observed no early evidence of syphilis, and probably he is not mistaken. Not only does this experience prove to

me the practical importance of the complement fixation test, but sustains my belief founded upon an extended use of the reaction that syphilis may be acquired in a manner unknown and unrecognized and remain unmanifested until the appearance of some tertiary or parasyphilitic lesion.

Finally the fixation test is of value as an index to treatment and an assurance of a cure. With the beginning of a vigorous mercurialization the reaction should disappear, speedily from a mild case, more slowly from a severe one. When we have obtained a negative reaction in the course of treatment proper medication should preserve it until at the end of several years it remains permanent without further treatment. The time has come when almost every case of syphilis can be carried to a complete cure without symptoms further than those that drew attention to the condition. Of course we must recognize the fact that there are cases which do not respond well to the ordinary treatment with mercury, and of these we cannot at present presage so hopefully. We expect also that the time is coming when by repeated fixation tests we can determine accurately the quantity of medication required for each case and the time required for a permanent cure.

To sum up, a positive complement fixation test is valuable: (1) as corroborative in company with other characteristic symptoms; (2) as determining the presence of syphilis in diseases either of probable or possible luetic, or of unknown origin; (3) as suggesting that syphilis may run a course without displaying itself until tertiary or parasyphilitic lesions appear; (4) as an index to treatment and assurance of a cure.

147 East Eighteenth Street.

Infantilism of Malarial Origin.—H. de Brun has had the opportunity of observing during a residence of twenty-five years in Syria forty cases of infantilism in individuals who were also the victims of chronic malaria. Thyroid insufficiency could not account for all of the manifestations. Nevertheless it was apparently responsible for the smallness of stature, the absence of the secondary sexual characteristics, and the arrested mental development. On the other hand the exaggerated size of the abdomen contrasting with the extremely slender limbs, the almost total absence of adipose tissue, the emaciation, the precocious wrinkles of the physiognomy, and the weakness of the muscles, are all characteristics that distinguish malarial infantilism from the other forms. The infection produced by the malarial organism, and causing enormous engorgement of the liver and spleen, is responsible for the greatly enlarged abdomen; it also accounts for the striking emaciation seen in some of the cases, and for the polyneuritis which in turn results in muscular atrophy, chiefly of the lower limbs. To these symptoms there are added others that form a group by themselves. These consist of lassitude, depression, inertia, and indifference, amounting in some cases to a profound prostration. These are analogous to similar symptoms seen in cases of Addison's disease, and, taken in conjunction with the pigmentation of the skin so conspicuous in a large number of cases of malaria, may be attributed to a chronic insufficiency of the suprarenal capsules. The arterial hypotension with the occasional smallness and irregularity of the pulse, the gastric crises accompanied by dysentery, the deficiency in the vasomotor reaction of the skin, all symptoms observed in some of the cases, are familiar manifestations of the malarial cachexia. It would appear as if the pigmentary sclerosis resulting from this infection affects the suprarenals as well as other organs. The suprarenals, therefore, share with the thyroid and pituitary glands in the evolution of the phenomena of infantilism.—*Revue de Médecine.*

Contribution to the Surgical Treatment of Jacksonian Epilepsy and Traumatic Intracranial Hemorrhage.—G. Ninni gives his experience with intracranial surgery in a case of Jacksonian epilepsy of traumatic origin. The operative wound healed by first intention and the convulsive attacks remained absent for five months. They then returned to be repeated about once in three months. The patient though not cured had gained, in that his attacks were much less frequent than before the operation, when they had occurred every two weeks. He was able to go about his usual occupations. The author also details the result of operation on a young man of twenty years of age who received a blow over the left eyebrow and another over the right parietal region. Immediately after the blows he lost consciousness, and after two days there were spastic contractions of the fingers of the right hand, and the following day of the left hand and foot. After twelve days he was carried to the hospital. The day after his first contractions he had seventeen attacks of clonic convulsions and the number increased to fifty in twenty-four hours. His skull was opened and a hematoma was found subdural, and extending over a large surface. Two hundred grams of clots were removed from the Rolandic region and the frontal lobe. Three hours after operation the patient recovered consciousness and the next day convulsions ceased entirely. Ninni demonstrates that in cases of cranial hemorrhage one should operate as soon as possible in traumatic cases so as to prevent the occurrence of Jacksonian epilepsy.—*La Riforma Medica.*

Indications for the Treatment of Syphilis with Arsenic.—G. Milian says that, while arsenic is not by any means a substitute for mercury, there are cases of intolerance for mercury that are benefited by its use. There are cases of absolute intolerance for mercury and of partial intolerance. In the latter mercury may be taken for a time, and then the stomach revolts. This is apt to occur after treatment has been given successfully, in the second or third year of the disease. In these cases arsenic should be substituted for mercury. In other cases it may be used as an adjuvant to mercury, since it increases the effect of the mercury. It may be given during intervals of mercurial treatment. It is also indicated in case of anemia.—*Le Progrès Médical.*

Electrical Treatment of Obesity.—A. Laquerriére details Bergonié's electrical method of treating obesity by exercise of the various muscles, the surface of the body being entirely covered with large electrodes, so that all the large muscular masses are affected. The operator then applies a tetanizing faradic current through the electrodes, in such a manner that there is a rhythmical action, the excitation lasting half a second, and the interval of repose a half second. The current should be strong enough to cause marked muscular contractions. During this treatment the body becomes covered with sweat, but the patient feels no disagreeable sensations, only the contraction of the muscles. The heart and respiration are increased in frequency, in response to the need of increased oxygenation in the contracting muscles. There is no appreciable fatigue when the sittings are properly managed; the appetite is increased and sleep is improved; blood pressure is lowered as it is after simple exercise. One gets general active gymnastics, but involuntary ones, and without the interference of the psychic centers. It is difficult to find any other system of gymnastics that approaches this in the general action of all the muscles. This form of exercise may be used even for persons who are persuaded that exercise is bad for them. Since the movement is involuntary the nervous system does not become fatigued. In the fearful and the neuropath one may get the benefits of exercise without their having any of the inconveniences of it. Bergonié has obtained brilliant results by this method in the obese, but the method may be employed also in all the nutritional troubles. This method is both preventive and curative, since it increases the musculature of the patient, and he will not again fall into the hygienic faults that have caused his obesity.—*Journal de Médecine de Paris.*

Cerebral Hemmorrhage from Luetic Vessels.—Henry Head reports the case of an engineer aged 32, who, in July, 1902, contracted gonorrhea, which lasted about two weeks. This was followed by rash and sore throat. There was now a scar at the orifice of the meatus, pointing to the probability that the infection was syphilitic. In April, 1904, he felt dizzy, and within twenty minutes became paralyzed down the right half of the body. He lost his speech, but did not become unconscious. Since that time he had shown no material alteration. He was still hemiplegic, his tongue was protruded to the right, the right knee-jerk and wrist-jerk were greatly exaggerated, ankle clonus was obtained, and the plantar reflex on this side gave an extensor response.—*Proceedings of the Royal Society of Medicine.*

HUMAN AND BOVINE TUBERCULOSIS.

WHEN, in 1901, Robert Koch threw a bomb into the camp of the bacteriologists by declaring that human and bovine tuberculosis are not identical, that the human variety cannot be transferred to cattle, and that human infection with bovine tuberculosis rarely occurs even if human susceptibility to such infection be admitted, there began a series of investigations in all parts of the world which have succeeded in disproving, in great part, the contentions of the discoverer of the tubercle bacilli. The far-reaching importance of settling this problem concerned chiefly the question of human infection from tuberculous cattle, particularly in view of the fact that a large part of the milk and butter consumed in large cities contains tubercle bacilli. In spite of the general fallacy of Koch's original conclusions, these, nevertheless, contained important germs of truth. Thus it has been shown that human and bovine tuberculosis are not identical, but are caused by distinct varieties of the tubercle bacillus possessing marked differences of character in cultivation and in virulence. Furthermore, while the second contention, namely, that the human variety of the organism cannot be transferred to cattle, has been overthrown, it has, nevertheless, been shown that cattle are less susceptible to the human virus than to their own. Finally, in disposing of Koch's last contention it has been established that a fairly large proportion of the cases of human tuberculosis are caused by the bovine bacillus. Thus, out of a total of 1,042 cases examined by various investigators, 10 per cent. have been found to be due to the bovine bacillus; the percentage is even greater in childhood—of 220 cases of tuberculosis in children under five years, the bovine bacillus has been found in 27 per cent.

In a most elaborate investigation to determine the relative importance of the bovine and human types of tubercle bacilli in the different form of human tuberculosis, William H. Park and Charles Krumwiede, assisted by a large staff at the Research Laboratory of the Department of Health, New York City, have made valuable contributions to this subject, reporting their results in the *Journal of Medical Research*, October, 1910. These studies were begun in view of the fact that nearly all the cases hitherto examined had been selected either with the view of finding bovine infections, that is, tuberculosis of alimentary origin, or adult pulmonary tuberculosis. It seemed that with the knowledge at hand a large series of non-selected cases of every type of disease and under average conditions of exposure would give valuable information, particularly with reference to sanitary control. In addition, the investigators hoped to simplify the methods of differentiation and to settle many disputed or doubtful points in biology or virulence.

The results of their work led to the conclusion that there is no constant qualitative cultural difference between the human and bovine types of tubercle bacilli. Quantitatively and with respect to the effect of glycerin there is a marked difference in the great majority of cultures, so that the type can be determined from cultures alone, particularly from the amount and rapidity of growth of early cultures. All bovine types of bacilli are dysgonic (have sparse growth) and all human types are eugonic (have moderate or luxuriant growth). Glycerin egg was found to be the best medium for eliciting this difference. They draw the general conclusions that all cultures growing luxuriantly on glycerin egg from the start are of the human type, and that those growing sparsely or even not at all on this medium in the first few generations are of the bovine type. In studying the relative virulence of the two types of organism it was found that the bovine type always causes in rabbits a generalized tuberculosis, when given in doses of 0.01 milligram intravenously, the tuberculosis being progressive and causing the death of the animal. Human cultures injected in the same amount produce no disease at all or lesions of varying severity in the lungs or kidneys, or both, never causing a progressive generalized tuberculosis. If a rabbit survived a dose of one milligram for sixty days and showed no generalization the virus was considered a human one. The results of the inoculation work with calves were parallel with those in rabbits—the bovine type caused generalized tuberculosis and the human type caused a localized infection or extension to the neighboring lymph nodes. It is thus seen that the bovine virus is more virulent than the human. The great majority of the cultures group themselves around two extremes from which there are a few cultures showing variant characteristics. The two types are probably different because of residence in different hosts over long periods of time and as such are stable. The evidence in favor of rapid change of type is incomplete and inconclusive.

One of the most important divisions of this research was the determination of the type of infection in 436 cases of human tuberculosis representing all the various clinical forms of the disease. Of 297 cases in adults 16 years and over, only one instance of bovine infection was found, and that in a case of genitourinary tuberculosis. Of 54 cases in children between 5 and 16 years, there were 9 in which the bovine bacillus was isolated and 8 of the latter were cases of tuberculous cervical adenitis. Of 84 cases in children under 5 years, 22 gave the bovine bacillus, 12 of which were from cases of cervical adenitis, and 3 from abdominal tuberculosis. A separate tabulation of 43 fatal cases from the Babies' Hospital, representing average conditions better than the total cases, showed that 9 per cent.

were due to the bovine type. In an unusual series of 9 cases from the Foundling Hospital in children under 6 years fed practically exclusively on cow's milk, 5 cases, or 55 per cent., gave evidence of infection with the bovine type of tuberculosis.

The practical importance of these investigations is obvious. They have shown that it is possible by means of simple methods to differentiate the two types of tubercle bacilli. They have confirmed the results of other observers in determining that the dangers of human infection from tuberculous cattle are real, and that these dangers are greatest in early life, when cow's milk forms the main article of diet. As an example of scientific research of a high order of practical utility, this work of Dr. Park and his associates of the Research Laboratory is one in which the City of New York, under the auspices of whose Department of Health this research was undertaken, may feel a sense of deep satisfaction.

SOME USES OF THYROID MEDICATION IN OBSTETRICS.

There is apparently no end to the suggestions as to the value of the administration of various preparations of the thyroid gland in different morbid conditions. The broad field of thyroid therapy is to be attributed to the fact that this organ elaborates a large number of distinct substances, some of which are indispensable to the entire organism, while others are needed only by certain organs.

The dried substance of the thyroid gland has recently been employed with good effect in the vomiting of pregnancy and in deficient milk secretion, as reported in the *Zentralblatt für Gynäkologie*, October 15 and 22, 1910, by A. Siegmund. In the former condition five severe cases are reported in which the results of the treatment were prompt and lasting. It was found that the best results are obtained by a definite mode of administration. The thyroid is given on an empty stomach several hours before the severest vomiting is expected. The patient is awakened at 4:30 or 5 A. M., and given the first dose; after several hours of sleep she takes her breakfast in bed, and at 9 A. M. is given a second dose. The administration is repeated one-half hour before dinner and supper and before retiring. The morning dose should not be less than 0.3 gram (5 grains) and sometimes 0.45 gram (7½ grains), or 0.6 gram (10 grains) is advisable. If the severest attacks of vomiting occur at other than the morning hours, the large doses are to be given at the former periods. The exact dosage is to be determined by means of daily observation. The powdered dried substance of the thyroid glands obtained from female animals is recommended; the glycerin extract of fresh thyroids is even better. The largest doses are required at the beginning of the treatment, in order to neutralize the greater amount of toxins present in the blood. The diet is to be carefully regulated; small amounts of food are to be taken at one time, and meat is interdicted in the beginning.

The value of the administration of thyroid as a means of increasing the activity of the mammary glands had already been demonstrated by Hertoghe in 1900, in patients presenting mild symptoms of thyroid insufficiency. Seigmund confirms the latter's observations, but believes that the period of lactation is not the best time during which to begin the thyroid medication. He has obtained better results by beginning the treatment in the early months of pregnancy, during the time when the mammary glands are transforming from a state of rest to one of activity. This therapeutic measure is recommended particularly in women who have already given evidence of inability to nurse their children wholly or in part. The dose of thyroid administered is about 0.1 gram (1½ grains) from one to three times a day. The result of this treatment is a copious secretion of milk after the birth of the child. There are no untoward effects of the administration of thyroid during pregnancy; on the contrary the general condition of the patient is improved.

THE EARLY DIAGNOSIS OF TUBERCULOUS BRONCHIAL ADENOPATHY.

The frequency during childhood of tuberculous infection of the bronchial lymphatic glands, with or without similar infection of the lungs or other parts of the body, is an observation that post-mortem investigation has repeatedly confirmed. Until recent years there had been no definite sign by which the presence of these glands could be demonstrated clinically. The importance of early diagnosis can be best appreciated when one realizes that the bronchial lymph-nodes frequently present the first barrier to the invasion of the rest of the organism by the tubercle bacillus, that the infection in these glands may remain latent for many years, and that early treatment, particularly with the aid of sea air, is of permanent curative value in many of these cases. The latent primary infection in these glands is often the starting point of general constitutional invasion after debilitating diseases such as measles and whooping-cough.

Among the signs whose clinical value has received recognition may be mentioned the presence of dullness at the level of the manubrium sterni; the sign described by Rilliet, Barthez, and Baréty, of an area of dilated veins observed on the front of the thorax; the sign of Eustace Smith, or the demonstration of a venous hum beneath the clavicle when the head is thrown back; the sign elicited by vertebral percussion, of dullness corresponding to the fourth, fifth, and sixth dorsal vertebræ, and the evidence furnished by the *x*-rays when these are made to traverse the thorax in such manner as to fall at a point either to the right or left of the vertebral column.

A new sign has recently been added to this list. At the last meeting of the Section on Diseases of Children of the British Medical Association, held during the latter part of July, 1910, Adolphe D'Espine of Geneva described a sign which he had elicited, and which he believed to be more constant than any of those already known. It is based on auscultation of the voice sounds at the level of the seventh cervical or first dorsal vertebra, which corresponds to the first portion of the trachea, a

region known as the posterior glandular, and described by Guéneau de Mussy as the earliest attacked by tuberculosis. If the child is made to speak or count in a low voice, the latter is accompanied by an added whispering sound localized to one or two vertebræ or even extending to the fourth or fifth thoracic vertebræ. A bronchial quality of the respiration has the same diagnostic value as the whispering sound; but the bronchial breathing is present only when the glands are already extensively and considerably enlarged. It is pointed out that a definite dullness at this level, similar to a loud bronchophony, is pathognomonic of a large glandular mass uniting the trachea with the vertebræ. The whispering sign is present long before dullness or bronchophony manifests itself, and for this reason it is accorded a far greater value than either of these. According to D'Espine, neither Eustace Smith's sign nor the area of dilated veins is pathognomonic. The validity of his observation has been confirmed by post-mortem examination. This observer emphasizes the importance of differentiating tuberculous from simple enlargement of the bronchial glands, such as is seen following measles, pertussis, and influenza, the signs of which are less marked and more ephemeral than those of tuberculous enlargement, and in which the percutaneous tuberculin test is negative. In some cases the glandular lesion simulates disease of the pulmonary apices, but it has been shown that the glandular lesion often extends more to the right than to the left, and may even by pressure cause a weakening of the vesicular murmur at the right apex, and also give rise to a loud bruit heard in the suprasternal fossa and under the clavicle.

Pulmonary Hemorrhage in the Tuberculous at High Altitude.

In Public Health Reports, October 7, F. C. Smith, of the Public Health and Marine-Hospital Service, discusses pulmonary hemorrhage in the tuberculous at a high altitude. The Marine Hospital Sanatorium at Fort Stanton, New Mexico, situated 6,200 feet above sea level, is the institution from which Smith collected his data. It appears that since the sanatorium was opened in 1899 fifty-six deaths from pulmonary hemorrhage have occurred there. Smith gives the following summary: (1) Hemorrhage from the lungs is responsible for about 10 per cent. of the total mortality from pulmonary tuberculosis at Fort Stanton. (2) Syphilis and chronic alcoholism increase the liability to fatal hemorrhage. (3) Small pulmonary hemorrhages are rarely suddenly fatal but may cause a dangerous insufflation pneumonia. (4) Recurrence of hemorrhage is rarely or never seen after bronchopneumonia develops. (5) No age period of adult manhood seems especially predisposed to fatal pulmonary hemorrhage. (6) Exciting cause of fatal hemorrhage was noticeably absent; the majority of subjects were in bed at the time and a large number presumably asleep. (7) Acute types of pulmonary tuberculosis are least liable to this accident; negroes showed a lower mortality from hemorrhage than whites. (8) Hemorrhage has not been common immediately after arrival from sea level; the increased mortality from hemorrhage after prolonged residence at high altitude may properly be ascribed to the chronic type of disease in these individuals. (9) Disease of the heart or embarrassed circulation from any cause predisposes to a fatal issue when pulmonay hemorrhage occurs. (10) Pulmonary hemorrhage is not more frequent at high altitude than at sea level, but the results are perhaps more often serious especially in those with impaired circulation. Perhaps the most interesting points of Smith's observations are that cardiac disease seems to be a somewhat frequent accompaniment of tuberculosis; in forty-two autopsies made at Fort Stanton seventeen of the subjects had some serious form of heart disease. The preponderance of left-sided cardiac lesions in the immediately fatal cases was also noticeable. On the whole, although of course the data were insufficient whereon to base any conclusive arguments, the experience with tuberculous patients at Fort Stanton would appear to favor the view that elevated regions are unfavorable for the treatment of ordinary hemorrhagic cases of tuberculosis of the lungs.

News of the Week.

Typhoid Fever at Annapolis.—An epidemic of typhoid fever at the Naval Academy has caused the authorities to make a test of anti-typhoid inoculation on all midshipmen willing to submit to it. The source of the epidemic, which has been confined to the Academy, no cases appearing in the town, has not yet been determined. The water supply of the Naval Academy is obtained from artesian wells.

Cholera on Steamship.—The Italian steamship *San Giorgio*, out from Naples and Palermo, which reached New York on November 16, reported two deaths at sea and nine passengers ill. Of these one was found to be suffering from cholera, which was probably the cause of the two deaths also. All the steerage passengers were detained at Hoffman Island for observation. The *San Giorgio* left Naples on November 1 and touched at Palermo on the following day. A number of new cases of cholera have been reported throughout the infected districts in Italy.

Smallpox Among Indians.—Ninety-three Indians on the Arapahoe Indian Reservation were reported to have died from smallpox in the four days preceding November 18.

Health Report of Nashville.—During the month of October there were 150 deaths and 117 births in Nashville, Tenn., as against 156 deaths and 151 births in October, 1909. The death rate per 1,000 of population is given as 11.38 for whites, 17.66 for negroes, or 13.76 for the entire population. In the mortality list heart disease comes first with 18 deaths, and tuberculosis next with 13.

Lower Death Rate in Springfield.—Fifty deaths were reported in Springfield, Ill., during the month of October, the rate being estimated at about 11 per thousand. The figures are considerably lower than for preceding Octobers. The causes of death were as follows: Organic heart disease, 6; infantile diseases, 6; accidents, Bright's disease, pneumonia, and bronchopneumonia, 4 each; typhoid fever, diphtheria, cancer, croup, and meningitis, 3 each; pulmonary tuberculosis, 2.

City Birth Rates High.—During the month of September, according to the statement of the New York State Department of Health, the excess of births over deaths in the urban localities was 5,947, while in rural sections the excess was only 37. The

urban population of the State is 6,763,934, and the rural population 2,107,786. Of the urban excess New York City leads in number as well as in percentage, having an excess of births over deaths of 5,202; the total number of births was 10,876. Of the other first-class cities, Buffalo, with a population of 423,715, had 670 births, an excess over the deaths of 105; and Rochester, with 218,149, had 384 births, an excess of 133. Of the second-class cities, six in number, Albany and Troy showed an excess of deaths over births, Albany having 13 and Troy 44. In the aggregate, however, there were 932 births and 701 deaths in this class. The sixteen third-class cities reported 786 births, an excess over deaths of 163; and the 23 fourth-class had an excess of 104 births.

Death Rate Discussion.—The Health Department of New York is authority for the statement that comparisons of the death rate of cities may lead to wrong conclusions. Dr. Guilfoy, the statistician of the department, points out that such a comparison should not be made unless correction is also made for the varying age-groupings of populations. St. Paul, Minn., for instance, has a death rate of only 11 per 1,000 of population, while in New York City the rate is 16. In St. Paul, however, Dr. Guilfoy says there is an unusually large percentage of persons between the ages of five and forty-five years, in which the death rate is very low, a condition which does not obtain in Eastern cities. Many of the Western towns are mainly composed of young healthy persons from the East, and have low death rates; while others, because of their very healthfulness, are used as the resort of invalids, and consequently show high rates.

City Death Rate.—For the week ending November 12 there were 1,334 deaths in New York, a rate of 14.49 per 1,000 of population. During the same week last year there were 1,389 deaths, the rate being 15.87. The deaths from typhoid fever and heart disease were slightly increased over last year, being 26 and 168 respectively; but the 162 deaths from pneumonia and the 163 from tuberculosis represented a decrease. Of children under the age of five, 324 died during the week, 232 of whom were under one year.

Nobel Prize in Chemistry.—Professor Otto Wallach of the University of Göttingen has been awarded the Nobel prize in chemistry for 1910.

The New York Milk Committee, having for its objects the improvement of the milk supply of the city and the education of the public in the proper use of milk, was incorporated on November 17. Among the incorporators are John G. Saxe, Mrs. Florence Harriman, F. D. Roosevelt, and W. C. Phillips. The committee will hold a conference in New York on December 2 and 3, which will be open to the public. The subject of controlling the milk supply will be discussed under four heads: Milk Economics, Milk Supply and the Public Health, Milk Standards, and Milk Commissions. Information regarding the program may be obtained from Dr. Ira S. Wile, 230 West 97th street, New York.

Traffic in Rotten Eggs.—An investigation carried on by Commissioner of Accounts Fosdick of New York has apparently revealed a considerable trade in condemned eggs, familiarly known as "rots and spots," which after being declared bad have been disposed of to bakers' supply stores. Dr. Harvey W. Wiley has offered the help of the United States Government in the investigation, and it is probable that his staff, working in conjunction with the municipal authorities, will extend the inspection to conditions surrounding the sale of many other foodstuffs, the use of preservatives, filthiness of small bakeries, etc.

Dirt and Ice Cream.—Out of fifty-one ice cream factories in New Jersey inspected during the past year only fifteen were found to meet with the requirements of the law, according to a statement made at the recent meeting of the National Association of Ice Cream Manufacturers by the Chief of the Division of Dairies of New Jersey. Ice cream plants were found in operation in cellars and dwelling houses, with no protection against contamination. In only ten were there sterilizing equipments.

The Common Drinking Cup.—The New York State Department of Health is seeking the cooperation of the various railroad companies operating in this State in abolishing the common drinking cup and the common towel from all trains and railroad stations.

Aged Mexican.—Juan Burcel, a Mexican living in San Diego, Cal., died on November 18 at the reputed age of 122 years.

Red Cross Seals.—On December 1, 8,000,000 Red Cross Seals will be placed on sale throughout New York by the Committee on the Prevention of Tuberculosis of the Charity Organization Society, which will conduct a widespread advertising campaign. The Tuberculosis Committee of the State Charities Aid Association, which is sole agent for the seals in New York State, exclusive of this city, has offered prizes to the town or village selling before January 1 the largest number of seals per capita of school registration. The first prize is a vacuum cleaning plant; the second, an equipment of sanitary drinking fountains; the third, a set of school text-books on physiology and hygiene.

Red Cross Endowment.—The $2,000,000 endowment fund for the Red Cross in the United States is in a fair way to be realized by the appointment of committees throughout the country to raise definite apportionments. In New York City practically the entire amount apportioned, $500,000, has already been subscribed.

Cuban Medical Affairs.—A National College of Physicians and Surgeons of Cuba was recently organized at a meeting at the Academy of Sciences in Havana. Dr. Juan Santos Fernandez, president of the Academy, who presided, made an address setting forth the need of such an organization to promote the interests of the medical profession at the end of which a committee on organization was appointed. President Gomez in his message to the Cuban Congress referred to the institution of the collge as an important step in the progress of the medical profession in Cuba.

Following a protest on the part of medical students in the University of Havana against a recent decree of the Secretary of Public Instruction permitting graduates of the veterinary department to enter the medical school without a bachelor's degree, the matter has been referred to the Academy of Sciences for decision. The University has hitherto required the bachelor's degree granted by provincial institutes from all students in the medical school. It is thought that the Academy will decide against the admission of any students without degrees, whether graduates of the veterinary school or not.

Need for Missionary Physicians and Nurses.—The Student Volunteer Movement for Foreign Missions calls attention to the great need for physicians and nurses in the missionary field throughout the world. More than fifty physicians, men and women, and nearly as many nurses could find places in China, Persia, Arabia, Egypt, Turkey, India, and the Philippine Islands.

American Museum of Safety.—With the slogan, "Fifty per cent. of industrial accidents preventable," the American Museum of Safety has opened a permanent exposition of safety devices in the Engineering Societies Building, 29 West 39th street, New York. Machines, models, and photographs demonstrating simple, practicable safeguards adapted to the needs of the American employer for protecting the lives and limbs of his workmen are shown.

Dr. James Tyson has been elected Emeritus Professor of Medicine in the University of Pennsylvania, and Dr. Louis A. Duhring has been elected Emeritus Professor of Dermatology in the same institution.

Dr. David Edward Hoag was elected Lecturer in the Department of Nervous and Mental Diseases in the New York Polyclinic Medical School at the October meeting of the Faculty of the school.

The Merritt H. Cash and Lucien Howe Prizes.—Dr. A. Jacobi, chairman of the Committee on Prize Essays of the Medical Society of the State of New York, desires to announce that the date for the presentation of prize essays in competition for the Merritt H. Cash Prize and the Lucien Howe Prize has been extended from December 1, 1910, to March 1, 1911.

The American Society of Medical Sociology.—This is the name of a new society, the purposes of which are stated in the following announcement: "Recognizing the intimate relationship between disease and the social-economic system under which we live, recognizing that many diseases are caused directly by our social and economic conditions, recognizing that the efficiency or inefficiency of our treatment often depends upon the economic condition of the patient, recognizing that there are many problems deeply and vitally affecting the welfare of mankind which are left practically untouched by any existing medical society, The American Society of Medical Sociology has been organized for the purpose of studying radically all questions of a sociomedical nature, and invites your cooperation." The president of the society is Dr. William J. Robinson; the secretary, Dr. A. C. Jacobson, 12 Mt. Morris Park West, New York.

Southern Medical Association.—The fourth annual convention of this association, representing the States of Georgia, Alabama, Mississippi, Louisiana, Florida, and Tennessee, was held in Nashville recently. The following officers were elected: *President*, Dr. Isadore Dyer, New Orleans; *Vice-Presidents*, for Tennesee, Dr. William Litterer; for Florida, Dr. W. P. Adamson; for Georgia, Dr. William C. Lyle; for Alabama, Dr. T. D. Park; for Louisiana, Dr. J. D. Guthrie; for Mississippi, Dr. A. G. Paine; *Secretary-Treasurer*, Dr. Seale Harris, Mobile, Ala. The next meeting of the association will be held at Hattiesburg, Miss.

The Late Dr. Ransom.—The Medical Board of the City Hospital of New York mourns the death of one of its former members, Dr. Charles C. Ransom. During the fifteen years that he served the sick poor in the wards of this hospital his colleagues learned to know him and to love him. His personality united in a rare degree scientific enthusiasm, genuine humanitarianism, and love of his fellowman. For a number of years he had interested himself especially in the welfare of the many sufferers from chronic joint disease who fill our wards, too often a mute but eloquent reproach to the boasted triumphs of modern medicine. Through careful study and painstaking perserverance with the individual Dr. Ransom accomplished wonderful results in the alleviation of this group of patients. When holding important office for the Medical Board, and equally when merely one of its members, Dr. Ransom took the responsibilities of his position seriously. To him we owe the first steps which were taken toward proper living conditions for house staff, and throughout his whole career Dr. Ransom was generously and wholeheartedly devoted to the welfare of the medical men who served under him, loyal to the hospital and all its interests, eager for its betterment, and always hopeful of seeing it realize the high ideals he cherished for it. It is with the realization of personal loss on the part of each of us that we meet here to-day to place formally upon our records our last tribute of affection and respect.

Therefore, be it resolved, That the Medical Board of the City Hospital, conscious of the loss it has sustained in the death of Charles Cook Ransom, a loss not only to each member of it individually, but also to the hospital which it represents, the department of the city government which it serves, and the larger interests of medical science, hereby places this minute upon its records, and be it also resolved that a copy of this minute be suitably transmitted to Mrs. Ransom; that a copy be posted in the staff house of the City Hospital, and that a copy be submitted for publication in the local medical journals.

THEODORE JANEWAY,
JOSEPH COLLINS,
HARLOW BROOKS,
} *Committee.*

Obituary Notes.—Dr. FRANK NEVILLE LEWIS of New York, a graduate of the Medical Department of the University of Vermont in 1882, a member of the American Medical Association, the New York State and County Medical societies, the New York Academy of Medicine, the American Ophthalmological Society, and the New York Ophthalmological Society, and surgeon to the Manhattan Eye, Ear, and Throat Hospital, died suddenly at his home on November 13, aged 53 years.

Dr. JAMES L. ROBINSON of Wheatland, Ind., a graduate of the Medical Department of the University of Louisville, Ky., in 1881, died at his home on November 8, aged 56 years.

Dr. DAVID W. SHARP of Woodstock, O., a graduate of the Cincinnati College of Medicine and Surgery in 1874, died at his home on November 7, aged 62 years.

Dr. JOHN D. WOODWORTH of Leslie, Mich., a graduate of the Rush Medical College, Chicago, in 1852, died at his home on November 7, aged 84 years.

Dr. JOSEPH S. FINN of Jersey City, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1854, the first county physician of Hudson County, a member of the New Jersey State and Hudson County Medical societies, and consulting physician to the Bayonne Hospital, died at his home of acute indigestion on November 19, aged 77 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DUKE OF CONNAUGHT AT SOUTH AFRICAN MEDICAL CONGRESS—OUTBREAK OF PLAGUE—TRYPANOSOMIASIS—MALARIA AND MOSQUITOS—FLORENCE NIGHTINGALE—KNIGHTHOODS—OBITUARY.

London, November 4, 1910.

Among the festivities in connection with the Duke of Connaught's visit to South Africa Wednesday's proceedings as reported by cable comprise two events of medical interest. At noon His Royal Highness presented certificates of the St. Johns Ambulance Association and referred to the world-wide value of its work, especially "in this land of great distances." In the afternoon His Royal Highness opened the Medical Congress, which is being attended from all parts of South Africa. The Duke commented on the healthful atmosphere and abundant sunshine of the country, and freedom from some of the most fruitful causes of disease in Europe and the East. Yet, he added, few parts of the world were exposed to diseases more obscure in their pathology and more baffling as to cure. He hoped, in medicine as in other fields, the benefits of union would include a more perfect coordination of medical energy wherever required. The health of the population was one of the first cares of a State, and it was difficult to overestimate the importance of the advancement of medical knowledge.

The outbreaks of plague in East Anglia are being met by active measures. The County Council has appointed Dr. Llewellyn Heath, of the East Suffolk Hospital, a temporary medical officer, and he has circularized the profession in the locality as to looking for early symptoms of a suspicious nature. The police are reporting to him places where dead or dying rats or rabbits are found, and an effort is being made by extending the area of observation and search to limit the spread of infected animals. Some of those found have evidently succumbed to poison which the farmers and others have freely distributed. So that without bacteriological examination any case is open to doubt. On the outskirts of Ipswich several such examinations have been made with negative results. It is hoped the infection has not spread to that part. On several estates the keepers have fed ferrets on rabbits with fatal results in some twenty cases, though it is not yet shown whether the disease or poison was the cause. A cat having been infected, the people are keeping a watch on domestic animals, and may be said to be waking to the importance of observation.

The Research Defence Society recently published a pamphlet on "Plague in India," by Lieut-Col Bannerman, of the Bombay Bacteriological Laboratory, which contains a full and authoritative account of research and prevention in reference to the disease.

Among our many societies, we have one "For the Destruction of Vermin," which was founded some three years ago. It was a delicate infant, and did not seem likely to survive, but the outbreak of plague has given it a new source of strength, and it has allied itself to the Royal Institute of Public Health. This body has well-equipped laboratories, and bacteriological researches are to be there actively carried on. A meeting was held on Wednesday when Sir J. Crichton Browne took the chair. He said there was no reason for panic, although caution was called for. It was certain that pneumonia plague was distributed by rats and other vermin, and when human beings took it their breath was infective. Rats had much to answer for as propagators of various diseases. So had house flies. A national effort should be made to destroy vermin through the whole country.

Dr. Sambon showed on the screen a series of illustrations of parasitic carriers of disease and the way in which the virus is conveyed, the transmutation from animal to animal, and eventually to the human host. He said the common house fly is known to convey typhoid, cholera, and other diseases. Fleas convey tape worms, as well as plague. Yellow fever is insect-borne. Cats and dogs are very useful to keep down rats, but when the virus has entered the body of the rat they may become infected.

Sir Lauder Brunton said the exterminating effort should not be confined to a district, but carried out all over the country.

William James Cantlie said suspected animals over a wide area should be driven into a condon, bacteriological examination made, and those infected slaughtered.

Capt. MacIlwaine recalled that rats also disseminated swine fever.

Capt. Tailby deprecated the destruction of birds which prey on vermin and urged the preservation of the owl, one of their most doughty foes.

At the conclusion of this meeting an executive committee was appointed to plan and carry out a campaign. Funds will be required and will no doubt be forthcoming as the public is getting anxious. In the last few days fresh areas have been reported as infected. Of these the port of London is most important, some dead rats having been found escaped from the shipping. Dr. Williams, Port M. O. H., is superintending and directing. Fumigation destroys most of the vermin on a ship, but a few may escape by swimming, though most are too enfeebled to reach the shore. Dr. Williams has also to contend with the fact that fleas from the rats may get on the Lascar and Chinese sailors, who huddle together in our chilly climate. A daily inspection of their lodgings is made and all their clothing fumigated. Suspects are isolated. In the wharves and warehouses a constant war is carried on by rat-catchers. At the meeting of the Court of Common Council the chairman of the Port Sanitary Committee reported that these and other measures were being energetically carried out. Altogether it appears that the authorities are determined that no precaution shall be omitted, while they are confident the danger can be averted.

At the Society of Tropical Medicine a paper was read on October 21 by Dr. Arthur Bagshawe on sleeping sickness. It was a careful review of recent researches and advances in knowledge which his experience in the tropics enabled him to summarize. The facts he presented were so numerous that only a small selection can be mentioned here. As to etiology, he reported an important piece of negative evidence. Of the two islands a few miles apart, Principé and San Thomé, the former has tsetse flies with much sleeping sickness, the latter neither. Further on San Thomé the Portuguese Commission found all the blood-sucking insects they had seen on Principé, with one exception, the genus *Glossina*. Yet in Rhodesia and Nyassaland the disease had been contracted, though it was practically certain that Nyassa if not the Zambesi, was outside

the *Glossina* area of distribution. That seemed to suggest another species might sometimes be the carrier, but, if so, why had not the disease spread in East African high grounds? Dr. Bagshawe suggested as a provisional hypothesis that in the uplands the air was too cold for the parasite to complete its development in the insect. Tsetse flies had been shown by Kleine to be capable, after a latent interval, of being permanently infected. Late development was probably the rule in those insects which transmitted trypanosomes from mammal to mammal. The experiments of the commission showed this interval might be very variable. They were still in the dark as to what went on in the interval. The flies caught on the shore of Victoria Nyanza after two years' removal of the inhabitants had been shown by Bruce to be infective of monkeys, so that the hope that the population might return seemed to be disappointed. If it were proved that wild animals formed a reservoir of sleeping sickness virus where such animals and the tsetse coexisted, man could not remain. As to symptoms, an analysis of fifty cases in Europeans showed the most frequent to be in descending order, fever, erythema, loss of strength, increased frequency of heart beat, somnolence, edema, large spleen, amenia, headache, epileptiform convulsions. As to treatment, little more has been learned of atoxyl and other arsenilates. Arseno-phenylglycin promised more, but the results had been uncertain, though both the locality and the mode of administration had differed. In Togoland the disease seemed more influenced by trypanocides than in German East Africa. Ehrlich's plan was to get the trypanocide into the blood when the parasites were more numerous, his theory being that those killed at once produced antibodies to which the others succumbed. He introduced a drug, tryparosan, which Broden and Rodhain tried, intravenously and orally, the latter more effectively. Aniline antimonyl tartrate was found by Thiroux useful and less toxic than the potash salt. None of the trypanocides could be expected to banish the parasites from the cerebrospinal fluid. Time emphasized the inefficiency of treatment in advanced cases. Experience showed that recoveries had sometimes occurred, so that, if recognized early enough, they might be more frequent. A case was diagnosed in 1903 which had existed in 1900 and now has been in vigorous health for years. Only two out of thirty Europeans survived above three years from the discovery of trypanosomes, which suggested that survival for three years with absence of symptoms indicated a chance of recovery. Five Europeans in good health in June last had lived 3, 3½, 3½, 5½, and 7 years, respectively, since the detection of the parasites. Possibly infection in them was mild. Of their treatment not much could be said. South American trypanosomiasis differed much from African, and the parasite discovered by Chagas in Brazil differed in mode of multiplication and otherwise.

The relation of malaria to mosquitos and the war on the insects in some places may encourage the hope of a successful fight against tsetse flies. But one can hardly forget the apparent failure of the Mian Mir campaign. It is true considerable controversy arose about this, but the report of the commission appointed to inquire into the matter by the Indian Government has now been issued and confirms the fact that the experiment which seems to have been carried out in a most determined way did not succeed in completely exterminating the mosquitos. Everything seems to have been done to abolish the breeding places, and yet the commission found adult anopheles as numerous as prior to the campaign, with the consequence that malaria was not much less prevalent, if at all.

Why measures so successful in Panama and other places should have been less effective in an Indian cantonment is not easy to explain, but the commissioners suggest that partial destruction of breeding places is not sufficient where other conditions favor malaria and further where many breeding places exist at some distance some of the mosquitos there bred may cover that distance in search of food. The protective measures would therefore have to be carried out beyond the distance which the mosquitos can cover. So, too, the destruction of breeding places must be extended nearer to total abolition. The commissioners advise that further efforts should be made to cope with the difficulty. It is to be hoped the Indian people will come to see the benefit of these efforts and heartily second them.

At St. Thomas' Hospital a meeting was held on Tuesday to promote a memorial to Miss Nightingale. A committee was appointed and directed to act in combination with another committee which had undertaken a similar work.

Dr. Kingston Fowler, senior physician, and Mr. Pearce Gould, senior surgeon to the Middlesex Hospital, have been knighted.

Dr. D. H. Stirling of Perth who died on October 14, aged 81, graduated in 1853, M.D., Edin. From 1868 to 1884 he was on the staff of the Royal Infirmary and then became consultant. He established the Hillside Homes, where last year 246 chronic cases were treated. He also founded the Perth City Mission and acted as secretary until his death. He had been a traveler and wrote on leprosy in Norway.

The deaths are also announced of Dr. Alexander Pole, late admiralty surgeon at Lerwick, aged 69. Surgeon-Col. C. G. Irwin, M.B., Army Medical Staff, retired, aged 79, who died on October 23, and Brig.-Surgeon J. McNeale Beatty, aged 82, who joined the army in 1854 and retired in 1880.

Spinal Anesthesia. F. Allen.
Etiology of Elephantiasis. G. C. Shattuck.
Congenital Ophthalmoplegia Externa. S. G. Webber.
The Technique of Arthrotomy. C. F. Painter and A. P. Cornwall.
Cutaneous Diphtheria—Fatal Primary Case. E. H. Place.
Conical Stump After Amputation in Childhood. C. A. Powers.

Spinal Anesthesia.—F. Allen believes that this procedure can no longer be considered dangerous, but is now relatively safe and has a distinct place in surgery. The indications are alcoholism, old age, debility, certain cardiac cases, bronchitis, arteriosclerosis, extreme dread of general anesthesia, diabetes, urinary septicemia, shock, intestinal obstruction, and renal insufficiency. Spinal anesthesia works so well as to be the anesthetic of election in simple herniotomy in men, prostatectomy, hemorrhoids, fistula in ano, amputations of leg or thigh, cystoscopy, and urethral or bladder operations. The solutions used are those of stovaine, novocain, or tropacocaine, always in combination with adrenalin. The technique of the operation is described.

Etiology of Elephantiasis.—G. C. Shattuck states that the essential characteristics of typical acquired elephantiasis are lymphangiectasis, hyperplasia of connective tissue, and chronic edema. The relation of these to each other in the production of elephantiasis is not clear. It appears that these changes may frequently be attributed

to the interaction of stasis and of inflammation. Stasis always occurs early and persists. Inflammation may precede or follow stasis, or may not be manifest at any stage of the disease. Inflammation when present may be acute or chronic, and is generally traceable to bacterial infection. Either chronic stasis or inflammation from any cause may predispose to elephantiasis, but even when they occur together, elephantiasis does not always result. There is reason to suppose that congenital weakness or anomalies of lymphatics may play an essential part in the production of some cases of elephantiasis, and that such weakness or anomalies can be inherited. The filaria is an important factor in the production of endemic elephantiasis of some regions, but it is not essential to the occurrence of endemic elephantiasis. Elephantiasis in filarial regions results indirectly from filariasis through bacterial infection. Sporadic lymphatic elephantiasis and endemic elephantiasis are not essentially different.

Congenital Ophthalmoplegia Externa.—S. G. Webber reports a case of this condition, in which the eyes were almost immovable, the head being moved in reading to follow the print across the page. This affection is a family disease and in many cases hereditary. The amount of loss of power in the muscles varies greatly in different cases, and in different muscles in the same case, from a slight impairment to complete loss of power. The muscles on the two sides may be unequally affected; often only one or two muscles are paralyzed. Sometimes the internal rectus is paralyzed so it does not act alone, but it will act in conjunction with the external rectus, as it has two sources of innervation. In a few cases the superior rectus is said to have been paralyzed, yet when the lids were closed the eyes rolled up as if the superior rectus acted. The causative pathological changes may be found in the muscles or in the nerve nuclei in the medulla. It is not likely to be in the nerves as the paralysis is too sharply limited to a few muscles for the lesion to be where the fibers for so many muscles lie as near each other as they do in the third nerve.

The Technique of Arthrotomy.—C. F. Painter and A. P. Cornwall continue their article on this subject. In the group of excisions and erasions, the danger of disseminating a tuberculous infection through surgical procedure is not a wholly negligible matter. Care must be exercised to allow nature to start her protective immunizing processes, both local and general, before one takes the risk of opening up new tissue to infection and absorption.

Cutaneous Diphtheria.—E. H. Place reports a primary fatal case of this condition, which is not uncommon, having been seen at the South Department of the Boston City Hospital during the past three years in the following conditions: (1) About the face and hands, often appearing much like an impetigo contagiosa, less often with distinct membrane. Cultures show virulent Klebs-Loeffler bacilli, and both types clear rapidly with the administration of antitoxin. (2) On the auricle, chiefly the concha, extending from the middle ear; and behind the auricle inoculated upon the eczema so common in this region in children. (3) Inoculated upon lupus vulgaris lesions on the face, following curettage. (4) In wounds and abscesses on the neck and face. (5) Inoculated upon varicella lesions, most commonly on the vulva or vagina. At times it is severe in these locations, and similar cases of cutaneous diphtheria have been known to be the cause of small epidemics.

Amputation in Childhood.—C. A. Powers calls attention to the fact that when a small child suffers amputation through the upper part of the arm or the upper part of the leg, a conical condition of the stump will result. It occurs because the humerus and bones of the leg develop in large part from their upper epiphyses. The growth takes place at the upper epiphysis and pushes the bone down into and through the soft parts. When the surgeon does his original operation it is best for him to tell the parents that this will probably take place. The younger the child the more frequently will the bone have to be cut off.

Accidental Detachment of the Normally Implanted Placenta. W. S. Picotte.

Sources of Venereal Infection.—F. Bierhoff found in 1,429 cases of gonorrhea, in which the diagnosis was based upon the finding of the gonococcus, that 74 per cent. of the cases had been infected by public prostitutes. Of the remainder almost all had been infected by "clandestine" prostitutes. In comparing his results with those obtained by Fournier of Paris, in 1866, and by the author in Berlin, in 1899-1900, it was seen at a glance how small a rôle the public prostitute plays in Fournier's statistics, as a source of gonorrheal infection, when compared with those obtained by the author both in Berlin and New York. It is concluded that the public prostitute is by far the most prolific disseminator of venereal disease.

Gross Drugs vs. Active Principles.—G. F. Butler states that the active principles alone can fulfill the main requirements of a medicament, namely, uniformity in strength and identity of action at all times. A great advantage of active principle therapy is the facility with which these principles of plants may be administered to patients.

Serum Diagnosis of Syphilis.—W. A. Groat states that the Noguchi modification of the Wassermann reaction is known to be positive in most cases of leprosy, a few cases of scarlatina at the height of the disease, frambesia, sleeping sickness, in malaria during the paroxysm, and in lupus erythematosus. None of these diseases is hard to distinguish clinically, and most of them are rarely met with. With these few exceptions the test is specific. It is positive with remarkable regularity in active secondary cases. While it would seem as though technical errors would account for almost all negatives in active untreated syphilis, yet as in every other infectious disease there must be anomalous cases in which the specific antibodies are not present. Primary cases usually give negatives early and are generally positive before the secondary eruption appears. Negatives should be repeated until well by the period of expected secondary symptoms. Active tertiary cases give more negatives than any other class of active syphilis, previous treatment being undoubtedly a factor in many of these. Congenital syphilis gives practically one hundred per cent. of positives. Brain syphilis and general paralysis usually give positives. Tabes probably gives nearly as high a percentage of positives in the acute stage, most of the negatives being in the old survivors in whom the infection has burned out. The test has been and is to be of great value in clearing up the etiology of diseases in which syphilis has been suspected as a factor.

Ehrlich-Hata Preparation.—J. A. Fordyce states that from an attitude of conservatism in the beginning he is becoming more and more impressed with the remarkable action of the drug, especially in the early period of the disease, and in cases which do not respond to mercury and potassium iodide. Decided improvement occurred in cases of luetic endarteritis of the base and of obstinate gummatous ulceration. It is possible with one dose, though that

be a minimal one, to completely eradicate the cause of the disease. The following points are also emphasized: (1) Primary lesions should be treated as early as possible, and in the young and vigorous with not less than 0.5 gram intravenously. As an aid to complete sterilization energetic local treatment should be employed, such as excision, cauterization, or other means of destruction. (2) In disease of the central nervous system or circulatory apparatus great care should be exercised and only small doses (0.2 to 0.4 gram) given. Whether the intravenous method is to be preferred in these cases has not yet been determined.

X-Ray and Special Senses.—E. H. Skinner presents the following outline of the possibilities of the *x*-ray in the specialties: The *x*-ray stands preeminent in the location with exactitude of foreign bodies in the eye, ear, nose, and throat. It is a valuable assistant in the diagnosis of pathological changes in any of the bony tissues of the ear, orbit, nose, and throat, whether this change is necrosis that is clearly and unmistakably recognized, or whether it is the presence of an exudate that alters the density of the shadows of a part. The *x*-ray gives definite information regarding the anatomy of those cavities which cannot be obtained in any other way than through operative procedure. It permits one to study the physiology of speech, singing, and deglutition. By the process of diagnosis by exclusion the probability of sinus involvement will be excluded where one has pains of a neuralgic character. The *x*-ray serves as an assistant in an operative procedure looking to the extraction of a foreign body from a sinus, cavity, or orifice, by noting that the instrument used to grasp the foreign body is actually attached to such body. This latter service is best afforded by the fluoroscope, thus insuring a vivid picture of the operation in progress.

Röntgen Treatment of Cancer of the Breast.—R. H. Boggs concludes that under the influence of the *x*-rays, used as a palliative remedy, glandular involvement has melted away, ulcerated masses have healed over, adherent tumors have become movable, inoperable cases have become operable, rapidly growing carcinomata have assumed a more scirrhous type, lymphatic pathways have been sealed against extension, and a fibrous wall has been erected against further growth, life has been prolonged and redeemed from misery. This would seem to call for routine anteoperative use of the rays even in favorable cases, but experience is not yet sufficient to permit one to assert this as a demonstrated fact. Postoperative treatment has diminished scarring, promoted healing, postponed or prevented recurrence. Such results demand not only technical competence, but judgment, clinical knowledge of both the disease and the remedy, promptness, energy, and courage. Surgeon and röntgenologist must work hand in hand, each availing himself of the other's aid, but each respecting the other's authority in his own field and each having a broad scientific understanding of the whole subject.

Prophylaxis of Enterocolitis.—W. H. Randle states that this can be summed up in one sentence: "Stop the milk of all bottle-fed babies during the hot weather." As a substitute diet he recommends barley water with a little expressed juice of beef and a pinch of salt; albuminized water with a little dash of pure orange juice; and to a limited extent the best brands of condensed milk.

Prevention of Lateral Curvature.—M. Strunsky advocates a routine examination of the backs of school children, especially at the "scoliotic age." As regards the effects of scoliosis, in the pronounced types and those of medium severity, the heart is displaced and the lungs are compressed. The stomach and intestines and liver are displaced, and the spleen and kidney upon the convex side are smaller than normal. This compression and displacement of organs interferes with their functions and by the mechanical pressure of bone on tissue, causes atrophy of vital structures. The elasticity of the spinal column is mainly due to the intervertebral discs. In scoliosis the latteral pressure of the vertebræ causes the discs to become wedge shaped and to lose their elastic power. The mobility of the spine is also lessened in scoliosis. Scoliotics lack endurance, often suffer from headaches, backaches, and fatigue, and have a frequent irresistible desire to lie down and rest. Often they are irritable. Undoubtedly these symptoms are to a great extent the result of the rigidity of the spine and thorax which act like transmitters to the nervous system of the jar resulting from walking or from various other movements of the body. The early treatment consists of the following: (1) Determining and correcting a possible exciting cause, such as tilting of the head either due to torticollis, deafness of one ear, disturbed vision, or a faulty position of the spine, either due to shortness of one leg, empyema, or paralysis of the trunk muscles. (2) Forbidding patients to carry bundles. (3) Providing frequent intervals of rest. (4) Building up the system. (5) Gymnastics. When structural changes have once taken place no treatment can restore the spinal column to the normal.

Ehrlich-Hata Preparation.—A. L. Wolbarst believes that this should be employed only in cases which by their nature and severity demand heroic treatment and only after a careful study of the technique of administration.

Detachment of Placenta.—W. S. Picotte reports two cases of accidental detachment of the normally situated placenta, and concludes that this condition is more serious than placenta prævia and eclampsia, and that there seem no salvation for the fetus and very slight chances of recovery for the mother. With the child, death follows interrupted nutrition. In the case of the mother, anemia is directly or indirectly the cause of death. If a physician is at hand when the first symptoms appear, the mortality rate might be lowered, but in general practice this is ordinarily impossible. Even were it otherwise, the question of an early recognition of this condition before the appearance of blood externally is sometimes difficult and has been mistaken for other morbid phenomena, and women have died without delivery. If seen before too much blood has been lost, the life of the patient depends greatly on the quick and dexterous action of the accoucheur, and no time should be lost to empty the uterus. In the case of moribund patients some attempt should first be made to stimulate, and to replace part of the blood by hypodermoclysis.

Kidney and Ureteral Stones.—M. F. Porter states that the first symptoms of ureteral calculus may be referred to the bladder, which should always be examined, and a stone found in the bladder should always cause search in the kidney and ureter, as calculi are frequently coexistent in both localities. One notices the important part played by infection in the etiology of these formations and that stone in the kidney or ureter as a cause of cancer has received less consideration than it deserves. Cancer with a large stone means that the stone antedated the can-

cer and might be considered its cause. Most surgeons seem to believe that tuberculosis of the kidney is primary and of hematogenous origin, but that trauma is often the exciting cause of tuberculosis is admitted, and these two facts together would seem to indicate that stone might cause kidney tuberculosis. The author does not, however, favor this idea, and an extensive search of the literature, he thinks, does not bear out this assumption. Personally he has seen no coexisting case of stone and tuberculosis of the kidney. Contrary to his former opinion, he finds the *x*-ray of more and more value in the diagnosis and agrees with Bevan that it is a more reliable method of examination than exploratory operation. Careful inquiry in cases of kidney and ureteral stone will reveal important diagnostic points in many cases which the patient would not mention. Hence the importance of careful history taking in such cases.

Clinical Use of Strophanthus.—R. A. Hatcher and H. C. Bailey believe that in the present state of knowledge the clinical use of strophanthus by the mouth is irrational. The absorption of digitalis and strophanthus, chiefly the latter, is variable. The digitalis bodies have a synergistic action. Caffeine is also synergistic to the latter. This should be remembered in prescribing digitalis to those who use large amounts of tea and coffee. Of the two digitalis principles, crystalline ouabain and crystalline digitoxine, the latter is insoluble in water; hence the former should be preferred. The intravenous injection of crystalline ouabain affords the most exact dosage possible in digitalis therapy, and the most rapid effect. It is possible that any Galenical preparation of digitalis or strophanthus will be found available for intravenous or intramuscular injection, but the activity should be determined in terms of crystalline ouabain on the mammalian heart. The cardiac action of any digitalis body is elicited promptly after the intravenous injection. The oral administration of the digitalis bodies will continue to be preferred for the general treatment of cardiac disease, and in such cases the tincture or infusion of digitalis deserves the preference, because they are more readily absorbed than the preparations of strophanthus. There is urgent need of more exact clinical studies of all of the digitalis bodies, particularly with regard to their relative effects on the centers and on the vessels, and there is equally urgent need of further pharmacological investigations of the rate of absorption and excretion of these several bodies, with an elucidation of the phenomenon of cumulation.

Council on Pharmacy.—D. L. Edsall describes the work of the Council of Pharmacy and Chemistry and speaks of its magnitude and of the cordial support given to it by the profession.

Nephritis Following Tonsillitis.—H. W. Loeb concludes as follows: Acute nephritis results from acute tonsillitis far more often than is generally believed. The symptoms ordinarily are not manifested until some time after the inception of the disease. The nephritis is of the hemorrhagic type and differs from that of scarlet fever in that pyrexia, edema, and oliguria are not marked symptoms of the disease. In addition, it follows the angina and is not concomitant as in scarlatina and diphtheria. Judging from the course of the cases reported, there must be many in which a mild nephritis occurs incidental to the tonsillitis, which goes on to resolution without patient or physician being conscious of its presence. As each case of lacunar tonsillitis may be a potential source of acute nephritis, it is incumbent on practitioners to observe the urine, not only during the height of the disease, but for some time after as well. Spontaneous or idiopathic nephritis is probably often due to a tonsillitis that has not been considered as an etiological possibility. Chronic affections of the kidney may well owe their origin to unrecognized acute attacks of nephritis of tonsillar origin. Much light may be shed on this subject by a study of the urine in a large number of cases of acute tonsillitis.

Typhoid Carriers.—W. J. Stone reports the case of a typhoid carrier successfully treated by inoculations of an autogenous typhoid vaccine. Reviewing the literature of cases similarly treated, he concludes that the time element is an important factor in the reaction of susceptibility to inoculations of bacterial vaccines in typhoid carriers. Typhoid carriers injected within a comparatively short time after their infection, will in all probability receive more benefit from properly prepared autogenous vaccine than from any other known form of treatment. "Contact carriers," who never to their knowledge have had typhoid, are more susceptible to the inoculations than carriers who have had a definite attack of this disease, and who are in all probability more immune. When the infection has persisted for years, it may be difficult to clear up the condition by bacterial inoculation. The effort should at least be made, since in the somewhat similar condition of chronic carriers of apparently non-virulent tubercle baccili, the bacilli often disappear from the sputum during a course of inoculations of some one of the tubercle products. The immunity manifested by typhoid carriers is in all probability a partial immunity, in the sense that while these individuals are protected against the infection through an augmented phagocytic power held by their body cells, the antibacterial substances, such as the bactericidins and lysins, are lessened to a degree insufficient to exert any destructive power against the infection.

Immunization in Non-Bacterial Diseases.—S. P. Beebe states that the reactions of immunity are not restricted to higher toxic proteins; the injection of any alien protein stimulates the formation of antibodies, the presence of which may be detected by several methods, such as the precipitin reaction or the deviation of complement, and such reactions are found to be in a high degree specific. Early in this work the suggestion was made that it might be possible to destroy unrecognizable cancer cells after an operation by a cytotoxic serum. The author has made many experiments with nucleoproteid serum which have confirmed his earlier view that it is possible to make a serum which will act primarily on a given organ. The evidence on which he draws his conclusion of specificity is based on precipitation, agglutination, absorption experments, and on the effects of animal injection. Serum has been developed against the human thyroid glands and used clinically in the treatment of exophthalmic goiter. In regard to immunity to cancer, the author says that he has produced an active cytolytic serum from the nucleoproteids of a breast cancer and treated the patient from whom the tumor was removed with this serum in order to prevent a recurrence. No recurrence occurred, but, as the operation was a radical one, no conclusions could be drawn. The observation by Gaylord and Clowes that a certain percentage of mice infected with the Jensen tumor recovered and were thereafter immune was the first authentic experimental production of immunity in tumors. It is known that a certain percentage of animals is normally immune to tumors, the reason for which is unknown. It is also known that a certain percentage of the successfully planted animals recovers spontaneously, the number depending on the virulence of the tumor and the resistance of the animal. The recovered animal also is immune for a long time to tumors of like virulence. The author refers to his experiments made with Crile, showing that the transfusion of large quantities of recovered blood to an animal with actively growing tumors would cause complete absorption of the latter with the usual subsequent immunity. Further research experiments have afforded clear evidence that the regression of the tumor is an essential factor in the future immunization of the animal and transfusion of immune blood

into a susceptible animal without tumors at the time would confer no immunity. There apparently must be some interaction between the tumor and the serum to start the regression. Recent observations by Gaylord, Gay, and others have shown that a method of vaccination is a logical procedure in the treatment of malignant tumors, but that living tumor cells must be used. The author mentions the results obtained by Hodenpyl with the chylous asitic fluid of a cancer patient which at first caused complete absorption and recovery for a time. It is impossible to say how this fluid acts, but the procedure seems to be a logical one and, whatever the ultimate outcome in these cases, they are suggestive for the future.

Vaccine Therapy.—E. E. Irons states that the fundamental theory of the method assumes that the body is capable of reacting to the inoculation by the formation of antibodies, and the giving of vaccines to a patient already overwhelmed with infection is theoretically wrong and practically in most cases a failure. The therapeutic value of vaccines is best shown in chronic or recurrent localized infections, such as furunculosis, acne, carbuncle. Infections of the urinary tract due to the colon bacillus have received much attention recently and the reports indicate that good may be accomplished by the inoculation of autogenous colon vaccines. About 50 per cent. of urinary affections are due to this organism and in still more it is associated with other bacteria. Colon infections of the prostate resistant to ordinary treament have in a number of cases been benefited by vaccine. Streptococcus infections have not been so amenable as the staphylococcus ones. It is possible that it may do good in erysipelas, using autogenous vaccines. Opinion is divided as regards puerperal sepsis and in severely toxic cases one should hesitate. Localized affections about the nose, throat, and ear have been reported benefited, and it has been proposed to use prophylactic inoculations before surgical operations to prevent possible postoperative infection, but the data are not sufficient as regards the advisability of this. Gonococcus metastatic lesions of the chronic and subacute types are often greatly improved and cure hastened by inoculations, and a possible prophylactic value has been suggested. The treatment of localized tuberculosis other than of the lungs has been aided by their careful use. A striking instance of their value is afforded by the statistics of the inoculations against cholera, plague, and bacillary dysentery, and the incidence of these diseases in regions where they are endemic as well as the mortality has been in some cases largely reduced. Similar results have been obtained by the prophylactic use of typhoid vaccine in soldiers, but their value in the treatment of the disease is not determined. The prophylactic use of vaccines in scarlet fever has received much attention in Russia and remarkable immunity results have been reported. In ulcerated endocarditis the results have not been generally favorable. While the general practitioner will do well to confine the use of vaccines to localized infections, mention should be made of the recent work on the treatment of pneumonia by the inoculation of pneumococcus preparations from which the toxic portion has been removed. The work is still experimental but suggests some possibilities. More attention is deemed advisable to the local and general reactions from injection of dead bacteria and their products for diagnostic purposes. Bacterial vaccines are powerful agents for good or harm and the clinical results should be most carefully interpreted.

Autogenous Vaccine Therapy in Endocarditis.—E. C. Rosenow points out that, while the therapeutic injection of dead bacteria in certain localized infections can no longer be questioned, their value in more generalized infections, especially endocarditis, is still very questionable. The continuation of the infection in chronic endocarditis is due largely to a process of immunization or adaptation of the bacteria to the antibodies of the host. This is shown in his study of the subject by the facts that the bacteria grow much more rapidly in the patient's serum than in normal serum; that when grown in the patient's blood or serum, both *in vivo* and *in vitro*, they acquire a resistance to phagocytosis and a resistance to leucocytic destruction; and that they produce alterations in the serum of the patient which robs the leucocytes of something which they need to digest the bacteria when taken up. The destroying power of the patient's blood at these times is found far below that of normal blood. While the inoculations produce temporary improvement they later leave the patient worse. The destruction of the bacteria evidently liberates a toxic material that poisons the individual. Besides activating the blood, a neutralizing substance to prevent intoxication of the already overwhelmed patient will be needed in endocarditis.

Tuberculides in the Diagnosis of Infantile Tuberculosis.—J. S. Leopold and T. Rosenstern present the results of their observations which show how valuable this lesion, as yet unrecognized by most observers, is in the diagnosis of tuberculosis in children. The tuberculides consist of slightly raised rounded papules varying in size from a pin head to a millet seed. At first they are of a red color, but later become brownish and show a scale or crust in the center. When scratched away they leave behind a rounded depression which does not bleed but is dry, as a rule. Their most characteristic points are the absence of any tendency to ulceration, their central depression, their livid brownish color, and their glistening appearance when the skin is stretched. They may appear anywhere on the skin, but preferably on the arms, the lower back, and especially the extensor surface of the lower limbs. According to the author's experience there are rarely many present in one case, sometimes not more than four or five, or even less. Hamburger has called attention to the fact that they are easily overlooked on account of their minute size. They were found in asylum children in about 40 per cent. of the cases. They will be less frequent in dispensary practice, as they need watching for constantly, since they soon lose their characteristic appearance. In many hundred non-turberculous infants they have never been seen by the authors. Their tuberculous character is shown by the fact that in 70 per cent. of the cases tubercle bacilli have been found.

Thyroid and Adrenal Activity.—E. G. Hoskins performed a series of investigations which add to the existing evidence in favor of the theory that the thyroid stimulates the action of the adrenals.

Suspended Respiration during Operation.—J. L. Crooks reports a case of suspended respiration during an operation for depressed fracture of the skull under ether anesthesia. Resuscitation was accomplished by means of Sylvester's method of artificial respiration.

Gastric and Duodenal Ulcer.—H. Adler describes his method of diagnosis of this condition by means of the *x*-ray. He gives a single dose of 1.5 grams of bismuth subcarbonate in half a glass of water and then waits for the stomach to get rid of it, having determined in advance the motility. In cases in which there is no disturbance in motility the picture was taken in from four to six hours after the bismuth, which was given on an empty stomach. This would allow time for all the bismuth to disappear from the stomach and duodenum except that lodged in the crater of an ulcer. After the first *x*-ray examination, one ounce of the bismuth subcarbonate is given in a glass of water and a second picture taken immediately. The bismuth rapidly spreads over the entire gastric mucosa, but this can probably be facilitated by having the patient turn from side to side several times. This examination is for the purpose of obtaining a shadow of the entire stomach so as to localize any shadow made on the first plate.

Toothpicks as Foreign Bodies.—G. M. Livingston reports a case of severe irritation of the stomach and hemorrhage in the stomach and bowel caused by the swallowing of several toothpicks which the patient had been in the habit of chewing. Relief was obtained by the passage of the foreign bodies *per anum*, and there were no serious sequelæ.

Coccidioidal Meningitis.—H. A. L. Ryfkogel describes a case of this condition in which there was absence of the characteristic coccidioidal skin lesions and the case had been diagnosed as tuberculous or syphilitic in character. There were numerous skin abscesses, however, which revealed the organism. Secondary hydrocephalus set in and the question arose whether this was due to meningitis caused by the fungus or, as it occurred after the abcesses had been apparently cured, whether it was an epidemic cerebrospinal meningitis. Lumbar puncture did not settle the question. An injection of Flexner's serum was given without improvement, and about three weeks later a second one, which was followed in 34 hours by death. The author considers the cause of death in this case to be probably the anaphylactic reaction of Richet. Hutinel has published reports of four cases of death after a second injection of antimeningococcus serum, and the hypersusceptibility of tuberculous individuals to a second injection of horse serum is well known. The sensitiveness in this case bears some relation to these and is another evidence of similarity of the fungus granulomata to tuberculosis. There was a tendency of the lesions to heal in this case, and the meningeal lesions were found regressive on autopsy, indicating a possible curability of the condition.

Cultivation of Sarcoma.—A. Carrel and M. T. Burrows performed an experiment by means of which it is possible to cultivate outside of the organism fragments of a human sarcoma in a manner similar to that of the animal sarcoma previously described.

Acute Thyroiditis.—J. P. Lewis and B. J. O'Neill describe a case in which the noticeable features were the evident infection from horses suffering from "epizootic," although no history of trauma or other etiological factor could be elicited; the edema of the glottis at the onset; the seemingly very rapid development of the swelling of the thyroid gland; the lack of involvement of the lymph-glands until some hours later, and the rapid recovery.

Greek Medicine in Rome.—Sir T. Clifford Allbut, in the first lecture of the Fitz Patrick course, refers to Soranus, who was too great a man to be enthralled in any sect, who in learning and practice and in loyal regard to tradition stood on the heights of ancient medicine. Next the lecturer discourses on the origin of the idea of pneumatism, its doctrines and their relation to other doctrines, the Aristotelian influence in Alexandria, Alexandrian medicine, Athanæus, and the growth of polypharmacy.

The Traumatic Neuroses.—T. R. Glynn states that the neurosis excited by traumatisms is usually a hysteroneurasthenia. A predisposing cause is probably often to be found in a weakened nervous organization brought about by the abuse of tobacco and alcohol, and further exhausted by unhealthy or arduous occupations and unhygienic surroundings. Emotional disturbance plays a more important part than physical injury. The most severe cases of hysteroneurasthenia follow blows on the head. When an injury is severe the nervous symptoms may be manifested immediately by excitement, insomnia, night mare, headache, tremors, emotional disturbance, and diges tive troubles. In individuals with stable nervous systems recovery takes place in a few days; in others of neurotic temperament, after perhaps a period of temporary improvement, the nervous manifestations return with greater or less intensity. When the traumatism has been slight, the victim of the accident may experience few symptoms of depression immediately after it, perhaps only vague pains and some weakness of the legs and slight insomnia—nothing to prevent him continuing his occupation. At the end, however, of a few days, or weeks, or perhaps months, progressively or rapidly the symptoms characteristic of a traumatic neurosis appear, and a state of invalidism becomes more or less established. The period of time extending between the receipt of the accident and the development of the neurosis has been termed by Charcot the "period of meditation." According to certain German authors, this period may be prolonged to from two and a half to fifteen years after the receipt of the injury. A traumatism may be followed by a pure neurasthenia or hysteria or by a hysteroneurasthenia; in the latter case the more precocious nervous manifestations are, as a rule, neurasthenic.

Desmoid Tumors.—R. Morison and H. Drummond state that this term is applied to fibromata when occurring in the muscles or muscular fasciæ of the abdominal wall and possessing certain clinical characteristics apart from fibromata occurring in other parts of the body. These tumors are found chiefly in the upper half of the rectus muscle, but also in connection with the other muscles, and are of considerable clinical importance. They are likely to be mistaken for growths in the abdomen, unless the possibility of their occurrence is remembered. Their association with pregnancy is so frequent as to constitute more than a coincidence. Possibly traumatism, by muscle stretching or tearing, is of etiological significance. A firm, but not tender, sausage-shaped tumor, possessed of some mobility, across, but not in the direction of the fibers of the relaxed muscle with which it appears to be associated, becoming fixed when that muscle is made tense, and occurring in a woman recently pregnant, is a desmoid tumor. The treatment is to excise the growth at once, along with a free margin of the surrounding structures, including the peritoneum underlying it.

Vaccines of Unknown Organisms.—E. C. Bowsfield reports four cases treated successfully by means of vaccines, in three of which the apparent cause was an organism which did not lend itself to classification, either because of the unusual form, or because the condition of the patient was such as not to allow time for the purpose. The cases were the following: Pleurisy following measles; malignant endocarditis following phlebitis; puerperal toxemia due to *B. coli communis;* puerperal toxemia due to an unidentified organism.

Primary Acidosis; Recovery.—S. Bontor reports the case of a woman, sixty-eight years of age, who, following a chill, suffered from headaches, insomnia, and nausea. Later she became apathetic, delirious, and finally unconscious. The diagnosis of this case was difficult. It was evidently a toxemia and appeared to rest between uremia, an intestinal infection, and acidosis, but at first there was nothing to enable a differential diagnosis to be made. The urine, which was examined nearly every day, gave no definite reaction until thirteen days from the onset of the condition. Then diacetic acid was found to be present and the condition was shown to be one of acid intoxication, and a line of treatment was framed to meet the condition. In order to keep up the store of glycogen the diet was en-

tirely limited to carbohydrates, and with a view of neutralizing as far as possible the acid condition bicarbonate of soda was introduced into the system as freely as possible. It was given in every feed and by slow introduction into the rectum, according to Murphy's plan, of continuous rectal infusion as long as the bowel would tolerate it, and afterwards by occasional enemata. The author believes that the initial chill interfered with the digestive processes, that an intestinal toxemia was induced, and subsequently the liver cells were so damaged by their work in dealing with the resulting toxins that they were incapable of performing their normal function of transforming the carbohydrates into glycogen. It is thus possible that the patient's store of glycogen became exhausted during the first few days of her illness. In spite of the severe symptoms produced, the patient recovered. The author states that this is probably the first recorded instance of recovery after a severe primary acid intoxication.

Faradic Current in Aphonia.—F. H. Johnson reports a case of aphonia of twelve years' duration following laryngitis, and a similar case of more than two years' duration, both of which were successfully treated by means of external faradization. He finds that the secret of success lies in the regular and persistent use of mild currents, which are not calculated to produce violent contractions of opposing healthy muscles. Where the laryngoscope shows marked swelling and congestion of the cords the mucous membrane must be attacked vigorously on orthodox lines, and here again one is likely to meet with little success if the nasopharynx is in an unhealthy condition. The author urges the necessity, in any given case, of making sure that the aphonia has really resulted from such simple causes as catarrh, overstrain, or a combination of both. Thoracic aneurysm, lesions of the central nervous system, malignant growths, the ulceration of syphilis or of tubercle—these must always be borne in mind as sinister possibilities, and it is at least a waste of time to employ faradization in the case of a patient who subsequently dies from cancer or who is in condition to be cured by iodide of potassium.

Phlegmasia Alba Dolens.—J. C. Curtis reports a case of this condition, followed by pulmonary embolism and infarction of the lung; recovery took place. The chief points in the case were: The large area of lung involved; the almost simultaneous disappearance of the edema in the leg, coincident with the lung lesion; the small amount of pyrexia, pointing to an aseptic condition of the lung lesion; the high respiratory rate, due to the large amount of lung tissue thrown out of action; and finally the total absence of any sanguineous expectoration, and also practically no cough.

Influence of Quinine and Morphine Upon Phagocytosis.—H. L. Smith found that a combination of these drugs in the "ideal dose" (one-eighth grain of morphine hydrochloride to each ten grains of quinine hydrochloride) causes *in vitro* an increased phagocytosis. He believes that the stimulus to phagocytosis in the test-tube cases was due to the quinine and morphine acting as an opsonin to certain microbes. In the initial stages of a bacterial invasion, and particularly in cases of appendicitis, acute colitis, puerperal septicemia, cellulitis, erysipelas, and influenza, the prompt administration of quinine in the ideal dose (which seems to be about one grain to each fourteen pounds of the patient's weight) appears likely to strengthen the natural first line of defence. It is at this period, when the invaders are comparatively few in numbers, that a remedy which will quickly increase phagocytic power is of the greatest service and may possibly abort the attack. Even if the employment of quinine and of morphine fails to achieve complete success its use nevertheless postpones the immediate danger and affords time to bring into play more exact methods of serum or vaccine treatment.

A Bad Case of Strangulated Omental Hernia, with Very Few Symptoms. A. Z. C. Cressy.
A Case of Tetanus Treated by Chloretone. R. A. Hobbs. With a note by E. W. Sheaf.

Diaphragmatic Herniae.—A. Keith states that herniae through the diaphragm fall into two groups, the congenital and the acquired, the former being to the latter in a series of 34 cases as 26:8. The congenital herniae are chiefly those which occur at the unclosed pleuroperitoneal passages (21 cases), the others being formed (5 cases) by developmental extrusions of the abdominal viscera, chiefly liver, through the septum tranversum. In a certain proportion of congenital cases it appears possible to adopt surgical measures for the cure of the condition.

Typhoid Perforations.—G. E. Armstrong states that the pathogenesis of typhoid perforation is the coagulation necrosis of the lymphoid tissue opposite the mesenteric attachment, where the blood supply is poor. The problem before the profession is to lower the mortality rate; therefore, the first question is, What are the causes of the high death-rate in typhoid perforation? They are: 1. The condition of the patient at the time of its occurrence. Towards the removal of this cause one can do little, although it adds greatly to the difficulties of recognition. 2. The difficulties in diagnosis. This is almost the whole question at the present time. Once perforation has occurred, one may agree pretty well on the remedy to be applied and on most of the details of carrying that remedy into effect; but how to make the diagnosis—that is the question above all others in typhoid perforation. This condition is not announced by definite and distinct symptoms. One must clearly appreciate the difference between perforation and peritonitis. The absence of harmony in symptoms is a diagnostic point in favor of perforation. The change for the worse in the patient is often out of all proportion to the abdominal symptoms. Abdominal pain is the danger signal; with this there are tenderness, rigidity, and muscle spasm. One should not conclude that there is no tenderness present without a rectal examination. Later on, when peritonitis has developed, careful inspection may reveal lessened abdominal movement during respiration. If perforation occurs into the free peritoneal cavity the patient cannot recover unless the opening is closed. The only perforations that do not prove fatal unless closed by the surgeon are those occurring in the large bowel and between the layers of the mesentery. It has been demonstrated at the operating table that a small perforation in the small intestine may be temporarily closed by omentum, but that such cases would have recovered if they had been left alone is open to very serious doubt.

Bacillus Coli Infections.—J. S. Dick reaches the following conclusions: 1. These infections are commoner and more important than the average textbook would lead one to believe. 2. They vary within wide limits in respect of their virulence, and therefore in respect of their clinical features. 3. Their recognition is important, not merely from the standpoint of accurate diagnosis, but also from the standpoint of efficient treatment in the severer types. 4. The slighter cases are apt to be overlooked altogether, the severer cases are apt to be misunderstood. 5. Clinical observations alone, however conscientious, are at present quite inadequate; bacteriological evidence is a *sine quâ non* of decisive diagnosis.

Diet Before Operations.—R. W. Collum states that if an operation in an otherwise healthy subject is to be performed at 9 o'clock in the morning, the patient should be left asleep, unless he awakes of his own accord, until at any rate 7.30, when he may be given his enema. Then, if he be accustomed to breakfast at about 8 o'clock, he may have a thin slice of bread and butter, or a small piece of toast, with as much tea to drink as he desires. He will then be able to settle down much more contentedly to his newspaper until the surgeon arrives. Tea is preferable to coffee, as the former is usually taken with considerably less milk than the latter. The author believes that more attention should be paid to the ordinary habits of the individual patient, in order to relieve him as far as possible from the discomforts of anesthesia He mentions definite hours for the meals (8 a.m. for breakfast, 1 p.m. for lunch, and 4 p.m. for tea) merely for the sake of convenience. If the individual patient under consideration be accustomed to take his meals at some other hours, these should be substituted for the ones indicated. An exception may be made in the case of breakfast if the patient should awake much earlier than usual on the morning of the operation. In this case, if he feels inclined for food at an earlier hour than usual, there is no objection to his having it then instead of later.

Ophthalmic School Clinics.—R. B. Hird states that school medical inspection cannot be regarded as complete unless the defective children receive the treatment they require. An alternative to treatment at the hospitals is that of holding "school clinics," and paying medical men for undertaking the work.

Submucous Resection of the Septum.—T. J. Faulkner had the opportunity of observing a case three years after operation, in which there were two points of interest: (*a*) the comparative ease with which the mucoperichondrial layers were separated from each other after nearly three years in contact—there were only a few feeble strands of fibrous tissue crossing between the two flaps; (*b*) the entire absence of any regenerated cartilage, bone, or fibrous tissue beyond the weak fibrils above mentioned. This case also illustrates the occasional impossibility of making the septum hang truly vertical in the middle line without endangering the integrity of the bridge.

Bad Prognostic Signs in Eclampsia.—W. F. Shaw points out the following three bad prognostic signs in eclampsia: 1. Small amount of albumin in the urine during the eclamptic stage. 2. A high temperature. 3. Convulsions commencing after labor.

Diastolic Blood Pressure and Cardiac Strength.—Sir Lauder Brunton describes the physiology of blood pressure and the methods of its measurement in the laboratory. Diastolic pressure has as yet received comparatively little attention, because of the difficulty of ascertaining it, yet it is a factor of great importance, because by its amount, and by the difference between it and the systolic pressure one obtains valuable data in regard to the strength of the heart and the condition of the arterioles. The two conditions that generally produce low pressure are oversmoking and commencing phthisis. Nicotine has the most extraordinary power of contracting the vessels and raising the blood pressure. A single pipe appears to raise the tension for the time being, but it seems as if tobacco, and probably also opium, cause the organism to produce antibodies, which in the intervals between taking the drug, exercise an opposed action. It is in cases of high tension that the sphygmomanometer is most useful, because by early detection of a rise in pressure, and by the adoption of proper regimen and medicines, the tension may be kept at a lower standard, and dangers which would otherwise accrue to the heart or vessels and to the brain may be avoided. In such cases, as the treatment requires to be carried on, not only for months but for years, it is advisable to interfere as little as possible with the patient's ordinary habits. The only rule in regard to diet is that the patient should take very little, if any, red meat or strong soup. He should eat slowly and masticate thoroughly. He should take neither strong tea, strong coffee, strong wines, nor strong spirits. In regard to exercise, rest should be taken for at least twenty minutes after meals, and then exercise should be taken very slowly. Sudden strain of every kind should be avoided, but moderate exercise without strain is rather beneficial. Even in patients suffering from angina pectoris, gentle exercise is useful, provided the patient will begin very slowly, and will take care neither to go too fast nor too far.

Greek Medicine in Rome.—See abstracts of articles in the *Lancet*, November 5, 1910.

Strangulated Omental Hernia.—A. Z. C. Cressy reports a case of this condition presenting symptoms of pain in the lower abdomen; tenderness over an inguinal hernia, which was hard, dull, and with no impulse; normal temperature; pulse not affected; vomiting occurring only once; bowels open even more than once a day; and the patient walking about three days out of the four during which the symptoms were manifest. One point is strongly brought out in this case, namely, when an omental hernia does get strangulated, it is certain to be fatal if not relieved, as the gangrene does not stop at the stricture, but passes on into the abdomen. The case healed by primary union and did well.

Chloretone in Tetanus.—R. A. Hobbs reports a case of tetanus occurring in a man forty-six years of age, in whom, in addition to antitetanic serum, chloretone was administered by the rectum, in doses of thirty to forty grains, with olive oil, two to three times a day. The chloretone was given when indicated by an increase in rigidity. The total amount of antitoxic serum used was 390 c. cm.; and of chloretone, 420 grains. The points specially noted are: 1. The early onset of symptoms and consequent grave prognosis. 2. A marked decrease in the rigidity was noted a definite period after the administration of chloretone, the trismus being relieved in a constant and remarkable manner. 3. The complete absence of convulsions from beginning to end of the illness. 4. The relief of trismus enabled the patient to take ample nourishment throughout and thus maintain his strength. 5. The rapid recovery of the case. The author is convinced that this man's life was saved by chloretone, although the part played by the antitetanic serum must not be disregarded.

Berliner klinische Wochenschrift.

October 31, 1910.

Diagnosis of Nasal Diphtheria in Very Young Children.—Blochmann relates a case of nasal diphtheria in a child sixteen months old. The patient appeared at first sight to have erysipelas beginning at the nasal orifices. Anterior rhinoscopy disclosed membrane and bacterial diagnosis of diphtheria was made. In diphtheria epidemics the author also examined suspects and those exposed. He found that nasal diphtheria may run an afebrile course, and that membrane may persist in the nasal fossæ for weeks, while the children remained bacilli carriers for months. These latent cases naturally differ radically from the outspoken cases of nasal diphtheria so common in nurslings, in which membrane projects from the nostrils and the right diagnosis is otherwise readily suggested. In latent or beginning cases the author evidently believes that the use of the rhinoscope is an improvement on mere swabbing out of the nose for cultural purposes. A study of the two sides may show in one, or both, areas of intense congestion preceding membrane formation, and isolated patches of the latter may be seen on the turbinals or septum. But while rhinoscopy may represent a diagnostic refinement, it hardly seems calculated to supersede the use

of the ordinary swab for diagnosis of the disease or of a nasal carrier.

New Procedure for the Demonstration of Free Acid in the Stomach.—Fuld writes mainly in the interest of diagnosis of cancer of the stomach. He speaks of the extreme frequency of the latter and the absence of HCl in three-fourths of the cases. We examine the urine to discover the presence or absence of two great folk-maladies; hence one should be equally prompt to make routine tests for free acid in the stomach. In the author's method the patient takes a trial breakfast, and an hour later a swallow of sodium solution. The effervescence may be distinctly heard by the ear placed over the stomach, if acid is present. Hence absence of effervescing sounds suggests a possibility of cancer. When enough gas has been produced by the combination of gastric acid and swallowed soda, the percussion note over the stomach becomes correspondingly modified. It is necessary to control every case by auscultation and percussion before the soda is drunk. Further evidence of gas formation in the stomach may be shown by the fluoroscope. The author discusses the various competitive and analogous tests, but his real service lies less in devising a new test than in his insistence on routine examination for HCl in elderly men out of health from any cause, or even in special cases of men who do not seek medical relief. All tests thus advocated lack the simplicity of urinary tests and of others adapted to ordinary life insurance examinations, such as a routine digital examination of the rectum. But if the policy were a very large one, a test like Fuld's would not be out of place, and absence of free acid would perhaps justify a postponement.

Iodine Cachexia in Arteriosclerosis.—Emmerich refers to the extensive use of iodine in arteriosclerosis and to the great number of iodine preparations on the market to supply this indication. As the drugs must be given for long periods we should be hearing constantly of cases of iodism either as an expression of supersensitiveness or as the socalled iodine cachexia. One very popular proprietary substance is able to produce a very definite type of the latter. The patient emaciates and weakens rapidly and may suffer from insomnia. The symptoms, however, are precisely those common to the disease, and hence the remedy would perhaps be pushed to greater lengths, or dropped as inert. In any case iodism would not be suspected. The author has learned that the iodine was really responsible for the exaggeration of the symptoms by suspending the preparation and watching the development of the case. After an interval perhaps extended the patient would recover his original status. As some of these patented remedies contain a very large percentage of iodine the author prefers the original blood-salts serum with small doses of some iodide.

Münchener medizinische Wochenschrift.

October 25 and November 1, 1910.

Peculiar Case of Fish Poisoning.—Strauss relates the instance of a man, late in his fifties, who partook of some sardines which had remained for a time in the original tin. Patient recalled the fact that the inside of the box cover had turned black. Nothing seems to have transpired for three days, when overnight the patient broke out with a scarlatiniform eruption and angina. One day later violent colicky pains developed, along with constipation, meteorism, anorexia, insomnia, and so on. For three weeks all symptoms persisted. The exanthem then died out, leaving the condition otherwise unchanged. Thereupon a complete left facial paralysis set in, which soon vanished and was succeeded by a right facial paralysis which persisted for several weeks. Patient in the meanwhile complained of dyspnea, on exertion, general asthenia, and marasmus with emaciation. Patient made a slow recovery. The facial paralysis, which remained throughout the most decisive symptom, seems to have been wholly peripheral.

Röntgen Rays in Dermatology.—Löwenberg states that with fourteen years' experience one should be able to lay down the indications and contraindications for this resource in this class of cases. Most of the bad effects on record have affected the Röntgen specialist and his assistants, few having affected the patient. In the meantime the specialist has learned to graduate the dosage; and since 1902 Holzknecht has so mastered this difficulty that the use of the rays is relatively safe for operator and patient alike. Others have taken advantage of this improvement so that by to-day the radiometer of Sabourand and Noiré has been used by the author and his colleagues 3,000 times with relative safety. This instrument is practically a dosimeter, and through its use one reaches an erythema dose which serves as a maximum. One-half or one-fourth of this dose may often effect the desired result. Recent attempts in the sphere of dosimetry appear to add nothing to the Sabourand procedure. Many dermatologists continue to use the rays indiscriminately and without regard to dosage, and failures in depilation and in the reduction of tumors are ascribed to the inefficiency of the treatment, while on the other hand burns are common. One must not, however, fail to take notice of the Röntgen idiosyncrasy or supersensitiveness, which would be constantly in apparent evidence without dosimetry. Such an idiosyncrasy has been denied outright by some and pronounced very infrequent by others. The authors have not seen a single case in 3,000 radiations. Yet the profession and public are always fearful of such supersensitiveness. One should know all that is to be learned of the power of the rays. It appears, for example, that young animals may be stunted in growth by a certain amount of radiation, and, indeed, the known inhibitory action of the rays on cellular activity might justify such a surmise. But apparently human tissues, being more highly organized, are more resistant in these respects. Much depends, naturally, on the right of certain cells to survive. Thus we know that in hypertrichosis the rays are able to destroy certain hair papillæ while sparing the skin at large. Diseases, which by their very nature tend to destroy the hair papillæ, are naturally assisted by this resource, and the old time tedious epilation has been superseded, or if the latter resource is employed it is simple and painless. There is no evidence that the *x*-rays are actually germicidal—hence in all diseases caused by living organisms parasiticides must be employed. The removal of pronounced hypertrichosis, as in bearded women, does not lie within the province of the rays. When used in maximal doses they tend to cause ugly telangiectasias and scars. The rays seem to be efficacious in highly chronic and localized eczema. In fact, they should supersede all other treatments in certain local varieties of the disease. Psoriasis tends to yield to mild radiation, even in one-quarter maximal dose, but relapses occur with the usual frequency. The same is true of the results of radiation for other skin diseases. It is the record of other means of relief for these conditions. Some improve, some hold their own, and others recede under the treatment. When the authors' summary is digested one finds nothing new. Clearly if Röntgen rays give special results in dermatology, the method of demonstrating them is open to all the objections of any new treatment.

Causes of Sudden Changes in Blood Pressure.—Zabel, in a paper with this title, writes incidentally of the great constancy of blood pressure in many individuals. These might be termed normal subjects were it not for the fact that the merely nervous, who can hardly be termed abnormal, exhibit sudden and notable changes. The extreme type of these is seen in hystericals and neurasthenics. But a liability of the blood and vascular system is more deeply seated than an unstable nervous system, although it

often coexists with, or depends on, the latter. Extensive studies show differences in the people of different races or countries. Besides racial divergence, there is individual divergence. This is often seen only in connection with a line of questioning, certain inquiries causing a change in blood pressure. Despite the psychic factor thus placed in evidence it can hardly be said that such subjects are neuropaths or unduly excitable. Rather is it the effort to recollect that produces the alteration. Men who have been dissipating or who are in an irritable frame of mind show special liability for the time being, although generally normal. So also do women during menstruation. Change of pressure may be produced reflexly in many ways. Despite the abundance of detail the author is very conservative in his conclusions. He evidently believes that we must test and retest scores of times to establish actual facts, otherwise we are dealing with impressions only.

The Ehrlich-Hata Remedy and Filariasis.—Reichmann describes a filarial malady which is, if not unknown to parasitologists, at least uncommon. The case occurred in Jena, and had no exotic element. It was, however, rendered obscure by a recent syphilitic infection, which was perhaps responsible for some of the symptoms, although the patient had received proper and timely treatment (Hg). A positive Wassermann reaction accompanied the filariasis. The parasite appeared to attack the pleura and kidneys, so that the symptoms were those of both conditions. Increased intrathoracic pressure, anasarca, oliguria, etc., were present. The earlier symptoms, however, could only be likened to intestinal colic, which fact suggested that some general infection had occurred by the intestinal route. As soon as the positive Wassermann reaction was obtained an injection of 606 was given with astonishing success. Before that period a filarial parasite had been cultivated from a pleural puncture fluid. All attempts to find them in the blood and urine failed. The injection of 606 appeared to have destroyed the parasites. As already stated the filaria was not recognized as corresponding to any known species. Hence it may be claimed that it was not the cause of the severe disease. Whether the Ehrlich-Hata remedy possesses filaricidal powers, or whether it acted on a totally unrecognizable remnant of syphilis, the result was most remarkable.

Polythelia and Axillary Milk Glands.—Höfstatter gives a brief but fairly complete monographic study of this subject. Polythelia represents a condition of supernumerary nipples, while the axillary milk glands seem to be supernumerary mammæ. According to some authorities, however, they are merely exaggerated axillary sweat-glands. Supernumerary or accessory nipples are chiefly regarded as due to atavism. If we include slightly developed cases polythelia is fairly common, not only in women, but in men. Accessory nipples are often overlooked or confounded with other conditions, such as moles. The superfluous nipple, while only appearing as such, may in some cases be found to be connected with the rudiments of a mammary gland. This being admitted the proximity of the axilla to the mamma might imply that the axillary milk glands are merely a form of polythelia. But all the evidence seems to point in the opposite direction. A "deadly parallel" might be drawn up to show the radical dissimilarity of the two conditions. In addition to what we have already stated, it should be enough to state that the axillary milk glands do not represent a congenital condition, but are acquired in the course of gestation. They are moreover so rare that we do not usually find them mentioned and illustrated in obstetrical works.

Deutsche medizinische Wochenschrift.

November 3, 1910.

Significance of Quinquaud's Finger Crepitation.—Some years ago Quinquaud announced a new sign of abuse of alcohol, which, had it been proved trustworthy, would have been of great value in detecting secret drinkers. A considerable literature sprang up, which gave the subject a manysided aspect. As might have been expected this sign was soon found to denote general neuropathy instead of alcoholism, and was especially marked in tabes dorsalis, hysteria, and neurasthenia. When first announced, the alleged sign was given as a tremor of the fingers produced by pressing together with considerable force the tips of the digits of the two hands, or by any similar pressure, as of the patient's finger tips against those of the physician. A true crepitus of the phalanges or tendon sheaths was later exploited as an integral part of the test, while certain autopsy findings were brought out. It should be well known to the general practitioner that the hand of the heavy and steady drinker does not tremble except in cases of recovery from excessive debauch or in general withdrawal conditions. On the other hand, the born neuropathic subject may show tremor in childhood and through life. Tremor of the fingers in the simple sense of the term, unburdened with consideration of special diseases, is a simple appanage of constitutional nervousness. It is natural that, if such a subject is submitted to Quinquaud's test, he may give a positive result, but this does not mean that he abuses alcoholics. He may or may not, as the case may be. If, being neuropathic, he further abuses alcohol we naturally see the vicious circle in operation and a very pronounced reaction to the test. But to possess any diagnostic value whatever, the test should apply to the non-neurotic alcoholic who drinks for Epicurean reasons, or to be in the fashion, or for any one of a dozen reasons which do not involve a neuropathic craving. The author is radically opposed to Quinquaud's teaching. All sorts of theories have been advanced to signify that alcohol can cause structural alteration in some of the numerous tissues which go to make up the digits. In a few cases which have come to autopsy the subjects were tuberculous and might naturally have been expected to present some evidences of osteoarthropathia pulmonum. As a matter of fact, however, there were in these cases no pathological findings whatever. To come back to the crepitation sounds heard by auscultation over the digits; these or something much like them have been placed on record for neuropathic disorders in general. The phenomena, such as they are, are purely neuropathic and are only alcoholic because of the tendency of the neuropath to drink to excess. Given the neuropathic substratum, these phenomena could be called into existence by any kind of mental excitement.

Bacillus Coli Outside of the Body.—The *Bacillus coli* is a type of microorganism alleged to be, according to circumstances, the most indifferent saprophyte or the cause of most virulent diseases. In this respect it agrees with other pyogenic germs which are in abundant evidence outside the body, the exclusion of which by Listerism has marked such an advance in the healing art. The *B. coli* differs in some respects from the other familiars of mankind in that it is an intestinal parasite and one therefore specially likely to be conveyed to the host by food and drink. It is generally known that the *B. coli* appears to be able to set up almost any kind of enteric malady if its virulence is sufficiently pronounced. Diseases which would pass clinically for typhoid, cholera, and dysentery may have no other source. Neumann has made a special study of this germ from the outside—that is, from its incidence in common food and drink. He concludes that while the *B. coli* may not be the exciting cause of certain diseases its presence may serve as an "indicator." That is, in the height of an epidemic of enteric disease, he finds an undue presence of the *B. coli* on the ordinary articles of food use. In examining the rations of hospital dietaries he finds the germ on bread and rolls, butter and milk, and especially on fruit (with the exception of grapes).

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Fourth Annual Meeting, Held at Newburgh, October 27, 1910.

DR. THEODORE MILLS OF MIDDLETOWN IN THE CHAIR.

Election of Officers.—*President,* Dr. W. Stanton Gleason of Newburgh; *First Vice-President,* Dr. Daniel Bailey Hardenberg of Middletown; *Secretary,* Dr. Charles Ellery Denison of New York; *Treasurer,* Dr. James E. Sadlier of Poughkeepsie. Place of meeting, Tuxedo Park.

President's Address.—Dr. T. D. MILLS of Middletown discussed the relations of the medical profession to the community, the State, and the nation. He stated that the medical man did not occupy the position in the community to which his education and training entitled him. The physician was himself largely responsible for the existing order of things. Instead of having committees at work interviewing legislators, physicians should form a part of our legislative bodies. If this were brought about there would be less money wasted on barge canals and more spent on the improvement of our water supplies and the purification of our rivers; pure food laws would be made more stringent and the mortality from typhoid fever and other diseases would be reduced. Sanitation on the farm as well as in our cities would be improved and the general health of the people conserved.

Hints for the General Practitioner on the Nature, Etiology, and Early Diagnosis of Insanity.—Dr. CARLOS F. MACDONALD of Central Valley read this paper. (To be published in the MEDICAL RECORD.)

Sacral Suspension of the Uterus.—Dr. JOHN VAN DOREN YOUNG of New York City read this paper. He referred to a former paper on this subject in which he called attention to the importance of the uterosacral ligaments in uterine suspension and to his report of results in 100 operations for sacral suspension, covering his entire experience with the operation during ten years. He stated that he had since performed the operation 27 times and desired to give his experience during the last year and a half. He had concluded years ago that the recognized operations of ventral suspension, ventral fixation, the Alexander operation, all operations, in fact, on round or broad ligaments, as well as vaginal fixation and the Gillain operation failed to consider the relation between the under surface of the second sacral vertebra and the lower segment of the uterus. When this relation was taken into consideration it must be with the patient in the standing position. It then became apparent that the only rational method for holding the uterus in place was by suspension and not by support and consequently the uterosacral ligaments became of prime interest. He called particular attention to the fact that the levator ani, the perineum, and all the pelvic floor muscles had nothing whatever to do with uterine suspension except indirectly when tears existed. Dr. Young showed that the sacral ligaments were the only supporting ligaments of the uterus. The broad ligaments were strong factors in preventing lateral displacement, and indirectly helped to support the weight of the uterus, but their location and attachments were not such as to prevent retroversion or prolapse. The round ligaments acted only as guy ropes in holding the fundus well forward and keeping the intraabdominal pressure upon the posterior surface of the uterus. In performing this operation the incision should be made low, extending down to the symphysis and varying in length according to the thickness of the abdominal wall; two and one-half inches was usually an ample length. The patient was then placed in the extreme Trendelenburg position and it was a material help to have the body held in position by shoulder crutches, and not by flexion of the legs. This brought the posterior portion of the true pelvis into view. The intestines were held up from the true and false pelvis by abdominal pads wet in hot saline. The uterus was then lifted up and held in position by a volsellum, the ovaries and tubes inspected, and the necessary plastic work done. After the uterus was free the operator examined Douglas' cul-de-sac and located the origin of the uterosacral ligaments from the corporocervical junction. The ligament opposite the side upon which the operator stood should first be operated upon. The ligament was drawn upward, inward, and forward; the weblike relaxed ligament would be seen pulling out from the side of the pelvis; this should be grasped at a point three-quarters of the distance from the uterine end of the ligament to its sacral insertion. This gave the operator two fixed points to approximate. The point at which the ligament should be sewn to the uterus could be easily gauged. There was more danger of not shortening the ligament enough than of shortening it too much. However, if there was too great strain on the sutures they might yield. The next step was to grasp the relaxed portion of the ligament at a distance midway between the second clamp and the uterine origin of the ligament by a third French clamp. A suture of No. 2 chromic catgut was passed through the origin of the ligament and through enough uterine tissue to form a firm hold. This stitch was tied, the other end grasped by an artery clamp, and the needle again passed through the base of the ligament. The first clamp attached to the ligament was then removed and the second clamp with its reduplicated fold of ligament was brought upward, forward, and inward to a point where the needle which had just been passed through the base of the ligament might be carried through both layers of the reduplicated fold of the ligament. This reduplicated fold of the ligament was held close to the uterus by clamp No. 2 during the process of insertion of the needle and placing of the second knot. The second clamp should then be removed allowing the reduplicated fold of the ligament to be brought closely down to the base of the ligament. Much of the success of the operation depended upon the placing of this stitch as that was really the point of anchorage of the ligament. Clamp No. 3 was then drawn upward, outward, and backward, showing the three layers, and a stitch was inserted midway between the clamp and the stitch already in place A third stitch was placed through the two layers of the ligament at clamp No. 3 and through the sacral segment of the ligament high enough to bring the three folds of the ligament taut. Two stitches might be placed between those already in place. Care should be taken that the ureter was not in the folds of the ligament or in danger of damage. The uterus was held either by a volsellum put into the uterine body just posterior to the median line of the fundus, or the lower segment of the uterus might be drawn up by the first stitch. This procedure was repeated on the opposite side. In this series he had had three deliveries which were normal in every particular. The results of these operations had been most gratifying and had fully justified his expectations.

DR. RALPH WALDO of New York said that Dr. Young's paper dealt in a very masterly way with a subject that was most important. Only a few operators had appreciated the rôle that the uterosacral ligaments played in the support of the uterus and in its maintenance in the normal anteverted position. The uterosacral ligaments were not merely folds of peritoneum but they were true ligaments composed of yellow elastic and muscular tissue, as well as peritoneum, and with the broad ligaments were the main support of the uterus. The round ligaments acted as guy-ropes only. Several operators had shortened the uterosacral ligaments through the vaginal route but in many in-

stances the operation was very difficult if not impossible to perform in a satisfactory manner. There was another way that these ligaments had been shortened by the abdominal route, namely, by stitching the opposite ligaments together commencing at their attachment to the uterus and extending as far as one could without constricting the rectum. The method advocated by Dr. Young was very ingenious and suited perfectly the indications.

County Hospital Care for the Tuberculous.—Dr. D. B. Hardenberg of Middletown, N. Y., presented this paper, which consisted in a plea for the establishment of county hospitals for the care of tuberculous patients. He read the law of the State of New York which went into effect on May 13, 1909, providing for the establishment of such hospitals, and recalled the fact that Ontario County had been the first to take advantage of this act. Special committees had been appointed by the boards of supervisors of Orange, Oswego, Onondaga, Monroe, Cattaraugus, Cayuga, and Schenectady counties, to study the subject and report. Such a hospital had recently been donated to Newburgh by ex-Governor Odell and the citizens of Elmira had contributed a fully equipped hospital for patients from Elmira and Chemung County. The utility of the hospital in eradicating tuberculosis had general recognition. Newsholme of England had shown that in nearly every instance where contagious diseases had been brought under control it had been due to hospital care of those having the disease. He also showed that those cities and countries having a large hospital provision for tuberculosis had a rapidly falling death rate from that disease, while those having little hospital provision showed little or no reduction in such mortality. It had been estimated that the economic loss to the State of New York was $70,000,000 annually from tuberculosis. The cost of providing suitable accommodations for the care of this class of sufferers would be small in comparison to this. It had been estimated that the initial cost of construction for such hospitals would be at a minimum rate of $500 for each patient and that maintenance would be at the rate of $1.25 per day per patient. The site of an institution of this kind should be sufficiently removed from a center of population to insure air free from dust and smoke, but at the same time readily accessible by railroad or trolley. If possible an altitude of from twelve to eighteen hundred feet should be secured. The soil should be sandy and there should be a good water supply. A southern exposure and protection from inclement winds were also desirable. There should be sufficient land to provide light occupation to the patients and to provide to some extent for the table. The speaker described two styles of building, one for incipient cases and one for those more advanced. The depreciation in farm lands made it possible to acquire sites at reasonable figures and frequently a commodious farmhouse could easily be altered so as to fulfill all the requirements of a small sanatorium.

Dr. Hardenberg reviewed the benefits of sanatorium treatment both as it benefited the patient and as a means of educating the people and urged the establishment of such hospitals in the counties of this district.

Dr. W. Stanton Gleason of Newburgh said that the approximate cost of maintenance for one patient in the tuberculosis hospital was but one dollar. He told of what was being done in the State and what kind of buildings were needed for the proper care of the tuberculous patient. There had been forcibly impressed upon them the necessity for providing some means of combating this disease which was so prevalent; the necessity for the protection of others against this disease was more urgent than against any other form of communicable disease. In Newburgh through the courtesy of Mr. Odell there had been established a tuberculosis sanatorium as a memorial to his son who died a few years ago. The impetus given in this cause by this act was very commendable. Mr. Odell had given a remarkably good building for this purpose, one which was the nucleus of future development. The building was not yet finished. At present they were following out the best methods of care for these patients as far as they could by means of tent life. They had now eight or ten patients under their care. Mr. Odell said he would extend the building to meet the requirements of the county at a pro rata tax of one dollar per patient. The following resolution was presented by Dr. Gleason:

Whereas, Ex-Gov. B. Odell, Jr., has generously donated land on West street in this city and has built thereon a tuberculosis hospital, and has properly equipped the same for the care and treatment of persons suffering from this disease, and has already opened said hospital for the reception of patients, therefore,

Resolved, That the Board of Health of Newburgh does hereby agree to pay the estimated cost of not more than one dollar per day for each patient received or admitted to the said hospital upon a certification of the health officers. When the bills were drawn by the said health officers and the Auditing Committee of the Board of Health had certified them, the same was a charge against the City of Newburgh.

Embolism and Thrombosis of the Mesenteric Vessels.—Dr. Edward C. Thompson of Newburgh presented this paper, the purpose of which, he stated, was to call attention to a subject which had received little notice by American writers, and to add an interesting case to the comparatively few reported in the literature. He felt convinced that there were more cases of occlusion of the mesenteric vessels than the reports would seem to indicate. In 1904 Jackson, Porter and Quimby had collected 214 cases of embolism or thrombosis of the mesenteric vessels and in reviewing these cases found that 47 had been operated upon with a mortality of 94 per cent. Of the reported cases a large proportion were due to embolism of the superior mesenteric artery or one of its branches. The source of the embolism had usually been the heart, atheroma and general arteriosclerosis having been concomitant conditions, so that the etiology was identical with that of the coexisting endarteritis. There might be a spontaneous closure of the mesenteric artery due to local changes. In a few cases the closure was due to traumatic thrombosis. Thrombosis of the mesenteric veins was of less frequent occurrence than thrombosis of the arteries. The condition was often metastatic and due to coexisting infection in the abdominal cavity. Dr. Thompson reviewed the anatomy of the condition and from an analysis of the cases at his disposal found that the ileum had been most frequently involved. This might be because of the lower degree of its functional activity. The anatomical appearance of the intestine and mesentery, after occlusion of the vessels, varied from a simple hyperemia to a complete hemorrhagic infarction, depending on the site of the occlusion, its extent and the relief afforded by the compensatory circulation. If the infarction was complete and lasted long enough the appearance of the intestine and mesentery was practically that of moist gangrene. The walls of the intestine were thickened, infiltrated with blood, and presented a mott'ed, dark red, or black appearance. The peritoneum was lusterless and covered with a fibrinous exudate, or after the access of pus germs, it became the site of a purulent inflammation. The mesentery was infiltrated with blood and might be necrotic in patches. The glands were swollen and hemorrhagic. Bacteria sooner or later found entrance, usually the colon bacillus, and a purulent peritonitis was engrafted on the local condition. The clinical course of the occlusion of the superior mesenteric artery or one of its main branches might give either an acute or chronic symptom complex. This, however, was not always the same, and the matter of diagnosis was usually difficult. In

one group of cases the symptoms of an acute obstruction predominated; in another group diarrhea, hemorrhages from the bowels, and vomiting of blood were most significant, and here the diagnosis was liable to present difficulty. The blood might not be present in the vomitus or feces. The objective symptoms which examination of the abdomen presented together with the accelerated, weak pulse and the facial expression which went with shock, assisted in making a picture which had to be carefully considered; conclusions were reached by exclusion. Elliott had resected the longest extent of gut for a mesenteric thrombosis, 48 inches, with recovery and the author believed that his case, with a resection of 40 inches, came next. Treatment other than operation was too theoretical for consideration. Early operation gave some chance for recovery, but even here there was difficulty in knowing how much of the gut to resect as the extent of the infection might be still undetermined. For this reason Jackson and Quimby recommended not making an immediate anastomosis after resection, but bringing the gut well out of the wound with a liberal sound margin left at both ends and, after resection, fixing the open end in the wound well walled off with pads. The judgment of the operator would probably determine this point.

The case which Dr. Thompson reported was that of a boy, fifteen years of age, with nothing of importance in family or personal history. His present illness began on May 30, 1910, when he was struck with a ball in the stomach. On the night of June 3 he awoke with severe abdominal pains and nausea and later vomited. He was rather cyanotic with feeble accelerated pulse, but in view of the fact that he had eaten rather imprudently the night before he was given calomel. An ice bag was applied to the stomach and all nourishment stopped. The symptoms continued but there were no hemorrhages from the bowels or the mouth. On the evening of June 4 he was sent to the hospital. His rectal temperature was 98.4°, pulse 84. Towards the morning of June 5 the pulse became more rapid and respiration slightly accelerated. The abdomen was rigid and tender to the right of the pubis. There was no evidence of fluid on percussion. The facies was indicative of shock. The urinary analysis was negative. An incision was made in the median line of the abdomen and a small quantity of serosanguineous fluid was found in the peritoneal cavity. Several coils of ileum were found deeply cyanosed with a rather sharp line of demarkation at either extremity; they were covered with a lusterless peritoneum. The mesentery was thickened, succulent, hemorrhagic in spots, and, on incision, a small quantity of blood exuded from the vessels. There was no evidence of internal strangulation. The whole area was wedge-shaped with the apex near the root of the mesentery. Forty inches was resected with an end-to-end anastomosis with a Murphy button. The mucous membrane of the excised bowel was deeply cyanosed, but intact. The patient made a good recovery, and passed the Murphy button on July 17. A slight diarrhea persisted but was gradually disappearing. This was probably due to the lessened area of absorption presented by the intestines due to the large amount of intestine resected. The age of the boy, the exclusion of any known source for embolism, the acute onset of the symptoms following trauma, the definite wedge-shaped area of infection, the non-pulsating arteries, and the condition of the veins substantiated the diagnosis of thrombosis of the superior mesenteric artery due to trauma.

Rabies and Methods of Its Control in New York State.—Dr. J. F. DeVine of Goshen, N. Y., Chief Veterinarian, New York State, read this paper. He reviewed the history of the disease, showing that it was known in ancient times, having been referred to by Aristotle, Virgil, Horace, Plutarch, and Ovid, and expressed regret that the specific character of the affection was looked upon with doubt by many laymen and even by some physicians and veterinarians just because the bacteriologist had been unable to isolate and point out the specific organism which caused the disease. The organism was probably one of the ultra-microscopical organisms, yet experimental inoculation had proved its specific character beyond a doubt. The specific virus was present in the saliva of animals affected with rabies and was transmitted to other animals and persons usually by a bite; but it might be transmitted through the saliva without a bite, if there was an abrasion, in the same manner as any other inoculable disease. Rabid virulence had been observed also in the suprarenal capsules, in the urine, spermatic fluid, and lymph. The possibility of its being transmitted through the placenta seems to have been established though it did not seem possible to transmit it through the digestive tract. The apparent lack of danger from milk or a product which might be manufactured therefrom was a point of knowledge of particular advantage. The climatic conditions or the time of year had little or no influence on the disease, the idea that the disease was more prevalent during dog days being without any confirmation. The period of incubation was very uncertain; it had been produced by inoculation of fixed virus in a rabbit in six days, though in other instances it had extended to a year or more. The usual period, however, was from three to six weeks. The location and character of the bite in the human family had been found to influence materially the period of incubation. Since it was pretty well agreed that the virus traveled along the course of the nerves, rather than by means of the blood current, the nearer the point of inoculation was to the nerve centers the shorter the period of incubation. The more severe the bite or tear the surer the infection and the shorter the period of incubation. Two forms of the disease were recognized, the furious and the dumb or paralytic. The symptoms of the first stage were a decided change in disposition, morbid appetite, searching and scratching about, licking cold stone or metal, gnawing at the point of inoculation, hideous howling, baying at the moon, melancholy, hopeless expression of the countenance, without, perhaps exhibiting any disposition to bite. There might also be a change in voice. The idea that a dog in this condition avoided water was erroneous. The second or maniacal stage was ushered in by more pronounced manifestations of these symptoms, all becoming greatly exaggerated. A pretty reliable test at this stage was to bring another dog into the presence of the infected animal, which was quite apt to arouse the animal to a fury. The rabid dog seemed to have a preference for biting dogs rather than other animals or human beings. It was even probable that if in reach of its master's voice its actions could be controlled to a limited degree, depending upon the discipline to which the dog had been accustomed. The premonitory and maniacal stages might consume from two to five days and in the course of a day or two more the disease advanced into general paralysis and death. In some cases the preliminary furious stage was omitted and the disease tended to immediate prostration, weakness, dullness, and stupor. Paralysis of the masseter muscles and dropping of the lower jaw seemed to be the most notable symptom after the first stage. It would be seen from these symptoms that the dog which had acted perfectly well and suddenly acted strangely and fell down, frothing at the mouth, etc., was not the mad dog, but was apt to be affected with epilepsy or some benign complaint. It was important to watch with care the strange action of any and every dog in any district where rabies was present. In rabies there were no absolutely characteristic post-mortem findings. If the mucous membrane of the stomach was inflamed and foreign bodies were present, while food was absent and there was an authentic history, the indications were that the animal had died from rabies. A negative postmortem with a history of rabies

was always suspicious. In laboratory diagnosis microscopical examination had largely superseded animal inoculation. As to methods of control, the only one of known merit to-day was confinement and seclusion or muzzling the dogs in the exposed territory. Statistics furnished by Great Britain showed how effective muzzling was. A study of these figures showed that from 1895 to 1899 the number of cases had been reduced from 672 to nine and at the present time the disease was said to be entirely stamped out. Dr. DeVine described the methods used for the control of rabies in New York State and read portions of the Agricultural Law bearing on this subject. One point upon which he advised positively was that in case a person was bitten by a dog that to all appearances was normal, instead of killing the dog immediately, as was frequently done it was advisable to have the dog confined under close observation for twelve days. If at the end of that time no symptoms of rabies were exhibited, the person bitten need have no apprehension of the bite causing the disease. The saliva had never been found to be virulent for more than eight days prior to the development of symptoms in the dog. No known case was on record where a human being had developed rabies when this precaution had been taken. If at any time during this period symptoms developed the dog was immediately killed, and the brain promptly sent for examination. If the dog that developed symptoms had been killed before this occurred the examination might have been negative and animal inoculation would then be necessary, a process which meant two weeks delay. The most positive results were obtained with rapid methods of diagnosis only when symptoms had developed or the dog had died naturally. Negri bodies were present much earlier than changes in the ganglia, still the failure to find Negri bodies in the brain of a dog that had not developed symptoms might be misleading. It was essential that the brain should reach the laboratory in a condition fit for rapid diagnosis. The animal should not be shot in the head nor the brain removed carelessly. In cold weather the safest way was to cut off the head and forward it *in toto* to the laboratory. The most satisfactory method was to remove the brain carefully and put it in a jar containing pure commercial glycerine, sufficient to entirely immerse the brain. The container should be packed in a box and sent to New York State Veterinary College at Ithaca. Examinations were made without charge, which was an advantage not appreciated as it should be. Statistics showed that for the past two or three years New York State had suffered from a severe epidemic of rabies and that if they were to stamp out this disease as had been done in other countries they would have to cooperate and follow the system that had been used in countries that had handled the matter successfully.

The Rewards of the Obscure Physician.—Dr. Merton J. Sanford of Suffern, N. Y., read this paper in which he said that it was customary on occasions of this kind to discuss the duties of the physician to the public and diseases in all their forms, but he thought it well to occasionally discuss the duties of the community to the physician and the diseases of the physician. He asked to what end the great army of physicians were plodding, grinding struggling? For what were they sacrificing leisure, privacy and even life itself? Business was not the average physician's strong point nor wealth his reward. The physician who became great was even more rare than he who became wealthy. A study of history seemed to show that in many instances great men lived at a time when their respective work was imminent. Their success depended upon their ability to adapt known principles to new purposes. The discovery of the blood was not the work of one man but of thousands of hard working, self-denying, unknown men. Each added his mite to the great work. Harvey completed the task and each one breathed the breath of a conqueror. Each cheered the name of Harvey, for it stood for his own victory. Had it not been for this unknown element to what would the proof have amounted? The same was true of many other discoveries. Truth was always welcome to an Æsculapian. This was one of the physician's most marked characteristics. With renewed vigor the new principle was elaborated, utilized, and practised and its proven merits scattered broadcast. This was the best test of the true doctor. This it was that distinguished the physician from the commercial worker. The ordinary doctor, unheralded and unknown, could not do the work of the great man but he did as great a work in another way. He had learned how in emergencies to make the most of what happened to be at hand, and his work was as imperative to humanity and deserved as much admiration as the skill that distinguished the name of the great. Medicine worked a radical change in one's attitude toward the community. The more the physician studied man the more he became differentiated from him. The physician was forced to know the exposed character and his former social equality and harmony had been disturbed. Medicine had disqualified him somewhat as a social being, but it had made him a better judge of character, more intelligent and more charitable. His list of the community's worthy was different from that of anyone else and he was the community's most liberal giver. The physician might have isolated himself from his environment but he had gained the fellowship of his profession. There was no other society so free from veneer as a gathering of medical men. Although fraught with the keenest objectionable features the reward of the physician was adequate, but to appreciate this reward presupposed a broad mind and a self-sacrificing nature. There were thousands of good, earnest, unassuming doctors, working along in an honest matter-of-fact way, meeting every day duties and perplexities in a capable, conscientious manner. Enslaved to their profession they were oblivious to everything save its interests. Thoughts of fame, glory or wealth never diverted them. Their keenest satisfaction was in the thought that pain had been stopped, or a life prolonged. They were men adding a large share to the advancement of humanity and medicine. Their reward was the reward of the unselfish—a reward that could not be stolen.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 3, 1910.

The President, Dr. John A. Wyeth, in the Chair.

Committee on Alcohol.—Dr. John H. Huddleston, the Secretary, announced that the Committee of Fifty had been appointed to study the subject of alcohol in the City and State of New York and had consented to serve. He read the names.

Nomination of Officers.—Nominations were made to fill the following offices: President, Vice-President, Corresponding Secretary, Trustee, Chairman, Committee on Admission and Chairman, Committee on Library. The election will occur in December.

Radium and Its Application to the Treatment of Malignant Tumors.—Dr. Louis Wickham, Chief of the Department of Pathological Surgery of the Radium Institute of Paris, read this paper, which he illustrated with lantern slides. The most interesting and important aspect of radium therapeutics was the selective action of the rays. Radium played the rôle of a subtle modifying agent, which sought out those elements which were most sensitive to its action. All tissues were not suitable ground for this selective power; the most favorable were cancer, angioma, keloids, eczema, and some other diseases. The exact meaning of selective action was that a certain quantity of measured radioactivity could modify the cancerous cells and arrest their malignant evolution without producing any

modifying action on the normal cells surrounding the cancer, thus enabling a cancer to regress and disappear without producing on the surface any signs of irritation or inflammation. This selective action could work on the superficial or the deep-seated pathological tissues, the rays possessing the power of traversing them both. The determinative cause between the caustic action, which burned or destroyed, and the selective action was the quantity of rays absorbed in a given time by the tissues. If composed of slightly penetrative rays in great quantity a superficial necrosant action resulted; but let the quantity be measured and a selective action without irritation resulted. If composed of superpenetrative rays in great quantity there resulted a deeper necrosant action, but let the quantity be measured and a selective action in the deep-seated tissue without irritation resulted. Dr. Wickham showed a series of projections representing histological sections taken from a voluminous cancer of the breast where the selective action was demonstrated. In this instance the selective action was visible on fragments taken even from a depth of 9 centimeters, a depth at which it was thought until the present time that tissues could not be affected by the radium rays. The depth at which radium worked depended on the quantity of radioactivity employed, which in this case was 19 cgm. of pure radium applied for 48 hours in the same place. It was important to act simultaneously on several points of the tumor by his "cross-fire" method in order to concentrate the greatest possible quantity of rays on the points in the deep-seated tissues and to act with greater homogeneity. Projections were shown of cases in which Dr. Wickham, in collaboration with Dr. Degrais, had secured very remarkable regressions in cancer, angioma, and keloids. A study of methods for the treatment of cancer by radium had led Dr. Wickham to the following conclusions:

1. The excellence of the results could not be attained without long experience and profound knowledge of these methods, and principally of those without a great quantity of radium.

2. In the majority of cases surgery should be associated with radium. The radiotherapeutist, in the presence of a case of grave cancer, should first consult a surgeon in order that the patient might not be deprived of the prompt help of surgery. If it was difficult or impossible to operate on a case, radium could be applied in order to prepare the ground or to consolidate it. Surgery ought to be used in making the perforations, incisions, or partial extirpations which diminished the thickness of the tissues and rendered more effective the action of the radium introduced into the wounds. Surgery should also be employed in opening a way for radium through artificial orifices or for conducting tubes of radium to the tumors through the natural orifices. Under such conditions Dr. Wickham had treated cancers of the esophagus, of the neck, of the bladder, intestines, rectum, larynx, uterus, subcutaneous cancers, and deep-seated cancers, cancers of the breast, etc. Dr. Wickham related cases in each of these groups, which according to the usual theories would have succumbed within two or three months, and which were still, after one year, having their condition ameliorated. Surgery should develop through its ingenuity methods of helping in the application of radium apparatus, above all in localities which were difficult of access.

3. The tumors should be inundated by the rays and to this end the apparatus chosen should be the most powerful possible, and there should be sufficient apparatus to enable the operator to make applications at several points at the same time. If there were any skin, mucous membrane, blood vessels, or nerves to be protected, metallic screens should be placed between the apparatus and these tissues. These screens should vary in thickness in proportion to the radioactivity needed and in proportion to the power of the apparatus and the duration of the application. This was the method of filtration which Dr. Wickham had inaugurated in 1905 and which was very useful in acting at a depth without injuring the surface. On the quick of the tumors the apparatus could be employed with very light filters in order to utilize the maximum of rays.

4. Like surgery radium had neither an action on the general state, nor could it prevent relapses and metastases. This should be insisted upon in order that the term cure, which on principle should be avoided, might be attributed only to the regression of the tumor itself, so that there might be no risk of deceiving either the patients or the doctors.

5. Even thus limited radium was a valuable weapon. In the struggle against cancer they were so badly armed that any new therapeutic agent if it were in some way really effective should be taken into serious consideration. By the help that radium had brought to those suffering from cancer, it occupied a high place in the esteem of the writer and was the principal reason of the gratitude due to the discovery and scientific work of Curie, Ramsey, and Rutherford. There was no doubt but that radium had a very beneficial effect in certain cases of rebellious eczema, of keloid, flat angioma, and superficial cancers, such as those situated on bones and cartilages, those developed in scars, those surrounded by lymphatic inflammation, and cancers situated inside the nose and in the conjunctiva. These cases were especially difficult to cure by ordinary means, and here radium sometimes succeeded when other means had failed. There were three qualities of radium, perfectly distinct from one another, whose association gave radium a special and unique place. The first was a biological quality, the rays being able in certain doses to act on pathological cells by selective action, modifying these cells without having the same action on normal cells in the vicinity. The second quality of radium was that appertaining to pure physics. It consisted of a great power of penetration. The third quality was of a mechanical kind. It consisted in the possibility of concentrating in very minute apparatus a very powerful radioactivity. This diminutiveness permitted the introduction of the powerful apparatus into the depths of the tumor and into different parts of the body. The maximum usefulness of these combined qualities became evident in the treatment of malignant tumors, especially lymphadenoma, mycosis fungoidis, and giant-celled sarcoma, also in epitheliomatous and glandular growths. If a cancer was situated in a natural passage where the endoscope might be utilized radium could be brought into close contact and in this way cancers of the esophagus, the rectum, the neck of the bladder and uterus had been treated in a satisfactory way. Cancer of the uterus was one of the best grounds for radium. In breast cancer radium also did excellent work. Dr. Wickham had succeeded with some cases in which operation had been refused. Radium in its effects on cancer must be regarded merely as an agent, capable, either by itself or as an adjunct to other means, of bringing relief to the patient by stopping hemorrhage and secretions and by producing local and sometimes entire regression of the tumors; these results, of course, were temporary, but sometimes of such long duration that they succeeded not only in relieving the patient but in prolonging his life for years. Dr. Wickham said in conclusion that he had done all his work with his collaborator, Dr. Degrais. He spoke very highly of the work done in this country by Robert Abbe of New York and Williams of Boston, and in France by his colleague Dr. Dominici Taboin and many others. He referred to the works of Mr. Armet of Lisle, where radium was extracted.

Dr. Robert Abbe said that he had seen amazing results from the use of radium that had not been equaled by anything in surgery that he knew of. For instance, cases of mammary cancer with little nodules treated by laying the

radium upon the nodules with Dr. Wickham's lead film resulted in their quick disappearance without even burning the skin. He reported many cases in which the results had been remarkable, such as sarcoma, epithelioma of the face, especially in old people, etc., in which the cures had been permanent. The good results depended entirely upon the question of dosage; if the right dosage was given, the cases in almost every instance would be permanently cured. Dr. Abbe believed there was a field for the use of this agent in sarcoma and conditions which represented embryonic tissues. In spindle-celled sarcoma his results were not so good. He had seen keloids that surgeons would not touch disappear under the use of radium; they seemed simply to melt away. The penetration of tumors by means of tubes containing radium was an important factor in the cure of these cases. He had devised a celluloid tube; several of these were introduced into the tumor; one of these tubes was then withdrawn, and the radium tube inserted in its place; another dummy tube was withdrawn, and again the radium tube inserted, and so on. It was surprising to see the retrograde changes that occurred under this procedure. He believed there was a great future for the use of radium in the treatment of malignant growths. Small doses were not of much use in his experience; massive doses were required: then a period of waiting for about three months, when if necessary the dose should be repeated. This treatment applied especially to cancer of the face.

Dr. Max Einhorn called attention to his new method of catheterizing the pylorus and duodenum (see Medical Record, October 9, 1910) and how this could be utilized in applying radium to cancers situated about the pylorus.

SECTION ON MEDICINE.

Stated Meeting, Held October 18, 1910.

Dr. C. N. B. Camac in the Chair.

The evening was devoted to reports from the Columbus and Washington Heights Hospitals (medical section) and the Cornell Clinical Laboratory.

Aneurysm of the Ascending Arch of the Aorta.—Dr. Charles Henry Lewis presented this specimen. The patient was a male, forty-eight years old, an Italian. He was a constant smoker and a heavy drinker. Over two years before his admission to the hospital he noticed deep pain in the region of the right nipple; this was accompanied later by a feeling of fullness, and a throbbing sensation became very prominent. A pulsating tumor was seen on the right side between the second and fourth ribs which beat synchronously with the pulse. It was most apparent on palpation and appeared somewhat spherical in its general outline. Over it the percussion note was flat. There was no murmur nor bruit. The heart could not be located satisfactorily; the apex beat could not be felt in the usual area, but there was a diffuse throbbing like an epigastric pulsation around the junction of the cartilages of the fifth and sixth and the sternum. The liver was apparently in its normal position. He was given iodide of potassium and sent to bed. One and a half months after admission to the hospital he left with less pain and was generally improved in his subjective symptoms, but the tumor was somewhat larger. The tumor gradually increased in size, the patient got weaker and weaker, was readmitted to the hospital, and died about one year later. The case was noteworthy (1) because of the unusual location of an aneurysm of the ascending arch and (2) because of the unusual position of the heart which was apparently dragged or pushed from its position by the growing tumor.

Dr. William B. Noyes presented a specimen of a heart with a well-marked aneurysm. The autopsy was performed on October 18. The patient was a male. When dissecting the pectoral muscle, a tumor two inches in diameter was seen bulging between the fifth and sixth ribs. It was four inches to the right of the midsternal line. Upon opening this tumor a large amount of straw-colored fluid and some blood escaped. This tumor or sac communicated with the ascending arch of the aorta. The arch of the aorta was enormously dilated, occupying a space extending from the second rib to the sixth, filling the anterior part of the chest. In the aneurysmal sac was a large clot. The fifth and sixth ribs were atrophied because of the pressure of the aneurysm. The heart was somewhat enlarged, the valves normal except for some thickening of the mitral and aortic. There was a marked atheroma of the aorta. The sac of the aneurysm was about one-fourth of an inch thick, with an eroded surface. The aneurysm ended at the transverse aorta, the carotid and innominate arising from the top of the aneurysm. The descending aorta was not much enlarged, although it was atheromatous. The right lung was somewhat congested and compressed and one lobe was in a state of gray hepatization.

A Case of Bothriocephalus Latus Infection.—Dr. G. R. Satterlee reported this case, a woman forty-two years of age, born in Hungary. About five years ago she visited Hungary and upon her return to this country began to grow weak, suffer from headaches, and lose weight, but had a fairly good appetite. About six months after the onset of these symptoms profuse irregular menstruation without pain set in. These symptoms gradually increased until February, 1910, when she noticed segments of tapeworm in the stools. The blood showed an anemia amounting to 3,800,000 red blood cells, 70 per cent. hemaglobin, index 92; poikilocytes and microcytes were present. The total leucocyte count was 11,200 with 72 per cent. polynuclears, 23 per cent. lymphocytes, 1 per cent. basophiles and 4 per cent. eosinophiles. The feces were said to contain undigested muscle fibers, mucus and ova resembling those of bothriocephalus latus. The length of this parasite which was presented was one and one-half meters. The segments were broad and very numerous. The uterus opened in the center and had numerous racemose glands. The head was small and spoon-shaped and had no hooklets but a grooved sucker on the under surface. The ova were oval, about twice the size of an erythrocyte and contained yellowish yolk granules and a hood at one end containing two hooklets.

A Case of Raynaud's Disease.—Dr. Frederick F. Kosak reported this case, which came under his observation in July, 1909. The patient was a young woman whose father had tuberculosis, one sister chorea, and she herself had had the usual diseases of childhood and several attacks of malaria. On July, 1905, the right toe on her left foot began to swell, felt numb, turned purple, and became markedly flexed. After two weeks the condition disappeared. After eighteen or twenty months the three outer toes of the left foot became affected in the same way and the blueness, swelling, and numbness extended up the foot. Ulcerations between the toes and on the foot followed. The toes of the right foot then became affected, but never to the extent of the left foot. She was confined to bed but after several months recovered. In December, 1908, eight months later, she had a similar attack and came under the observation of Dr. Kosak. At this time she was anemic, had headaches, and complained of dizziness and palpitation. Her head and face showed all the signs of exophthalmic goiter. There were a systolic murmur at the base and an accentuated second aortic. The abdomen showed marked tenderness at McBurney's point and there were large bluish spots over the spines of the ileum. The arteries showed more or less general hardening. The blood pressure was 160 mm. She was put on glonoin, 1/100 of a grain every four hours and iodide of potassium, five grains

three times a day. The toes were wrapped in vaseline and boric acid. Under this treatment she gradually improved and was sent to the country. During the last fourteen months there had been no recurrences.

Three Cases of Gonorrheal Arthritis, Treated by the Gonococcus Vaccines Obtained from the Research Laboratory of the Department of Health, New York City.—Dr. G. R. Satterlee made this report, previous to which he said good results following the administration of the antigonococcus serum had been reported by Rogers, Torrey, Swinburne, Perey, Miro, Herbst, Dimirand, and others, and Shumway had recommended the use of the vaccines in gonorrheal arthritis and iritis in large doses. The ideal treatment of this affection was to attack the gonorrhea which had been carried through the system at its original focus. If this could be done early, before the joints became disorganized and the bone and cartilage attacked, good, if not perfect, joints should result. Vaccines produced an active immunity by stimulating the body to produce for itself a large amount of the immunal substance. In giving the vaccine it must be presumed that the body was not already overwhelmed by the poison of the disease. This could be taken for granted in the ordinary cases of gonorrheal arthritis.

Case I.—A woman twenty-nine years old entered the Washington Heights Hospital suffering from an acute arthritis of the left ankle. No history of gonorrhea could be obtained, but a probable diagnosis of pyosalpinx was made. The salicylates were given without any effect upon the pain. On January 8, a short time after her admission, a vaginal discharge appeared containing gonococci. On February 1, 25,000,000 gonococci were injected into the buttocks without producing any constitutional effects. On February 6, 30,000,000 bacteria were injected, and about two hours after the injection severe pains in the ankle were complained of, and also pain in the abdomen. These pains lasted about twenty-four hours. On February 10 the vaginal discharge stopped. A cystic ovary was removed, but there was no pus. On February 21, 35,000,000 bacteria were again injected and pain in the joint returned for a few hours. On February 26, 40,000,000 bacteria were injected and six hours later pain and swelling in the joint appeared and lasted for twenty-four hours. On March 2, 50,000,000 bacteria were injected and pain appeared after five hours which lasted for forty-eight hours. On March 5 the left inguinal gland was swollen, soft, and tender and there was a rise of pulse and temperature, together with paroxysmal pain. On March 7, 60,000,000 bacteria were injected and on March 13, 70,000,000 more. On March 18 the patient had no pain, was able to walk, and was discharged as cured except for stiffness in the joints.

Case II.—This patient was a woman thirty-five years of age and single, whose family and personal history were good. She had had an attack of leucorrhea about a year ago just before the present attack of joint trouble began. In this case the left elbow and wrist were involved and vaginal examination showed an endocervicitis with a yellowish sticky discharge from the cervix in which gonococci were present. The attempt to make an autogenous vaccine was unsuccessful and on April 21, 50,000,000 gonococci were injected. Twelve hours later the pain in the affected joints was severe. Just previous to this time the knees and ankles had also become involved. On April 26, 50,000,000 bacteria were again injected, but without resulting pain. On May 2, 60,000,000 bacteria were injected and on May 5, 70,000,000. On May 10, 90,000,000 bacteria were administered and on May 20, 100,000,000. Doses of 110, 120 and 130,000,000 bacteria were given on May 24, May 30 and June 4, respectively. The pains were increased following all the injections excepting one. Nearly all the large joints were involved and the pains were very severe. Permanganate and bichloride douches formed a part of the treatment. On June 7 there was no vaginal discharge. On June 10, 140,000,000 bacteria were injected. On admission the leucocytes were 14,000, polynuclears 75 per cent. On May 23 there were 10,000 leucocytes and 76 per cent. polynuclears; on July 8, 8,000 leucocytes and 68 per cent. polynuclears. Anemia was moderate. In addition to the vaccines guaiacol was applied locally and codeia and iron were given internally. The patient was discharged on July 1 with no pain or tenderness in the joints which, however, were stiff. She was able to walk and was considered cured.

Case III.—This patient was a woman twenty-six years of age, married, and with no history of gonorrhea obtainable, but with the history of an induced abortion a few weeks before admission to the hospital. Her left knee became involved on December 18 and she was admitted a week later. There was no vaginal discharge. On January 7, 12,000,000 bacteria were injected and five hours later there was burning of the skin and a pink papular eruption over the knee which extended over the body and arms. On January 8 there was vaginal discharge, with soft cervix, and gonococci were found. The injections were continued at intervals of a few days and in increasing amounts until March 25, the largest doses being 90,000,000 bacteria. Salicylates had been given without effect. She was discharged with good function of the joint and without deformity The leucocytes increased in number under treatment. Cultures from the cervical discharge made for an autogenous vaccine were unsuccessful on account of the inability to obtain pure cultures.

From these cases Dr. Satterlee concluded that when the dose was sufficiently large reaction pain occurred in the affected joints from two to twelve hours after the injection and lasted from five to twenty-four hours and that there was no pain in the unaffected joints. This might be of diagnostic import. The treatment should have two months' duration and the patient should be under observation for a longer period. The leucocyte count was apparently no index in the treatment. Large doses of the vaccine should be used and there should be local treatment of the mucous membranes affected by the gonococcus. Autogenous vaccines were a failure in women because of the great difficulty of obtaining pure cultures.

The Bacteriology of Non-Tuberculous Infections of the Respiratory Tract.—Drs. T. W. Hastings and Walter L. Niles presented this paper, which gave the results of investigations undertaken with the idea that ultimately they might be able to correlate some relation between the secondary infections in tuberculosis and the infections in which the respiratory tract was involved without the tubercle bacillus being found. The work had been continued over a period of eight years with the idea that possibly some variation might be shown from season to season. The conclusions reached in regard to the sterility of the respiratory tract agreed with those of Ritchie and they also agreed with him that the bacteria contained in the respired air were probably withdrawn in the upper air passages. The nasal mucous membranes possessed bactericidal properties. Bacteria introduced into the bronchi of healthy animals soon died. In the non-tuberculous conditions, bronchitis, lobar- and bronchopneumonia, they had probably 3,000 records. There were 178 cases with culture from the sputum, something like 460 examinations of sputum having been made. The method employed for getting the culture had been practically that of Kitasato. The clean, recent sputum was the one to collect for culture. An analysis of the cultures showed that of the 178 cases 12 were laryngitis and tracheitis, 27 were influenzas, 57 bronchitis, acute and chronic. There were two cases each of bronchiectasis and asthma. There were pneumonia with pneumococci in the cultures in 23 cases, pneumonia with no pneumococci in the cultures in 43 cases: there were 12

bronchopneumonias. Cultures were taken in the pneumonia cases from which the sputum was not typical of lobar pneumonia, so that the results had no bearing upon the occurrence of the pneumococcus in lobar pneumonia. The acute and chronic cases of laryngitis and tracheitis showed a large number of organisms. The *Micrococcus catarrhalis* was found seven times, the *Micrococcus pyogenes aureus*, six, mostly mixed infections. Four of the infections were with the *Micrococcus aureus*, one with the *Micrococcus catarrhalis*. In the grip cases the *Micrococcus catarrhalis* was the organism most frequently found, being present in thirteen cases. The streptococcus, pneumococcus, and the influenza bacillus were present in seven cases each. In the grip cases there were seven pure infections out of twenty-seven. The *Micrococcus aureus* and the *Micrococcus catarrhalis* each occurred twice. In the bronchitis cases the *Micrococcus catarrhalis* was found most frequently. Of twenty-three cases of lobar pneumonia with pneumococci in the culture only nine were pure infections. As a rule lobar pneumonia was a mixed infection. Of the forty-three cases of lobar pneumonia that did not show the pneumococci in the cultures only four showed pneumococci in the smears.

Philadelphia Neurological Society.

At a stated meeting held October 29 Dr. N. S. Yawger presented a communication entitled "Colloid Bodies in the Central Nervous System: Their Presence after Severe Traumatism in a Case of Dementia Paretica." He pointed out that these bodes may represent derivatives of medullary substance displaced in consequence of physical influences. They differ from so-called amyloid bodies both in appearance and in staining properties. The former take stains readily, but they lose them spontaneously in the course of a short time. Dr. Alfred Gordon exhibited "A Case of Asymbolia, without Astereognosis and Other Sensory Disturbances." The patient was a girl 12 years old, who at the age of six had a convulsive seizure involving especially the left side of the body and subsequently presented weakness of the left side of the face, the left arm and the left leg. The fingers of the left hand exhibited athetoid movements and the left upper extremity became involved in incoordinate jerking on volitional movement. The identity of objects held in the left hand could not be recognized, although their form and dimensions were correctly appreciated, and all other forms of sensibility were essentially preserved. The kneejerk was increased on the left side, but ankle clonus and toe-phenomenon were absent. Some improvement had been observed as a result of educational efforts. Dr. Eugene Lindauer demonstrated a case of multiple exostoses in a boy of about 14 years in which brachial palsy had resulted in consequence of pressure exerted by growths of bone from cervical vertebræ. Dr. S. W. Ludlam presented a communication entitled "The Variations in the Serum Tests in Nervous Diseases." He detailed the results of observations made in conjunction with Dr. E. P. Corson-White, various tests being employed, including that for globulins, the Wassermann and its modifications, the butyric acid and the cobra venom, and their practical utility demonstrated in a wide range of cases. Dr. James Hendrie Lloyd and Dr. Joseph M. Spellissy reported "A Case of Cerebral Decompression of Four Years' Standing in Which a Large Cerebral Hernia Has Resulted, with Marked Improvement in Optic Neuritis." The patient was a woman who exhibited bilateral papillo edema threatening blindness together with left hemiplegia and other symptoms suggestive of intracranial neoplasm, and for the relief of which an osteoplastic flap was reflected in the indicated motor region, but no growth was found. Some improvement in the paralysis took place and the disturbance in the optic nerve subsided in part with the retention of some measure of vision, but with the development of cerebral hernia. Dr. Tom A. Williams reported (1) "A Case of Hysterical Dyspraxia." The patient was able to perform a given motor act, on command, but had difficulty in dissolving it. For example, he would extend the arm, but would hold it in the position attained; or he would extend the tongue and keep it protruded. When left to himself, or if quietly asked to perform the second movement, he would succeed. Dr. Williams discussed (2) "Professional Cramp and Its Treatment by Psychoanalytical Measures." He reported a group of cases of writer's cramp, in one associated with torticollis from repeated twisting of the neck, and in which good results were obtained by securing the patient's confidence, learning the genesis of the disorder, and directing certain large movements of the affected parts. Dr. Williams further described (3) "A Case of Unilateral Retrospinal Tremor and Dysergia with Ocular and Facial Paresis in the Course of Acute Anterior Poliomyelitis. Finally he described (4) "A Case of Psychasthenia in a Child of Two Due to Coffee-drinking." The child exhibited an habitual movement, consisting in a constant rubbing of the wrist of one upper extremity with the fingers of the other. This tic, the speaker thought, was directly due to the fact that the parents gave the child coffee to drink.

College of Physicians of Philadelphia

At a special meeting held October 14 Dr. Paul A. Lewis presented by invitation a communication entitled "Recent Studies in the Etiology of Acute Poliomyelitis." He related the results of experiments made in conjunction with Dr. Simon Flexner, showing how the disease could be conveyed from human beings to monkeys and from monkey to monkey. Animals that recovered from the disease proved immune to a second attack, and animals treated with serum from a recovered animal proved refractory to inoculation. Dr. Allen J. Smith discussed "The Lesions of Acute Poliomyelitis." He expressed the opinion that the disease is to be looked upon as a general infection with a local manifestation. Studies of the blood had disclosed the presence of protozoa and these may prove to be the cause of the disease. Dr. Charles K. Mills presented a communication entitled "Special Features in the Symptomatology and Treatment of Acute Poliomyelitis, with Some Discussion of the Probable Pathogenesis—Based Chiefly upon Studies Made During the Recent Epidemic." He had found the period of incubation to average two weeks. In some instances death may take place early. Pain was a prominent feature in a number of cases, and also the upper extremities were involved in a noteworthy degree. Dr. Joseph S. Neff presented "A Study of the Cases of Acute Poliomyelitis Occurring in Philadelphia, Especially in Relation to the Etiology of the Disease." A careful analysis of the distribution of the cases showed that they occurred in private dwellings rather than in public institutions and in the houses of the well-to-do, situated in salubrious localities, than in the houses of the poor, in the congested districts. While the disease must be looked upon as a transmissible one, and cases should be reported, it does not seem necessary or desirable at the present to isolate them. Dr. B. Franklin Royer, speaking on behalf of Dr. Samuel G. Dixon, related that more than 900 cases had been reported throughout the State during the present epidemic of the disease, and that two-thirds of these occurred in children under the age of five years. Of the entire number only two occurred in negroes. Males were affected in larger number than females. In only a few instances, the speaker said, were more cases than one observed in the same household.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Anaphylaxis Toward Cow's Milk in Nurslings.—Barbier regards the intolerance manifested by certain infants toward cow's milk as a manifestation of anaphylaxis. There are infants in whom this intolerance is congenital or developed during the first few days after birth, and there are others in whom this intolerance is acquired as the result of excessive feeding with cow's milk. This intolerance causes a loss of weight and the condition of athrepsia, which disappear upon feeding the infant with breast-milk.—*Archives de Médecine des Enfants.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended November 18, 1910.

SULPH-HEMOGLOBINEMIA, WITH A REPORT OF THE FIRST CASE IN AMERICA*.

BY T. WOOD CLARKE, M.D.,

UTICA, N. Y.

FORMERLY ASSISTANT IN DISEASES OF CHILDREN IN COLUMBIA UNIVERSITY; CLINICAL ASSISTANT, VANDERBILT CLINIC,

AND

ROBERT M. CURTS, M.D.,

PATERSON, N. J.

ATTENDING SURGEON, ST. JOSEPH'S HOSPITAL.

THE case which we have to present is of some considerable interest for three reasons: It presents a very striking clinical picture; it is of exceptional interest from the standpoint of physiological chemistry; and though we do not believe that it is the first case of the kind which has occurred in America, it is unquestionably the first one to have been diagnosed on this side of the Atlantic Ocean, and when it is published it will be the eighth case to have appeared in literature.

In order that the condition may be properly understood, a few words upon the normal and abnormal blood pigments are necessary. You all know that the red color of the blood is produced by the pigment oxyhemoglobin, and that the bluish tinge of venous blood is the result of an admixture of reduced hemoglobin. You further know that the action of various chemicals will produce various compounds of hemoglobin; that coal gas will cause a brilliant scarlet color from carboxyhemoglobin, that cyanides will produce a somewhat similar cyanhemoglobin, and finally that different drugs, as nitrites, potassium chlorate, and especially the coal tar antipyretics, acetanilid, phenacetin, sulphonal, and trional, if given in excessive doses, will cause the formation of the brown pigment, methemoglobin. Probably every physician of experience has been called to see at least one patient who has indulged too freely in one or another of the so-called harmless headache powders and has found a man, or more probably a woman, markedly cyanosed, but without signs of cardiac or pulmonary involvement. This condition of cyanosis in acetanilid poison was originally considered to be due to cardiac depression, but was soon found to be caused by a direct action of the drug upon the blood, transforming a portion of the red oxyhemoglobin into the brown methemoglobin, and thus markedly altering the patient's appearance.

The first case of the so-called idiopathic enterogenous cyanosis was discovered in 1902 by Stokvis[1] of Rotterdam. This author reported the case of a soldier who had suffered from chronic diarrhea and cyanosis for five years. Though there was no history of his having taken any of the drugs which usually cause blood changes, large amounts of methemoglobin were found in the patient's blood. Talma[2] of Utrecht, the same year found three similar cases and further showed that the abnormal pigment was entirely within the corpuscles, and was not to be found in the serum. In 1905 Van der Bergh and Gutterink[3] of Rotterdam, in a similar case proved that their patient's blood contained an excess of nitrites, and as these are powerful methemoglobin forming drugs they believed that the condition of idiopathic methemoglobinemia was due to the absorption of nitrites from the diseased intestines, all of the cases having suffered from diarrhea or dysentery.

At about the same time Van der Bergh[4] had the opportunity of observing the case of a young boy who, as a result of an old rectal stricture, had marked intestinal retention, and was also cyanosed. At first believing the case to be one of methemoglobinemia, he soon found that the characteristic absorption band in the red part of the spectrum was not quite typical of that of methemoglobin, and after diligent investigation he discovered that it in every way coincided with the purple pigment produced many years before in the laboratory by Claude Bernard and Hoppe-Seyler, by the action of suphuretted hydrogen upon blood, and called by them sulph-hemoglobin. The following year Van der Bergh briefly reported three similar cases of sulph-hemoglobinemia, all occurring in women suffering from obstinate constipation. He was unable to find the origin of the sulphuretted hydrogen, but as all four cases recovered after systematic purgation, he believed the condition to be due to the absorption of an excess of sulphuretted hydrogen from the bowel.

In the fall of 1906, one of us (Clarke), while working in the laboratory of chemical pathology in St. Bartholomew's Hospital in London, under Dr. Archibald Garrod, was asked to investigate a case which had been observed for a year and a half by Dr. Samuel West, and had puzzled many of the best clinicians of London, the patient's blood having been reported by the professor of physiology of St. Bartholomew's, to contain methemoglobin, for which no explanation could be given. A search of the literature brought out the facts concerning idiopathic cyanosis, as given above, and a careful study of the patient demonstrated that the pigment in her blood was sulph-hemoglobin and not methemoglobin. The case was therefore reported at the Royal Medico-Chirugical Society by Dr. West and one of us[5] as the first English case of idiopathic sulph-hemoglobinemia. Several months of careful investiga-

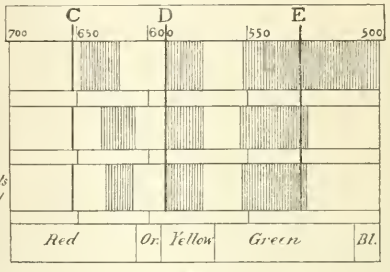
*Read by title before the Medical Society of the State of New Jersey, June 28-30, 1910. The patient was presented before the Society of Internal Medicine and the Roosevelt Hospital Alumni Association in New York in December, 1909.

tion of the patient and of artificially made sulph-hemoglobin, failed to show the origin of the sulphuretted hydrogen which was having so powerful an effect upon the blood. The usual blood examination revealed nothing. The red cells were normal in number, and the leucocytes slightly low. The blood was sterile. The etherial sulphates in the urine were not increased and there was no excess of indol. Careful examination of the stools failed to show any excess of sulphuretted hydrogen or an abnormal number of sulphuretted hydrogen forming organisms. The only clue which was obtained was the discovery that the presence of a reducing agent enabled the most minute traces of sulphuretted hydrogen to act upon the blood, to form sulph-hemoglobin, and the theory was suggested that the pathological condition might possibly be the absorption of some as yet undiscovered reducing agent from the bowel, which enabled a minute trace of sulphurated hydrogen normally in the blood to combine with the hemoglobin and produce the violet pigment sulph-hemoglobin.[6] This is purely theory and is supported by no clinical findings.

Within a week after the publication of this paper in the *Lancet*, the author was invited by Dr. Russell of the West London Hospital, to see a case of cyanosis which had been observed for seven years. This was at once shown to be another case of sulph-hemoglobinemia.[7] A third English case has been discovered since and reported by W. Essex Wynter.[8]

In the winter of 1908-1909, having returned from London to go on the staff of the Rockefeller Institute for Medical Research, one of us was invited to deliver an address before the Passaic County Medical Society, and chose for his subject, "The Rare Forms of Cyanosis, Polycythemia, Methemoglobinemia, and Sulph-hemoglobinemia."[9] A few months later, in September, 1909, the patient whom we now report, made her appearance at the office of the other of us, who was present when this paper was read. The patient, a woman 24 years of age, had never been robust, having suffered from most of the ills to which woman is heir. A few days previously she had noticed that her lips had become blue and her color ashen, though she herself did not feel ill. She was somewhat weak and markedly constipated. Her appearance at that time was much as it is to-day. Her skin was of a steel blue, and her lips purple black. The general appearance has been described as being cadaveric, or better as "of the ghastly hue seen in a person standing under the Cooper-Hewitt mercury light." This was so striking that on many occasions while going through the streets she was advised to go home at once, people believing that she was dying. Physical examination was, however, negative except for the remarkable discoloration of the entire body. The heart and lungs were practically normal. The patient was observed for some weeks, and as the ordinary blood examination failed to reveal any polycythemia or other abnormality to account for the condition, a tentative diagnosis of sulph-hemoglobinemia was made and toward the end of November, 1909, the patient was sent to New York for consultation and a spectroscopic examination of the blood.

When seen at the Vanderbilt Clinic the patient presented the same characteristic appearance of deathly cyanosis as did the two cases seen in London. The almost complete absence of signs of impaired heart or lungs was confirmed and 2 c.c. of blood were withdrawn from a vein in the arm. The blood, which was of a rich chocolate color, was shaken with twice its volume of distilled water in order to lake the corpuscles, and then filtered several times to remove all of the corpuscular remains and fibrin, and give a clear solution. This solution then being further diluted with distilled water was examined with a small pocket spectroscope and showed an intensely dark absorption band in the red portion of the spectrum, in the situation characteristic of the band of sulph-hemoglobin. Artificial solutions of sulph-hemoglobin made by the passing of sulphuretted hydrogen through laked and diluted dog's blood and of methemoglobin by adding potassium ferricyanide or sodium nitrite to similar blood were made for comparison.



Absorption Bands in Spectra. MHb = Methemoglobin. SHb = Sulph-hemoglobin.

The methemoglobin solution when mixed with oxyhemoglobin showed the two absorption bands of oxyhemoglobin in the yellow and green portions of the spectrum, and the characteristic methemoglobin band deep in the red much nearer the C than the D line. The artificial sulph-hemoglobin showed also the bands in the yellow and green, and a band in the red, but not so far in the red as in the methemoglobin spectrum, the band being midway between the C and D lines. The patient's blood in a concentrated form showed complete obliteration of the oxyhemoglobin bands, and the presence of an exceptionally clearly defined band half way between C and D absolutely indistinguishable from that of the artificially made sulph-hemoglobin. It having been shown that sulph-hemoglobin and methemoglobin behave very differently when treated with weak ammonium sulphide, a drop of such a solution was added to all three specimens. The absorption band of methemoglobin disappeared instantly, that of the patient's blood and of the artificial sulph-hemoglobin was unchanged. During the investigation on the first case in London, it was discovered that if carbon monoxide were passed through a specimen of sulph-hemoglobin a new compound was produced called by us carboxysulph-hemoglobin,* the spectrum of which closely resembled that of sulph-hemoglobin, but with the band in the red slightly nearer the yellow. Methemoglobin treated with carbon monoxide produced no such spectrum.[6] Accordingly illuminating gas was allowed to bubble through a specimen of our patient's blood, and the characteristic spectrum of carboxysulph-hemoglobin was produced. The ordinary examination of the blood showed nothing abnormal. There was a slight oligocythemia and a normal leucocyte count.

*After the publication of this report in 1907 it was learned that Angelo de Dominicis had previously reported the preparation of carboxysulph-hemoglobin. The credit of priority is willingly accorded to that investigator.

Accurate hemoglobin estimation was impossible, the chocolate color of the blood making comparison with the standards out of the question.

Through the kindness of Dr. F. C. Wood the patient was admitted to St. Luke's Hospital and kept under observation for three weeks. Our findings were there confirmed. Careful bacteriological examinations and chemical analyses of the excreta including the sulphur and nitrogen partition made by Drs. Hans Zinsser and K. L. Vogel confirmed the findings in the cases worked up in Rotterdam and London, but failed to throw any new light on the origin of the sulph-hemoglobin. While in the hospital the patient, who was kept well purged, improved decidedly, but since her return home some difficulty has been found in keeping the bowels open, and the disease has remained stationary. From these findings it is evident that we have to deal with a case of idiopathic sulph-hemoglobinemic cyanosis.

These two diseases, so much alike and still so easily differentiated, methemoglobinemia and sulph-hemoglobinemia, are probably not common. On the other hand, we do not believe them to be as rare as at first sight they would appear to be. In every instance, when attention has been called to their existence, one or more cases have promptly made their appearance, and nearly every clinician of large experience to whom we have shown our case has remembered that at some time or other in his practice he has seen a case, which, in looking back at it, he believes to have been one or the other of these two diseases.

In making the diagnosis two factors are necessary: The physician must know of the existence of the enterogenous cyanoses, and he must examine the blood with a spectroscope. This latter procedure may at first sight make it appear that the diagnosis of the disease would lie solely in the hands of the expert laboratory technician. Such an idea is, however, a most decided misconception. A spectroscopic blood examination is in reality the simplest of procedures, and requires but little technical ability. The method is simplicity itself. The blood is drawn from a vein, or if this is not allowed, a few drops from the finger or ear will usually suffice. It is immediately diluted until twice its volume of distilled water, before clotting has taken place, and is thoroughly shaken. After the fibrin has separated the solution is filtered several times through one filter paper and the clear solution is looked at through a spectroscope, a simple and inexpensive instrument. The solution is then diluted drop by drop with water, until the red color stands out clearly. If there is a black absorption band in the red, either methemoglobin or sulph-hemoglobin is present. If such a band persists after the addition of a drop of dilute ammonium sulphide, the pigment is sulphemoglobin, if it disappears it is methemoglobin. For a clinical examination nothing further is required.

The recognition of these diseases is of especial importance from the standpoint of prognosis. If undiagnosed the patient's appearance suggests immediate dissolution; when recognized a most hopeful prognosis as to life can be given, though the complete recovery may, as in the present case, be a matter of weeks or months.

As to the clinical picture, the single point of similarity between the two conditions is the cyanosis due to a chemical change in the blood, and unaccompanied by dyspnea or other signs of cardiac or pulmonary disease. The methemoglobinemia cases have usually occurred in men, and have invariably been associated with a chronic enteritis. The sulph-hemoglobinemia cases with one exception have been in women with marked constipation. The one exception was in a boy in whom a stricture of the rectum caused intestinal retention, but fluid stools. A characteristic of the methemoglobinemia cases was pointed out by Van der Bergh. If these patients are put on a strict milk diet, the cyanosis disappears within forty-eight hours, and all trace of methemoglobin leaves the blood. This improvement is, however, but temporary, as one full meal causes the reappearance of cyanosis in four hours and within twelve hours the clinical signs are again as intense as before. No such effect is produced by a milk diet in cases of sulph-hemoglobinemia.

As to the etiology of the diseases, the origin of the sulphuretted hydrogen in the sulph-hemoglobinemia cases is a complete mystery. The methemoglobin is considered to be caused by the absorption of nitrites from the intestines. In an article published by one of us a year ago,[9] attention was called to the recent discoveries that the bacterial flora of the intestines are at times able to break up bismuth subnitrates thus liberating nitrites,[10] and the suggestion was made that, all of the cases of so-called idiopathic methemoglobinemia having occurred associated with chronic long-standing diarrhea, possibly these patients had been receiving bismuth subnitrate over a long period of time, and the condition might really be one of chronic bismuth poisoning. No such explanation is as yet forthcoming as to sulph-hemoglobinemia.

The contention of Gibson and Douglas of Edinburgh that methemoglobinemia is a colon bacillemia, being based on the examination of a few drops of blood taken from the patient's ear, and the observation being unconfirmed, the finding may safely be relegated to the class of technical errors. Owing to the indefinite etiology of the disease, treatment is difficult, inasmuch as obstinate constipation and disturbances of the digestive tract have been found common to most of the cases reported, purgatives would appear to be indicated, and such drugs when effective produce good results. The usual drugs which act upon the blood and circulation give no beneficial results other than would be expected from their general tonic properties. Intestinal antiseptics may be of some value. Betanaphthol and salol were used in the present case, and during the period of administration the patient improved considerably, losing much of the general cyanosis. From observations for over six months, it appeared that rest in bed for weeks with massage, purgatives, and intestinal antiseptics gave the best results. Many varieties of diet have been tried in an experimental way, but nothing of practical value has been learned thereby.

In the present paper we do not pretend to be reporting any new discoveries, or to be making any valuable addition to medical literature. The study of the present case has made no single advance in knowledge; it has merely confirmed what has previously been proved. The purpose of the paper is to put on record the first case of the kind to have been diagnosed in America, and to call the attention of the medical profession to the existence of a disease which as yet has received but little general recognition. We confidently believe that with a dissemination of knowledge of these diseases, many more will be recognized, and we sincerely hope that each case which is found will

be studied with care, with the hope of solving many of the mysteries which still befog our knowledge of the etiology of the idiopathic or enterogenous cyanoses.

Clinical History.—In consideration of the rarity of this disease, and the many obscure points in its etiology it has seemed admissible to append a full clinical history of the case. The following history is taken from the records made at St. Luke's Hospital during the patient's sojourn in that institution. For the use thereof we wish to express our thanks to Drs. Wood and Lambert of the Visiting Staff.

Miss E. H., aged 24, was admitted December 1, 1909, and discharged December 19, 1909. Case No. 79,577. Diagnosis. Enterogenous cyanosis (sulphhemoglobinemia) or idiopathic intracorpuscular sulph-hemoglobinemic cyanosis of enterogenous origin.

Family History.—The father, mother, two brothers, and three sisters are living and well. One brother died at 10 years of age of dropsy, one sister died in infancy of marasmus. There is no history of tuberculosis, but there is a marked history of kidney disease on the father's side.

Personal History.—The patient was a seven months' child. The general health was good up to 1900. She was a blue baby at birth and for the first six weeks of life. The habits are regular. She drinks no coffee, but 6 or 7 cups of tea each day. She does not use alcohol. For the past 9 years her appetite has been poor, but the digestion good. The bowels are constipated. Menstruation began at 16 and has always been irregular, painful, and scanty.

Past Illnesses.—The patient had measles, whooping cough, mumps, and chickenpox in childhood. Up to 7 years of age she had considerable bronchial trouble and tonsillitis. In 1900 she had malaria with considerable anemia, and had recurrences of this disease every summer for six years. In 1902 she had glands removed from the neck, which the doctor said were tuberculous. In 1903, she had osteitis and periostitis of the left hand and in 1904 a similar condition in the nose. In 1905 she had appendicitis with appendectomy. In 1906 she had a long period of illness with profuse night sweats, severe abdominal pain, vomiting, and great general weakness. The right shoulder, right elbow, right hip, and right knee were swollen at different times with great purplish discoloration of the skin over the joints. There was also almost continual headache of a severe nature and occasionally periods of a low fever. In 1907, double oophorectomy was performed, following which the patient enjoyed fairly good health for a year. In 1908 she had very severe pains in the lower back. Since the first illness in 1900, the patient has been quite constipated. She has been under an anesthetic nine times in the past seven years.

Present Illness.—On August 20 and 21, 1909, the patient complained of feeling tired and weak and her friends joked her for being lazy. On August 22 she lay down for a nap and slept five hours and on awakening noticed a bluish color of the skin. She did not grow weaker, but the bluish color became progressively deeper for a week, then remained stationary for about five weeks and then gradually cleared up almost entirely and remained so for three weeks. Then the skin again became gradually darker up to one week ago, since when it has gradually improved. (This last week represents the time since a definite diagnosis of sulphhemoglobinemia was made and systematic purgation instituted). The patient has suffered no other symptoms but weakness, bluish discolorations of the skin, and perhaps more marked constipation. The patient says that preceding each improvement she had had periods of severe vomiting lasting about twenty-four hours.

Physical Examination.—The patient is a woman of slender frame, fairly well nourished and developed, not feeling at all ill despite a very marked cyanosis. There is no dyspnea or orthopnea as she lies in bed. Her skin looks smoky. Her mucous membranes are a dark purple. The fingers and toe nails show extreme cyanosis. Eyes: The right pupil is very slightly larger than the left. Both react sharply to light and accommodation. The bridge of the nose shows the healed scar of an operation; there is slight flattening. Mouth: The tongue is cyanotic and very slightly coated; the teeth are in good condition. Chest: The respiratory excursion is good. At the outer part of the right apex behind there is very slight dullness and increased slightly high pitched expiration and voice. The whispered voice carried through well. Elsewhere percussion is resonant. The breath sounds are of good quality and vesicular. No râles are heard. The heart: There is no dullness to the right of the sternum; the upper border is normal; the left border is four inches from the midline; the apex is palpable in the fourth interspace in the nipple line, and is localized; there are no thrills. The first sound at the apex is booming and accompanied by a short soft systolic murmur transmitted slightly to the left; the second sound is booming. At the base the aortic sounds are normal, the pulmonary second sound is a little accentuated. In the third and fourth spaces close to the sternum a much louder slightly reduplicated ringing sound is heard simultaneous with the basal second sound. No pericardial sounds are heard. The action is regular and of good force. The pulse is of good volume, soft, regular, and with no increased tension. There is no thickening of the arterial wall. The abdomen: In the midline below the umbilicus is the healed scar of a median laparotomy. There is a similar scar over the appendix region. The liver percusses from the free border to the sixth rib. The edge is not felt. The spleen is not felt. There is neither tenderness nor rigidity. No masses or fluid are made out. Extremities: The knee jerks are active; there is no clonus or Babinski sign. There is no edema or varicosities. On the dorsum of the left hand are two linear scars.

The urine is acid; the specific gravity is 1.014; there is a trace of albumin; there is no sugar; there are no pus and no casts. The leucocyte count is 11,000, polymorphonuclear 72 per cent.; lymphocytes 28 per cent. The red blood count is 5,000,000. The hemoglobin is 70 per cent. (?)

December 9. Blood culture was negative.

CHEMICAL PROBLEMS IN DIABETES.*

BY ADOLF MAGNUS-LEVY, M.D.

PROFESSOR OF MEDICINE IN THE UNIVERSITY OF BERLIN.

METABOLISM OF ENERGY.

THE metabolism of energy is in general regarded as fairly constant in healthy individuals under like conditions. The unit in which we express it is the unit of heat, the calorie. The measurement takes place either directly by determining the actual loss of heat, for which large and expensive apparatus is necessary, or indirectly by a determination of the expired carbonic acid and the oxygen taken in. From both these values, and at the same time taking into consideration the decomposed protein, we can, with tolerable certainty, estimate the metabolism of energy. As the total metabolism of energy is influenced at different times and in different individuals to a different extent by the food taken in and the muscular work performed, we have accustomed ourselves to exclude these two factors. We study the metabolism of heat and energy in a state of fasting and rest, when none of the muscles are in a state of tension. The figures thus obtained are considered a suitable standard for comparison.

Experiments of this kind generally last only an hour, and I am of the opinion that this method of procedure—which is called the method of Prof. Zuntz, and which I have applied in more than a thousand experiments—needs supplementing by twenty-four-hour measurements, including the digestive and the muscular work.

On the whole, respiration experiments have given the result that the metabolism of energy in diabetes is not essentially different from that in a healthy person under similar conditions. The deficiency of oxidation in this disease concerns only *single* processes. A diminution of the *total* oxidative process does not take place if we may rely exclusively on those respiration experiments which have been carried out up to the present time. But clinical observations, measuring the ingested food for a number of weeks and taking the weight into consideration, point to exceptions from this rule. Naunyn was the first to emphasize the fact that the metabolism of energy, under certain conditions, remains below the values accepted as normal. Diabetic patients who have lost much flesh can, after glycosuria has disappeared, not only keep up their nitrogen equilibrium, but also increase many kilos in weight, on receiving only 1600-1800 calories. On the other hand, there is the fact that polyphagous diabetics often lose flesh, although the available energy of their diet far exceeds the normal, that is to say, 2000-2300 calories. In calculations of this kind the loss of energy by sugar elimination through the urine is of course allowed for. Both these facts, taken together, are of great theoretical and practical significance. They touch on a question of general physiological interest.

At all times the view has been common among a large number of laymen and also many physicians that we eat too much, and that it would be possible and probably also healthier if we were to partake of less nourishment. Excess of food is held to be completely superfluous; also that the yielded energy not only renders no service to the organism, but on the contrary causes a useless waste of force. This would be called in technical language a "luxury consumption."

This is not exactly the same as what Chittenden calls physiological economy in nutrition. Chittenden paid attention principally to the proteid metabolism, and did not go deeply into the problem of "luxury consumption."

Many rigidly scientific observers have not in general been inclined to concede the existence of a luxury consumption. Respiration experiments on healthy animals and men at different times seemed to refute this opinion, and conclusions based on grounds of analogy were likewise unfavorable to this assumption. Breathing in pure oxygen, that is to say, placing more oxygen at the animal's disposal, does not raise the combustion according to the well known experiments of Pflüger. The same thing was also assumed in the case of an excess of food. Of course, an increased introduction of food raises the combustion by a certain percentage for a few hours. This is attributed to the digestive function, or, as Rubner thinks, to the specific dynamic energy of food. And it is very well known that increased intake of protein increases the metabolism of energy more than other foodstuffs. But this increase of metabolism generally lasts only as long as digestion lasts. In general no summation of these actions takes place, no lasting and definite adaptation to a higher metabolic level has been noted. The principle of all cures by overfeeding depends on the fact that the organism does not increase its metabolism corresponding to the surplus of food, but that it stores up a part of the superfluous food. In the same way a diminution of the metabolism of energy in the case of insufficient food has also been regarded as improbable.

But it now seems that we must change our opinion as to this point. Experiments have been made in which healthy strong men with moderate muscular work have apparently thriven for a long time on a diet which placed at their disposal less than thirty calories per day and kilo. Neumann while doing laboratory work has apparently maintained his equilibrium on twenty-five calories for many weeks, while at other times he metabolized thirty-five to forty calories per kilo like other men. We should have the best support for accepting a "luxury consumption" on the basis of such comparative experiments in the same individual. Perhaps we might better use the term adaptation of the organism to different quantities of food.

It seems to me that in none of the experiments carried out up to the present time has any absolute proof for the existence of such an adaptation been brought forward, although they point toward this.

In any case such an adaptation needs a long time and the new equilibrium first appears when the weight has materially diminished. On the other hand an equilibrium following the introduction of greater quantities of food also is reached only after a more or less considerable increase in weight. The whole problem would accordingly resolve itself into a kind of self-regulation, a suitable provision of nature, which prevents overfeeding and loss of weight from becoming excessive.

*The third of the Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons, Columbia University, New York, for 1910.

The adaptability differs in different persons. It apparently plays an important part in pathological conditions; in obesity and above all in diabetes it seems to be of great importance. I will here touch only on the conditions in diabetes. If some diabetic patients can live for a certain time on 1,500-1,600 calories, while 3,000 or 4,000 are insufficient for others, it seems to me that the adaptation is strongly pronounced in this disease. In principle we find the same conditions as with healthy persons: on the one hand, accommodation to a restricted diet takes place only after a considerable loss of weight and after the organism has subsisted for a long time on a small quantity of food; on the other hand a great waste of energy in diabetics occurs only after they have been overfed for a long time and in an unreasonable manner. The extreme variations in the metabolism of energy in severe diabetes point to the probability that the disease itself —the essential disturbance of which consists in a decrease in sugar combustion—may induce also a lability in the whole oxidative metabolism.

I again repeat that the foundations on which this assumption is based are not sufficient. New systematic investigations with direct measurement of the carbonic acid output and of the metabolism of energy are necessary.

Although the experiments carried out on diabetic subjects by Joslin and Benedict last winter afford no support for these ideas, I feel convinced that with other patients and at certain periods the changes which I have pointed out might be found.

SUGAR COMBUSTION IN DIABETES.

Does sugar combustion totally cease in cases of severe diabetes? This question has been put in various forms by different authors and has been attacked by various experimental procedures. In the first place Külz put the question, whether diabetic patients eliminated sugar quantitatively, if it was added to a strict diet; he found that a large part was catabolized. Troje also observed that only 270 grams of grape sugar out of 300 reappeared in the urine. Naunyn confirmed this for the majority of cases. A complete elimination of the sugar introduced was found by Naunyn only once. But it seems that the majority of all these patients were not suffering from severe diabetes. In any case there are some diabetic subjects—and this is important in principle—who eliminate a surplus of sugar quantitatively. Aside from some cases observed by von Noorden, von Mehring, Lusk, and Mandel, I will only mention an especially convincing example of Cantani. A patient on being fed exclusively on 800 grams of meat and some fat had an average loss of 61 grams of sugar during eight days. Then he received in two days 500 grams of cane sugar. The amount of grape sugar that could have been formed from this is 530 grams, but, as a matter of fact, the excretion of sugar rose by 580 grams.

The differences with different patients as to this point are especially important from a practical point of view. There are some diabetics whose glycosuria ceases immediately after one or two days of a strict diet. These will generally be considered as cases of slight diabetes. But they can stand no carbohydrates without immediately eliminating corresponding quantities of sugar. Thus their carbohydrate metabolism is affected rather severely. Their tolerance is very small, although they do not lose sugar on a strict diet. Other patients on the contrary eliminate some grams of sugar although adhering for weeks to a strict diet. According to the usual definition of slight and severe diabetes they seem to belong to the severe type. Now, if 100 or even 200 grams of bread be given, the excretion of sugar rises only by a small amount, perhaps by 10 or 20 grams, that is to say, these patients decompose large quantities of sugar. Accordingly their tolerance is fairly high. Naunyn has called this a "paradoxical phenomenon." There is no doubt that such patients will do much better on being fed with bread and on eliminating 20 grams of sugar than if carbohydrates were totally avoided. The objections of many practitioners who believe that suppression of glycosuria is not the leading principle of treatment refer to patients of this class, who indeed are not very rare.

Another question is whether in cases of most severe diabetes an extremely high sugar output can be diminished for some time without change of diet, but rather by muscular work or by other measures. That is to say, whether such sugar, which was lost in the ordinary course of diabetes, may be burnt under special conditions. The favorable influence of muscular work has been proved over and over again in cases of human diabetes. I attach less value to the exact investigations of Külz and von Mehring than to the very convincing clinical observations of Bouchardat, Zimmer, Schmitz, etc. Schmitz reports that a considerable glycosuria quite disappeared in the case of several officers when they had taken part in maneuvers, although no special diet had been adhered to. I believe also in opposition to Naunyn that the favorable influence of muscular work not only holds good during the time of actual movement, but also extends far beyond that time. But this is immaterial for the principle of our question. Apparently in none of these cases were the patients suffering from severe diabetes. The same has probably also been the case with the depancreatized dogs, in which Heinsheimer and Mohr observed a diminution in the sugar output after working on the treadmill. See has given this point his particular attention. In the dogs working on the treadmill, in which there was a diminution of excreted sugar, he found remnants of the pancreas; the diabetes was incomplete. But when the pancreas was totally extirpated, and sugar elimination was highest, no diminution of the sugar output took place in spite of muscular work.

Aside from these two aspects of the problem of sugar combustion the question must be put in a third and further form. In principle it is not so very important whether a part of the sugar which is usually eliminated can again be oxidized by work or other causes, but rather whether or not in the extreme form of diabetes some quantities of sugar are *always* oxidized. This, in other words, is whether or not in these cases life is possible without carbohydrates. In cases of slight diabetes some sugar is certainly always catabolized, and the same is true in cases of moderate severity, which on a strict diet yield only a few grams of sugar. Here no doubt more sugar is formed than eliminated. This follows from the fact that the blood contains unusually large quantities of grape sugar. A depancreatized dog of Lüthje's, also one of Mohr's, had 0.3 per cent. of sugar in the blood and none in the urine. On the other hand the striking regularity in the elimination of sugar in the severest cases of pancreas diabetes leads to the supposition that all the sugar formed is also eliminated, and that thus life is sustained without carbohydrates.

There are two methods of approaching this prob-

lem. One consists in respiration experiments, especially in regard to the control of the respiratory quotient, in a similar way to that which Zuntz adopted with healthy fasting men. Reckoned for an average of 24 hours, the respiratory quotient must amount in depancreatized dogs to about 0.05 on account of the sugar split off from protein and fat. When besides the eliminated urinary sugar still further quantities of sugar were formed but again catabolized, this would not be recognized in a 24-hour experiment. Nor would it be in shorter experiments if the formation and break down of sugar should occur at the *same* time. But if, as in Zuntz's experiments, sugar be formed and stored up in the organism to be catabolized later, then the respiratory quotient at the time of the sugar formation must fall below 0.65, the average value for the whole day, and must rise above this average during the combustion of the sugar. This manner of proceeding is in principle correct.

Mohr, who has worked along these lines, is of the opinion that he has found corresponding changes in the respiratory quotient, thereby proving formation and combustion of sugar at different hours of the day. But important objections arise on more detailed criticism to almost all of Mohr's experiments, so that I am unable to regard them as convincing.

There is still one more possibility of approaching the problem, namely the comparative analysis of the sugar content in the arterial and venous blood.

Permit me to make a few preliminary remarks. If an organ makes use of a substance brought to it in the circulation, as for instance the muscles do of grape sugar, or if a gland secretes a substance like uric acid, or hydrochloric acid, then of course the venous blood must contain less of this substance than the arterial blood. But it has usually been overlooked that the loss of substance, even when very great, gives extremely small percentage values in the blood, considering the large quantities of blood from which it was given off. If a healthy man burns 500 grams of grape sugar per day he must for this purpose pass from 5,000 to 7,000 liters of blood through his capillaries. This quantity of blood yields 500 grams of sugar. Accordingly each 100 c.c. of blood would lose only from eight to ten milligrams in one single passage. So instead of 0.1 per cent. of sugar in the arterial blood we should find 0.09 per cent. in the venous blood. This difference, however, is almost within the limits of error of chemical analysis. (I will only point out in passing that with other materials which are catabolized in smaller quantities in the organism, such as uric acid, etc., the absolute and relative diminution is naturally much smaller than that of grape sugar.)

But the above difficulty can be overcome, particularly in the case of grape sugar, by a special mode of procedure in which the blood is passed many times through the organ. Care must be taken that the used-up sugar is not replaced. In this method we should have to deal with the aggregate of the repeated sugar losses and this would be analytically recognizable. For this purpose the liver, which replaces the used-up blood sugar, must be removed from the circulation in the living animal. If this be done the blood sugar in the healthy animal sinks in about three hours to 50 per cent. or less of the original value.

This method, which is correct in principle, has been used by Chauveau and Kauffmann with depancreatized dogs. They report that they have found a decided diminution in the blood sugar in the course of several hours. But in every single case it remains open to question whether these animals had been really in the state of maximal sugar elimination at the time of the beginning of the experiment. The results of these French authors are directly contradicted by the extremely careful experiments of their own countryman Hédon, who has never found such a diminution of the blood sugar. Accordingly, a positive decision cannot yet be arrived at. For my own part, however, I should like to accept the theory adopted by our most distinguished German investigators of diabetes that together with maximal sugar elimination still more sugar is always formed in the body and also catabolized.

VARIATIONS IN THE EXCRETION AND IN THE TOLERANCE OF SUGAR.

The principle of the diabetes treatment of to-day consists in sparing the enfeebled functions on which the sugar metabolism depends, the aim being to strengthen them. You are aware that we sometimes fail in removing all the sugar from the urine of patients suffering from slight diabetes, so long as small quantities of carbohydrates are still given. Such patients, for instance, on being fed with fifty grams of bread still continue to eliminate ten grams of sugar, and the sugar output does not cease even by keeping this diet up for a length of time. But as soon as a strict diet is adhered to for several days, not only does the sugar immediately disappear from the urine, but it does not return if the patient be given a gradually increasing quantity of bread up to 100 to 200 grams.

This restoration of an impaired function by allowing it to rest for a short time has many analogies.

In the therapy of diabetes we have to deal with all the forces on which sugar tolerance depends. We have already discussed several points. At present I will mention only the influence of food proteids and food carbohydrates on sugar tolerance. Immoderate and prolonged feeding on carbohydrates in many cases of diabetes not only causes an elimination of sugar itself, but also damages the normal tolerance for sugar for a considerable period after the excessive ingestion of carbohydrates has ceased. In this sense an immoderate use of starchy and sweet food is to be looked upon as one of the accidental causes which provoke diabetes. It is difficult to recognize with certainty this influence in a single case. It was distinctly apparent in a case mentioned by Langstein. An infant of six or seven months without hereditary disposition was brought to the physician suffering from severe diabetes. The history of the case showed that the child had received for months enormous quantities of cane- and milk-sugar with its milk.

But unlimited consumption of proteids also acts harmfully on the tolerance in the same fashion as does immoderate use of carbohydrates. Here again, not only does more sugar originate from the large quantity of protein, but also the functions of the protoplasm become permanently damaged. The question accordingly runs: is the protoplasm damaged more by an excess of carbohydrates or by an excess of proteids?

But this question has generally been put in a somewhat different form. It has been asked whether sugar formed from protein or preformed

sugar is more easily combustible. The formulation of the question in either form is meaningless for therapeutics, the only point of importance being whether diabetic subjects thrive better on a limitation of carbohydrates or of proteids. From a theoretical standpoint, however, the question as to whether protein sugar or preformed sugar is more easily burnt seems to me wrong, for the following reasons: The molecule of protein-sugar differs in no way from dextrose, which is formed from starch. I agree that it could be assumed that the newly formed sugar, if in a nascent state, is more easily broken down than preformed sugar. If the combustion of newly formed sugar followed immediately on its formation, and if it occurred in the same place where it was synthesized, then perhaps the conditions for the catabolism of the protein sugar would be more favorable. But our knowledge up to the present is not in favor of such a supposition. From experiments made by Embden on the extirpated liver of depancreatized dogs it seems to follow that the sugar formation from protein, or at any rate its last phase, takes place in the liver. But this organ certainly takes only a very small part in the utilization and combustion of sugar which it had built up. It delivers its product to the other organs and here the sugar formed from protein arrives in the same condition as the sugar molecule, which has been derived from food starch. Accordingly, I cannot acknowledge any difference in the combustibility of protein sugar and of the preformed sugar molecule. So if a diabetic patient, besides ingesting 30 grams of sugar, forms 30 grams from protein, and if from these 60 grams of sugar 30 are eliminated, then it will be difficult to say whether these 30 grams of urinary sugar correspond to the carbohydrates of the food or to the sugar which was formed from protein. In my opinion they will have been derived partly from both. The protein sugar could behave more favorably as to consumption only in so far as its formation and passage into the blood take place more slowly and constantly than that of the food sugar, which causes a more rapid inundation of the organism. At present it does not seem possible to me to go further into details with these ideas. The practical establishment of the fact whether a restriction of protein or of starch is more suitable for a particular diabetic patient is essentially independent of theory.

It seems that the break down of the body protein is less harmful for some patients than that of ingested protein. Indeed, we know that fasting induces a sudden decrease in the loss of sugar. It has been thought that in this case less sugar was formed from the body than from the ingested protein. But it is not possible to establish an exact comparison, because the nitrogen elimination is usually higher when protein is given than when this is totally avoided or strictly limited. It might be exclusively a question of *quantitative* differences; but qualitative differences are equally possible. The protein of the food is not chemically identical, even when only meat is given, with the protein which is catabolized in the fasting organism. Possibly the differences in sugar formation might be essentially explained by differences in chemical composition. But on the other hand it might also be possible that the synthetic processes necessary for the building up of the split-up food protein make too heavy claims on the function of the protoplasm, thus damaging the tolerance for sugar. If the same side chains—to use Ehrlich's terminology—which are involved in the breaking down and the synthesis of protein are also concerned in the sugar decomposition, then it could be understood that the introduction of large quantities of protein interfered with sugar utilization.

I have already mentioned in my other lectures the influence of fat, alcohol, and muscular work on the sugar output, and I will only add a few words on the influence of drugs. We cannot doubt that occasionally some drug has appreciably diminished the sugar output of a diabetic patient. But since the efficacy of salicylates, antipyrin, and other drugs is not to be relied upon, these possibilities do not at this time require experimental investigation. Only opium has been shown to exercise a reliable, although limited, influence. If glycosuria resists a strict diet, adhered to for weeks, and all other measures as well, the use of opium has proved to be of great benefit. Unfortunately no experiments have yet been made to explain the mechanism of its action. It may be an action on the brain, and from there on the liver. The influence might be transmitted by the suprarenal capsules. We can also conceive an action on the kidneys in such a manner that these, under the influence of opium, retain the sugar circulating in the blood, although its percentage in the circulation is not diminished. I mention these points only in order to encourage experimental investigations. The same is also true of atropine, which some time ago was recommended by Dr. Rudish of the Mount Sinai Hospital, as being extremely efficacious. My own experiments with this remedy up to the present, although they have extended only over a short time, have shown me that this recommendation is justified, and that atropine has a part to play in the therapy of diabetes.

PATHOGENESIS OF DIABETES. UNITY OF DIABETES MELLITUS.

The conception of diabetes mellitus as a concrete disease is justifiable inasmuch as the metabolic disturbance itself and its intensity dominate the pathological process. However, it has always been considered necessary to assume different forms. This view is based on the great number of etiological factors and on the number of organs involved. Besides, the question of the unity of diabetes may also be raised from a metabolic standpoint, the question being whether or not the sugar elimination is always due to the same chemical and biological processes.

Science is not able as yet to give a definite and satisfactory answer to this question. Personally, I do not venture to take up a definite position in regard to all the points of the problem, a consideration of which always leads to a point where further speculation is impossible. The aim of such discussions can only be to find the point where new experimental or clinical inquiry has to set in and to determine new solvable questions.

Formerly only the brain and the liver were regarded as diabetogenetic organs, that is to say as organs that in some way or other cause diabetes. Mehring, who discovered phlorhizin diabetes, added the kidneys, Mehring and Minkowski the pancreas. In the last two decades the thyroid, the suprarenal glands, and the hypophysis have also been accepted as organs involved in the pathogenesis of diabetes, and it is not unlikely that in the future the range of organs will be still further extended. From a certain point of view all organs play a part in the etiology of diabetes, because they

all burn carbohydrates. If generally the muscles have not been considered responsible in this connection, it was because they were not thought to play an *active* part. It may be doubted whether this is completely justified.

If, as is probable, the greater part of the organs are involved in diabetes, the association between them can be based either on purely nervous connections or on mutual chemical influences. The old distinction between humoral and neural pathology is still alive and will be so in future, also in regard to diabetes.

The brain plays no primary part in the processes of sugar combustion. By means of the nerves, however, it exercises an influence on the liver and perhaps also other organs either automatically or by reflex action. The influence of the liver is probably a passive one. But as a storing place for the carbohydrates of the food and as a producer and supplier of newly formed sugar, the liver is of great significance, although probably only in a passive sense. Naunyn is the only author who considers the liver a truly diabetogenetic organ, responsible for the primary formation and accumulation of glycogen, and thus for the causation of diabetes. But I do not think that his opinion is shared by the majority of investigators. In opposition to the liver the kidneys rightly deserve to be called diabetogenetic organs. The brilliant experiments of Zuntz and of Pavy have shown that sugar is actively eliminated by the kidneys. But this activity of the kidneys is confined to phlorhizin poisoning. It has not been definitely established that renal diabetes also exists in human beings, and if it does, such occurrence is rare. Thus, there remain to be considered the pancreas, the thyroid, the hypophysis, and the suprarenal capsules with the chromaffine system.

After the discovery of Mehring and Minkowski we were inclined to attribute to the pancreas a dominant position in the pathogenesis of diabetes and to regard it as the organ chiefly responsible for it. The next conception was that this gland produced a substance necessary for the combustion of sugar. Recently, however, Falta and his collaborators have formulated another theory which they have tried to support experimentally. Their opinion is that the pancreas, thyroid, and suprarenal glands form a system which is responsible for the sugar metabolism. The suprarenal gland effects by the adrenalin a mobilization of the carbohydrate stores. This has been proved by the severe glycosuria following an injection of adrenalin. A similar function was ascribed to the thyroid. Since a substance which, similarly to adrenalin, induces glycosuria cannot be isolated from this gland, we must rely upon the clinical fact that diabetes is often associated with Basedow's disease, and that sugar elimination may also be caused in healthy individuals by overfeeding with thyroid substance. According to Falta the pancreas acts in contrast to these two organs, which effect a mabilization of sugar, by *preventing* such mobilization. Its removal permits the diabetic power of adrenalin to come completely into action. Accordingly, diabetes is essentially to be ascribed to the activity of the suprarenal gland, which is no longer interfered with by the restricting powers of the pancreas. Kraus also is inclined to attribute to the suprarenal gland a central position in the production of diabetes.

The mutual relations of the above three organs, both to each other and to the liver, do not necessarily depend on direct nervous connections. If the tail of the pancreas, after removal of the head, is transplanted under the skin, its antiglycosuric efficiency is conserved, although all direct nervous connections between the liver and the rest of the pancreas have been cut off. The active principles of the pancreas and of the other organs, the so-called hormones, perhaps do not act *directly* on the liver cells, but indirectly by the intervention of the nutritive nervous system. This would mean a combination of neural and humoral pathological conditions.

According to my views the experiments of the Viennese investigators were neither carried out in sufficient numbers, nor with sufficient accuracy. Some of their conclusions have also been contradicted by other authors. The weakness of their theory seems to me to lie in the fact that it considers only a single *aspect* of diabetes, namely the mobilization of the carbohydrates, while the new formation and the using up of sugar have not been taken into account.

Accordingly the necessity arises of throwing light upon the unity of diabetes and its pathogenesis from another, namely, the metabolic, point of view. The decisive question here is this: Is diabetes caused by increased sugar formation which exceeds the needs of the organism, or is it caused by deficient sugar combustion? (Phlorhizin diabetes, which stands in a class by itself, need not here be considered.) The expression of "increased sugar formation" in the alternate sense as here applied ought to be replaced by the expression "increased sugar supply." This expression includes both the formation of new sugar from proteids and fat, and at the same time the mobilization of preformed sugar molecules. I do not doubt the existence of glycosuria produced by an increased sugar supply without interference with disturbed combustion. Its prototype is puncture or *piqure* diabetes. Analogous phenomena are found in human beings. Many cases of transitory glycosuria in nervous patients are to be regarded as such. Furthermore, I consider it highly probable that mobilization of glycogen may increase glycosuria owing to deficient combustion. Adrenalin injected into depancreatized dogs acts in this way. But the question is whether the symptoms of severe diabetes can be exclusively explained by increased mobilization and formation of sugar.

In order to realize the extreme consequences of this idea, let us imagine that the using up of sugar is absolutely undisturbed so that there is not the least difference between healthy and diabetic beings. In this case the sugar is excreted simply because more sugar is passed into the blood than the normal organs can make use of. But, if their function is really undisturbed, they would still catabolize the same quantity of sugar as normally.

This conception may be examined best by a numerical example: A healthy man will just cover his loss of energy of 2,400 calories by being given 100 grams of proteids and 500 grams of carbohydrates. The diabetic patient will in this case eliminate 500 grams of sugar and will replace the lacking 2,000 calories by combustion of body fat. According to the conception that the combustion of sugar was not at all disturbed, the diabetic subject would burn 500 grams of grape sugar, just like a normal man; but at the same time he would be obliged to have another 500 grams newly formed, and of this at least 400 grams from 200 grams of

fat. For chemical reasons this is as good as impossible. And if indeed such a surplus production of newly formed sugar should take place, it would be highly curious if just as much sugar were formed as is introduced in the shape of preformed sugar. If 100 grams of starch be given then the formation of new sugar would have to amount to exactly 100 grams; if 300 be given then 300 would be formed. This seems to be absolutely impossible.

I will put forward a further argument against the doctrine of undisturbed sugar combustion by reason of the relations in muscular work. The working muscle of a healthy man, on being given a sufficient quantity of carbohydrates, prefers this material almost exclusively. According to the doctrine of undisturbed sugar combustion, this would also be the same in diabetic patients. We will say that a walk of one to one and one-half hours brings about, in a healthy man living exclusively on protein and on carbohydrates, a combustion of 40 to 50 grams of sugar. A diabetic subject who loses 10 or 15 grams of sugar per hour in the urine ought, accordingly, if he behaved like a healthy man, also to use 40 to 50 grams carbohydrate for the production of his mechanical work, since sugar is placed at his disposal in even greater quantities than in healthy persons. Since he eliminated 10 to 15 grams of sugar in the preceding hour of rest, we ought to expect that his sugar excretion would disappear, if he really used 45 to 50 grams of sugar for the mechanical action of an hour's walk. But, as a matter of fact, the sugar elimination sinks only inappreciably by several grams. If the diabetic patient, like the healthy man, had used up 50 grams of sugar for his muscular work, then he must, strange to say, have formed in this hour in surplus just the same quantity of sugar, that is to say 40 to 50 grams more than in an hour of complete rest immediately preceding his walk. The surplus of formation would have been determined by the amount of the muscular work. This is improbable.

For both these reasons which I have put forward, I feel compelled to assume a primary disturbance of the sugar splitting up in diabetes, as the essential and primary process in severe cases of this disease. The complete working out of the view according to which diabetes is based *only* on an increased formation and mobilization of sugar would lead to the conclusion that each molecule of protein and of fat also in normal life was quantitatively transformed into sugar. This view of Seegen's has not the slightest justification. I concede the possibility of a cooperation of an increased mobilization in diabetes. I acknowledge also in a certain sense the existence of an increased formation of new sugar, but I consider this increase in sugar formation and mobilization to be only the consequence of disturbed combustion. I can recognize it only as a secondary result. In spite of the fact that sugar is wasted in the body, those organs which need sugar do not cease in their demands for sugar. They behave just the same as in a normal organism. The liver and the other producers of new sugar strive to fill these requirements; thus they form new sugar and send it to the other organs, but without any advantage for the organism.

This disturbance in the using up of sugar will in cases of severe diabetes increase in the course of time, yet it never need be absolute. As I have already explained, some of this newly formed sugar will probably always be catabolized. Even in severest pancreatic diabetes the sugar elimination may decrease or even disappear before death. This seeming reappearance of an apparently quite lost function has been put forward as a principal reason against the doctrine of the disturbed breakdown of sugar. I cannot recognize this argument. For if according to the present conception the power of sugar combustion be never quite lost, then it could also be revived under certain circumstances. But the decrease in the sugar elimination before death might also depend on a decrease in the formation of new sugar and this conception is much more probable.

According to this conception the muscles as the principal organs implicated in the combustion of sugar would come more into the foreground of the disease. The mobilizing organs, such as the suprarenal capsule and the thyroid, lose their primary part. It must not be said, however, that a *primary* muscle diabetes exists in which the muscular system is involved exclusively. The view that it needs the other organs to make use of the energy of the grape sugar has again and again been shown by the action of pancreas extirpation. And also even if the attempts to isolate the pancreas-hormone and to prove the cooperation of the pancreas and muscles have not as yet succeeded, still I believe that the solution of the problem lies in this direction.

OCCUPATION AS A THERAPEUTIC AGENT IN INSANITY.*

By MARY LAWSON NEFF, M.D.,
BROOKLYN, N. Y.

The subject of occupation for the insane has no claim to novelty. In describing a visit to York Retreat in 1798 Dr. Delarive of Geneva says, "As soon as the patients are well enough to be employed they endeavor to make them work." He makes special mention of basketry as among the occupations employed.

In the "Case of Percival," published in 1838—a book similar in some respects to Mr. Beers' "A Mind That Found Itself,"—the writer says (of himself as a patient in a hospital for insane), "My need of wholesome exercise and occupation was denied. My want of exercise produced a deadly torpor in the moral functions of my mind." We can enter somewhat into his feelings when he exclaims in another place, "In the name of humanity, in the name of wisdom, I entreat you to place yourselves in the position of those whose sufferings I describe before you attempt to discuss what course is to be pursued towards them."

In the *American Journal of Insanity* for October, 1846, Dr. Isaac Ray reviews a curious poem devoted to the subject of insanity, written by an insane patient at Duddeston Hall, England. The following quaint verses will bear quoting:

"So far thy care in each particular course
Is well bestowed;—but neither physic's aid
Nor diet treatment, thou mayst here enforce
Will health restore, if maniacs are not made,—
Aye, urged by means resistless—to walk the shade,
Or strike the bounding ball, or use the arms
In labors healthful, and with hoe or spade

*Read at a joint meeting of the American Society of Superintendents of Training Schools for Nurses and the Nurses' Associated Alumnæ of the United States, at Teachers' College, Columbia University, May 18, 1910.

Clear well the recreant weed, or fence from harms
The tender plant, and screen the exotic's embryo charms.

"Sayst thou that storms and winter's blast deny
The walk, the game, or exercise in field?—
Think not therefore that his powers should lie
In dormant sloth,—nor day-rooms' areas yield
Full exercise; and be it ne'er concealed
That spacious rooms, alike for light and air,
Are needed here; but most that uncongealed
The torpid blood may motion's blessings share:—
And sure within the mansion's bound such boon is there.

"These various games, or such as these, we need,
To rouse the dormant sense, and stir its fires;
And though 'tis not in mortal hands to speed
A cure, 'tis well if sport some joy inspires."

In recent years strong papers have been written on this subject by several writers, among them Dr. Marie in France, Dr. Tomlinson, Dr. Cohn, and Dr. Hall in the United States, and Dr. Moher in Canada.

But much as the benefits of employment have been extolled, no one will venture to say that the most has been made of this remedy. Too often those who uphold the theory have not overcome the practical difficulties that prevent its application. I recall the chagrin of a medical friend who traveled some hundreds of miles to visit a hospital whose superintendent wrote eloquently of the benefits of occupation, only to find the same pathetic rows of idle patients as those on whose behalf the journey had been made!

It would seem almost superfluous to emphasize the extreme injury that idleness produces. We know that an idle child will usually become mischievous and incorrigible. We know that an idle young man will probably become vicious and dissipated. We are not surprised when an idle woman becomes hysterical and neuropathic. We are familiar with the fruits of idleness shown in vagrancy and crime, as well as in the follies of "the idle rich." The same condition that is so pernicious that a normal person cannot withstand its fatal blight, is surely a deplorable one for those already abnormal.

Yet the duty of classing idleness with hunger and thirst and physical abuse, which humanity forbids us to allow with any class of dependants, has not yet received the recognition that must in time be given it.

In the practical carrying out of our theories, the most desirable plan is to have occupation an integral part of the daily life of the patient on the ward or grounds. Like the Kingdom of Heaven it should come "without observation." It is as unpsychological to say to a patient—in words or conduct—"you are now about to be occupied" as to say "you are now about to be amused." The announcement in either case tends to defeat its own object.

The patient who fits into the industrial departments of the state institution is provided for, so far as mere employment goes, but should be carefully included in all plans for amusement, to counteract the monotony of routine work. Patients who are already skillful, and but slightly deteriorated mentally, are, of course, easy to occupy, and many of them have enough initiative to occupy themselves if materials are supplied. These two classes, therefore, may be eliminated from the number of those who constitute our real problem. This consists of the patients unskilled in handicrafts of all kinds, absorbed in their own troubles, and often already trained to habits of inaction and apathy. There is a wide gulf between the patient who can be useful in the sewing room or laundry and the patient who is absolutely unable to do anything; yet those who fall short of being able to work several hours a day to some purpose will too often have no other resource, and what little skill they have will ultimately be lost.

If segregation is unavoidable in providing occupation, the question of classification into groups must be considered. Where a limited amount of work only can be done it is often necessary to choose between the attempt to rescue chronic cases of long standing, and to spend the same time and effort in fitting into institutional life the patients who are just passing over from the acute to the chronic stage, so as to prevent deterioration as much as possible. The latter seems the more fruitful and compelling task, yet when one finds on a chronic ward a patient ravelling out a stocking and knitting up the threads with a hair pin, the appeal is almost too strong to resist.

The chronic insane with some skill, the acute patient with increasing mental grasp, the disturbed or exhausted case who can only be amused, the chronic case who must be patiently led to take up very simple tasks, must each be differently environed and instructed. Whatever plan or classification is followed, a regular schedule of occupation, rest, and exercise, which provides properly for every hour of the patient's time, is essential. This schedule should be posted in each ward of the hospital.

In devising such a schedule the various aptitudes and acquirements of different officers, nurses, attendants, and patients can be skillfully utilized.

The question of occupation should neither be decided by the patient nor left to the initiative of the attendant. Dr. Meyer says "Occupation is a matter of prescription"—and again, that in certain forms of mental disorder "a training in normal activities and a cultivation in fruitful interests is the surest and only efficient point of attack."

The motives to be employed in interesting patients are various. Praise will influence some, competition will reach a few, an appeal to the esthetic sense will be effective with a limited number. On others, simple rewards will have a constraining influence. Altruism and affection can be appealed to to a large extent—probably as largely as with children, and many patients will embrace an opportunity to make small gifts for relatives or friends. Some will enter into preparations for an entertainment—making decorations for Christmas trees calls forth almost universal interest. Many will gladly do charity work, which, in this case, will not begin at home, but will be for dependants of some other class, such as orphaned or crippled children. Some will take their first steps toward a more normal life by forming the audience which merely watches the activities of patients already able to respond to stimulation. Later some of these spectators will develop a desire to participate in the work they have watched.

The personal note, so easily lost in dealing with large groups of people, should be used repeatedly and to the fullest possible extent. It is far better for a patient to be asked to hemstitch a particular cover for the bureau of a nurse to whom she is

attached than merely to give her a cover and tell her that it is to be hemstitched. If we will put ourselves in the place of the patient for a moment we will see the force of this distinction very clearly. One of the most successful experiences we have had was interesting patients in making little gingham aprons and other small articles of clothing for the children in an orphan asylum. The children themselves came occasionally to the hospital to sing, either on the wards or in the amusement hall, and every response to the request that some small garments be made for these children was as unanimous and hearty as would have come from a group of people anywhere. Here the appeal was made to the deeply-rooted feminine instinct of caring for children, the personal note was used in asking them to work for someone they had seen and already felt an interest in, and no doubt the longing to be of some use in the world, which the more intelligent inmates of institutions frequently feel keenly, was somewhat satisfied. The work itself, moreover, was interesting, was more or less familiar, was easily done, soon finished, and of obvious use—all most desirable features.

The last of these—its obvious use—is an essential element in all occupation work. Work for the sake of work appeals to abnormal people just as little as to normal people. Trumped-up occupations that are evidently merely a perfunctory carrying out of the idea of occupation, will prove valueless. A certain amount of institutional work, however, can be utilized, especially if a personal note is added.

The articles to be made, besides being of obvious use, should be such as are quickly finished, so that results are not too long delayed. They should, whenever possible, have color and form to give them some esthetic value. They should not require very fine muscular co-ordination. This is an important point, too often overlooked. Very simple forms of embroidery, crocheting and featherstitching are practical, if not carried on until the patient has lost interest. The signs of fatigue should be watched for in all work with great care.

Basketry appeals to a somewhat limited number. Those who are satisfied with monotonous work will frequently work week after week at basketry. By varying the colors and styles and by limiting the basket work to certain days in the week, the great objection to basketry, which is its monotony, can be minimized. Where practicable, it is one of the most useful aids in furnishing occupation.

In the use of reading matter great skill can be shown in fitting the book to the patient, in bringing it at the psychological moment, or in reading aloud the opening chapters until the patient's interest is secured. A persistent campaign in this respect will multiply the number of reading patients many fold. No dependence should be placed on the initiative of the patient here or elsewhere.

In the way of amusements music in various forms is always available, the phonograph, pianola, or music box supplementing lack of talent. Home talent programs are most desirable, in which every patient with even slight ability to entertain is utilized. Afternoon card parties where patients who wish to learn to play cards have the opportunity to do so, have been successful. Many patients have never had the "play sense" developed, and much can be done along this line. Evening card parties for both sexes in amusement hall are a pleasant addition to the usual weekly dance. A "kindergarten party" with wooden tooth-picks and soaked peas for equipment, with a prize for the best design, is one of many simple plans for evening entertainment. Tissue paper parties, shadow plays, and old fashioned games of all kinds are entirely practical.

Now and then patients will have some unusual interest or capacity that will make them easily occupied. One patient had studied millinery and for several weeks amused herself and entertained the other patients by making doll hats from cast-off straw hats, ribbons, flowers, etc., contributed by employees. Another had been employed in making stock collars and stock collars she insisted on making. As the demand was limited the supply was soon more than could be disposed of and it was with the greatest difficulty that any other occupation would be accepted. Some will prefer to work along the lines of established habit, while some will wish for constant novelty and change.

The beginnings of occupation on the acute ward of one hospital were in the room of a convalescing patient who formed a little circle around her which she called the "Sunshine Club," urging the other patients to forget themselves and do all they could for others. An "esprit du corps" grew up in this little group that was remarkable. Convalescing patients are frequently most helpful in such ways.

Dr. Tomlinson calls attention to the fact that there is the same need for actual teaching in hospitals for the insane as in schools for the feeble-minded. The same methods that a successful kindergartner would use, or a capable mother in keeping her children busy and happy, are needed on the wards of a hospital.

Preliminary training for such work is provided in the admirable courses for attendants in institutions for the insane and mentally defective as outlined in the programs of the Summer Sessions of the Chicago School of Civics and Philanthropy and the New York School of Philanthropy. Too much cannot be said in praise of such courses, nor in emphasis of the desirability of having hospitals avail themselves of their advantages.

In furnishing motives for work, we must bear constantly in mind that our patients are deprived of the ordinary stimuli of life. The stimulus of necessity is taken away, as well as that of ambition, of competition, of love of adventure, and of expressing affection by working for dear ones. Custodial care practically deprives them of all these powerful normal stimuli. It is, therefore, necessary to utilize to the greatest possible extent those remaining. The play sense must be appealed to wherever possible. One of Gelett Burgess's clever sayings is this, "There is work that is work; there is play that is play; there is work that is play, and there is play that is work; and in only one of these lies happiness." It is only in furnishing work that is play that we can fully accomplish our object.

Play has certain very definite characteristics. It imitates the spontaneous activities of childhood, where we do what we want to do. The desire to perform an activity gives it largely its psychological and therapeutic value. Play should involve as little inhibition as possible, and as large a degree of motor response. It should substitute passive attention for active, and call for a certain degree of emotion, which must be sustained throughout. It should foster objectivity and thus lessen self-consciousness, than which there is no greater menace to a healthy mental life. Any occupation that makes a person forget himself entirely is a beneficial

thing. Interesting work is, psychologically speaking, play—and in furnishing this will success lie.

In planning work for insane patients many limitations must be considered. The first is in regard to expenditure of money and the second, expenditure of time. Work requiring one nurse or teacher to devote herself entirely to one or two patients is obviously impracticable in a State hospital. There are, of course, times when it is quite worth while for a nurse to give her entire attention to one patient for a few hours, or even a few days, in order to interest her in work that will later give her permanent employment, but many beautiful and interesting kinds of handicraft require a degree of supervision that makes it impossible to use them in a State institution. Occupations producing noise, or requiring sharp instruments, or demanding constant fitting and planning, or many decisions in the course of their development, are almost entirely impracticable. It is within these limitations then that occupation methods must be devised and carried out.

Some obstacles that at first seem real can be easily overcome if the interest in the object sought is genuine. These are lack of suitable places, furnishings, and equipment, the slight expense involved, and the deadly order that often creeps into an institution—not the order that *subserves*, but that which *subverts* the uses of a home. Between these two very different things a clear distinction should be made.

Less easily set aside are some more essential difficulties. The degree of ability required to supervise various forms of work with patients of varying degrees of intelligence is not easy to secure. The teaching of an ungraded country school in the old days when the teacher had to devise and make his own apparatus required the same sort of ability. The supervising, moreover, must be done by some one in an official position that enables him to correlate all the departments of an institution or his energies will be wasted in obtaining permissions, writing requisitions, filling in reports, and paying tribute in numberless ways to that Divinity that shapes the end of usefulness too often in institutional life—Red Tape.

The custodial features of an institution and the routine which is unavoidable are often serious obstacles, which must be compromised with when they cannot be overcome. The constant changing of nurses from ward to ward, which seems more or less inevitable, greatly hinders occupation work, which depends for its success on the nurse becoming personally acquainted with and interested in each patient.

The disposition of articles made will raise many questions. Some the patients may keep, some can be utilized on the wards, some may be given or sold to employees, some may be sent as presents.

In some hospitals patients are allowed to sell their work. Work may also be allowed to accumulate and a bazaar held occasionally, the proceeds to be used in some way that will stimulate the patients to further effort. Whatever disposition is made of it, it must seem to the patient to be worth while to make the article, or interest will flag. The sending of such articles as scrapbooks, dolls' clothing, etc., to children's hospitals has been one of the most satisfactory solutions of this problem of disposing of finished work.

Patients should not be allowed to work too long at any one thing, and the day should be properly broken by exercise and amusements.

Some of the best occupations and entertainments will require the cooperation of friends of the hospital in order to make them a success. This last factor is not difficult to secure and contributes effectively to the establishment of the proper relation between the public and the State hospitals.

A card index of the patients who are to be occupied is of great value. On the cards can be noted the patient's preferences, skill, and limitations.

Furnishing of work will require a wide knowledge of handicrafts, great resourcefulness, and a large amount of preparation in buying, selecting, and arranging. Yet the work is so stimulating and fruitful that once entered upon it will not fail to hold the interest of the worker. To the executive ability required must be added the subtler gift of being able to inspire and sustain the interest of the patient. And here we find the paramount obstacle to this work—the difficulty of obtaining in the hospital service people not only of ability, but with the spirit of social service. Yet this discouragement will be overcome as the need of this work is realized. To quote from Dr. Moher, "Once that the facts that occupation is an important remedy in the treatment of insanity and that it must be administered in an intelligent and systematic manner are firmly impressed on the minds of the attendants, little difficulty is found to keep patients employed."

It is to be deplored that this subject of occupation has not received due attention in textbooks on nursing. In Dr. Clara Barrus' book on "Nursing the Insane," however, there is an admirable chapter devoted to this subject.

In carrying out personally the supervision of occupation work failure came in unexpected quarters. It was expected that reading aloud and calisthenic exercises would prove two great resources. Both were for some reason of little help to us, though this does not seem to be the case elsewhere. Perforated brass work and hammock making were tried and given up. Both these could be fitted to individual patients but did not seem suitable for group work. The reason for failure in work such as designing rugs and quilts would seem to be more obvious, since this has to be done almost entirely by those who supervise. The offering of small prizes for competitive work produced negligible results and was given up.

For outdoor games a liberal supply of rubber balls and bean bags have been used. Ringtoss, pass ball, and basketball are available, and much enjoyed. A "gymkhana" on a small scale, including obstacle races, tug-of-war, etc., has been entered into very well. The folk dances, which the Manhattan hospital has employed, are an unqualified success and most interesting to the spectator as well as to the participant. Badminton would be admirable for a yard game, requiring little training and engaging a large group.* A liberal supply of folding tables and chairs, available for use on the wards, in the Amusement Hall, or on the lawn; and of small light rockers for sewing parties has been one of the most helpful features of our equipment. A set of dishes for afternoon tea, which the patients themselves prepare, is a highly prized feature. Many of the cups and saucers have been contributed by friends of the patients. Picture postcards, to be written at any time, are accessible, with ink and pen, and give much pleasure. Such

*This game is not well known in America, but is easily learned and far more useful than tennis or basketball.

trifling things may seem hardly worthy of mention to those who have not attempted this work, but it seems to the writer that just such trifles give the *atmosphere*, so to speak, to occupation work. In the same way the simplest and crudest handcrafts are often the best, therapeutically.

The tangible results of occupation methods, while difficult to estimate in the laboratory sense of estimation, are sufficiently evident to be convincing. Large numbers of chronic patients can be reeducated to some degree of usefulness or at least contentment, and occasionally buried talents are discovered that are surprising. The deterioration of patients in the post-convalescent period is often very rapid and can certainly be obviated to a large extent. The degree to which convalescence may be hastened by securing for patients happiness and wholesome employment, instead of allowing them to struggle unaided out of depressing or confused habits of thought, is not to be accurately estimated, but is surely considerable. Shortening of convalescence, of course, means, in a purely monetary way, a saving of expense to the State and of labor to the nursing staff. How far, in certain border line cases, the prognosis would be influenced by rescuing a patient from the introspection and unhappiness that accompany illness, and substituting a more nearly normal life is not to be accurately determined. Yet it is very easy to believe that there are not a few cases where the outcome would hinge on the wise and persistent use of occupation as therapy.

A superintendent of a Canadian hospital where good progress in occupation work has been made says: "I have no hesitation in stating that the cure of a large number of patients may be attributed to occupation." Several of the superintendents in our own State have also testified to the actual curative value of occupational therapy as well as to its benefit in chronic cases.

From the humane point of view no further appeal is needed than that which is made by a ward filled with idle and miserable creatures. No more ghastly sight can be found than the rows of such patients which are to be found in many State institutions. In being deprived of an outlet for their energies they almost inevitably develop mischievous habits, taking off and putting on their clothing, hammering, clapping their hands, screaming, etc. These outbursts of unutilized nervous energy are not so often symptoms of their disease as the fruit of the conditions in which they are placed. To restore to these people an agreeable and natural way of carrying on a normal amount of activity is certainly contributing as much to lessen the sum total of human misery as any charity that we could mention. Many cases which have at various times come under my personal observation have been transformed from unhappy creatures to cheerful and contented inmates of a hospital, which they then come to consider somewhat in the light of a home. In a record of visits to some twenty-five hospitals for insane, public and private, which the writer has kept, nothing is more noteworthy than that the general condition of the patients varies in close ratio to the amount of occupation that is provided.

Never before the present—unless in the golden age of Greece—has the value of happiness been so emphasized. This emphasis lies at the foundation of several of the modern semireligious cults, and permeates the philosophy of the day. No therapeutic agent is greater than happiness. Happiness will produce added blood corpuscles; happiness will stimulate metabolism; happiness will inhibit the growth of bacteria; happiness will restore sleep and renew the powers of digestion; it will improve the functioning of every organ in the body. One of the best definitions of happiness is: "The normal functioning of every faculty and organ." This is not possible without normal stimulation and the furnishing of this is a task alike for our humanity and our medical and psychological skill. When we speak of the value of occupation as a therapeutic measure we are reflecting some of this spirit of the age, for what we are practically doing is to bring about once more the normal functioning which is, in itself, happiness, and thereby calling to our aid, as physicians, the most powerful of all therapeutic agents.

VENTILATION OF CARS.

By W. A. EVANS, M.S., M.D., LL.D.,

CHICAGO.

COMMISSIONER OF HEALTH, CHICAGO; PROFESSOR OF SANITARY SCIENCE, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

The number of people who spend a considerable part of their time in cars is small compared with the number of people who ride on cars. Practically all of those who are on cars a considerable percentage of the time are adults. For these reasons the harm done by cars is principally in the line of air-borne infections, rather than air-caused conditions.

In the case of trains, the engineer and fireman get excellent air under ideal conditions. They sit at the windows of an open cab with the wind whistling by their faces and bodies. The smoke of the engine never comes into the cab while it is on the road. Around stations, and especially in covered sheds, the engineer and fireman participate in the use of the generally fouled air.

The baggageman and the expressman work in a badly ventilated car. They usually go to work a half hour before the car starts, and remain in the car for a half hour after the train stops. The number of occupants of the car is very few and at stops the doors are wide open, and the activity around the doors serves to change the air. Conditions, therefore, are not especially bad.

The mail clerk is in an especially bad position. His car is illy ventilated. It is usually hot and dusty. He goes to work in the car hours before the train starts. A mail car standing in a station will not ventilate. It is hot, offensive, and dangerous. The government should not tolerate the health conditions which prevail on mail cars.

The conductors and brakemen on passenger coaches spend hours each day in bady ventilated cars. The caboose of a freight car is more open, leaks more air, than passenger coaches; it contains fewer people. The conductor and brakemen are

in and out more. For these reasons the train crew of a freight train is better off than the train crew of a passenger train.

On an electric, interurban, street, or elevated car with an enclosed platform the motorman and conductor, remaining on the platforms have healthier places than the passengers. If the front vestibule is used as a smoking compartment the motorman loses some of this advantage.

The majority of the inhabitants of cars are the passengers, and the arrangements for passengers deserve especial consideration.

The ventilation of cars is of importance only in the late fall, the winter, and the early spring. As soon as the outside temperature is high enough the passengers take advantage of the easily secured currents through doors and windows and get comfort and health. It is only when the outside temperature is so low that unwarmed currents are uncomfortable that the passengers close all the openings which they possibly can and the air becomes fouled.

A car in use is being hurled rapidly and violently through the air. In consequence, leakage around doors and windows is much more of a factor in car ventilation than in any other installation. It is as though you were building a room expecting the air to blow against it at twenty to eighty miles an hour all the time. You would not need any ventilation except by windows and doors in the late spring, the summer, and the early fall, and it would be necessary to figure on heavy air leakage in your heating calculations for cold weather.

Even the tightest of cars, such as Pullman sleepers, while running rapidly, will leak enough air to take care of a small passenger load.

Another point which must be borne in mind in car ventilation is that the passengers are from many sources. You cannot assemble a hundred men together without finding that a heavy percentage of them have pneumococci in their mouths; a certain percentage will have tubercle bacilli; some will have ordinary cold bacteria; some influenza, and occasionally one will be a diphtheria carrier. When these men are jammed closely together, as they are in a street car during the rush hours, they can certainly be expected to infect the air of the breathing zone. Many will cough and do other violent expiratory acts during a ride of thirty to forty minutes. This still further adds to the harm which results from bad car ventilation. Many will smoke. The air of a smoking car always has a high CO_2 content when the car is in use. This, however, is of minor consequence compared with the spitting and concomitant acts which can be expected with smoking.

From the standpoint of pollution of the air by odors, no other room approaches the vestibuled day coach, loaded with passengers, and making a night run on a train with infrequent stops, say at intervals of two hours. The passengers remove their shoes, loosen their clothing, and go to sleep in all sorts of postures. Their mouths are open and dry, and there are breath odors. The shoeless feet contribute feet odors. There is an addition of body odors. The food in the lunch baskets—often a day or more old—adds to the bouquet. The vestibule prevents the relief that formerly came from the exposed door.

In a sleeping car the circulation of air is impeded by curtains, and every resource is employed to make the car tight, but conditions are much better than in the day coaches. The number of passengers is less, the passengers are sleeping in natural positions, and their bodies are cleaner.

There are two general types of ventilation in cars as elsewhere—the plenum and the vacuum systems. The vacuum system is that in which there is a vacuum in the outlet duct which sucks the foul air from the car and fresh air comes in to take its place. The plenum system is that in which fresh air is forced into the car and the foul air driven out.

In cars running in the open country it would seem foolish from the mechanical standpoint to employ any other than the plenum system. In surface and, possibly, subway street cars a vacuum system with free inlets properly located has its advantages, and may be best.

A railroad car (passenger, Pullman, baggage, express, or postal) hurling through the air at the rate of fifty miles an hour has an air pressure of ten pounds per square foot. This furnishes more power than any blower fan in use. If a ventilating duct has its open face exposed to this current of air a volume will drive in many times the need of the inhabitants of the car.

The requiremets, then, are these: (1) To regulate the volume of air taken in for the different car speeds; (2) to keep down the dust content of the air taken in; (3) to warm the air before it is introduced into the car; (4) to introduce it at the right place; (5) to provide proper exits for the foul air, properly located.

1. Discussing the first of these points: Sometimes the amount of air taken in is regulated by cut-offs operated by the brakeman. Such is the case on the Pennsylvania Railroad. Here the brakeman sets the ventilation soon after the car leaves the station. A better system is that in use on the Northwestern Elevated, in Chicago. They use a small cut-off device in their intake. When the car is standing still the blade hangs vertically and the duct is fully open. As the car speeds up, the blade rises toward the horizontal and diminishes the size of the duct proportionately. There is never any question as to getting air enough when the car is under way. The provision must be to keep the quantity down.

2. In a railroad train the dust is from two sources. The smoke tends to hang along the top of the car. Ducts at this level are liable to catch a good many cinders and much smoke. The pounding of the cars raises a good deal of track dust. The Pennsylvania Railroad takes in its air above the roof of the car and uses screens to keep out cinders. Such an opening has the additional advantage of being out of the way. A disadvantage is the amount of friction from the length of the ducts. In the case of elevated trains the ducts are advantageously located in the floor of the car and take air in from below the floor line. The question of the location of the ducts in surface street cars is somewhat more difficult. The short ducts, when the inlets are below the floor level, present great advantages. The only disadvantage is the dust. The swirl of dust raised by a street car can be seen to hang a little in the rear of the car, except when it is stopping. The dust at the floor line of the car is far less than superficial observation would indicate. Opening through the floor can be provided with cheesecloth dust arresters when this is found necessary.

3. The keynote of car ventilation is warming the

air as it is taken in. A street car jammed with passengers will have only ten cubic feet of air per passenger. If, then, 2,000 cubic feet of air per passenger per hour is furnished the air must be changed two hundred times per hour, or, say, three times per minute. No passenger will allow such a volume of air on a cold day without the air having been previously warmed. Even if these figures are markedly diminished, the passengers will not tolerate the air if it is cold. On the other hand, the radiation in the car is usually placed under the seats or in out-of-the-way corners of the car. The result of this is that the seats are usually scorching hot and the remainder of the car is uncomfortably cold. The efficiency of the radiation is at a minimum because there is no provision for heat distribution. The proper solution is to introduce the fresh air into the car through the radiation. In this way the air is warmed to a point where the passengers will tolerate ventilation. The radiation is cooled and the cold parts of the car are warmed; the car temperature is made more nearly uniform; the efficiency of the radiation is increased.

4 and 5. In the installations commonly in use, the air is theoretically taken in through the deck sash. The most efficient intakes we have found in such installations are the leaks around doors, windows, and joints. We think that the air entering through such openings when the car is crowded, when it is moving rapidly and when the outside temperature is around 10° F. above zero, will amount to 10,000 cubic feet per hour. Deck sashes we have found to be very unsatisfactory for ventilation purposes, either as inlets or outlets. They will sometimes act as inlets, sometimes as outlets, and sometimes as neither, according to the direction and force of the wind, and according as the car is gaining speed, speeding, or losing speed. The great volume of air which comes in through those sash openings which are acting as inlets will flow straight across and out of other sash openings acting as outlets. The best results in deck sash ventilation are had by opening the sashes forward on the windward side of the car for inlets and opening the rear sashes of the lee side of the car backward to serve as outlets. The theory of the use of deck sashes for inlets is that the cold air will mingle with the warm air and will therefore be somewhat warmed before it strikes the passengers. But no dilution system is ever safe with less than 1,800 cubic feet of fresh air per passenger per hour, and in the case of crowded passengers from miscellaneous sources 3,000 to 5,000 cubic feet is a necessity.

Now, cold air must be heated by something. The heating agencies in a car are the passengers and the radiation. Putting the air in at the deck sash and having the heat of the car heat it before it reaches the passenger may add to the passenger's comfort. It does not save any in the expense of heating. If the fresh air is warmed enough to keep it from being uncomfortable and is then discharged into the car below the seat level and the foul air is taken out through ducts around ceiling lights, a somewhat uniform upward flow of air is maintained in the car. The partial separation of the fresh from the foul air makes it possible to reduce the volume of air required for each passenger. With such an arrangement of inlets and outlets, the Chicago Department of Health thinks it safe to reduce the air requirements to 400 cubic feet per passenger per hour, and has had ordinances drawn along these lines.

Satisfactory results cannot be had with so low a quantity of air per passenger if cross currents and consequent dilution are to be brought about by open deck sashes. As car builders usually build deck sashes in cars, they should be closed in cold weather or only used in such a way that they will be outlets, *i. e.* by only opening those which are on the rear end of the car and on its lee side. A distinct gain in car ventilation will be made when cars are no longer built with deck sashes.

The most valuable contribution to the subject of car ventilation is to be found in the Master Car Builders' report for 1908. There are but two points which in my judgment should be changed or supplemented. The first suggestion is a change; the second a supplement.

The statement is made that suburban cars do not need any planned ventilation. This is because of the frequent stops and frequent opening of doors. We have made many observations and CO_2 determinations to ascertain the accuracy of this conclusion. It is not correct. It probably was with old-styled, open-platform cars, with doors opening directly forward; with vestibule platforms and side doors it is not true. Suburban cars and street cars with more than two inmates between stops need planned ventilation.

The second point relates to passenger coaches and sleepers standing in stations or moving slowly in narrow rights of way in cities. The proper ventilation of day coaches and sleepers makes use of the force of the car through the air to drive fresh air into the car and foul air out of the car.

But a car at rest is deprived of this force. Therefore, force should be otherwise supplied, else the car quickly gets hot, humid, close, and its CO_2 content rises. Such cars should be provided with fans in the inlet ducts; these fans so adjusted that they will start as the car stops and stop when it starts.

A most important question is: Does a surface street car need fans to get fresh air into the car or to take foul air out of the car? I am sure that fans would give a more even supply of air and will be found more satisfactory, but I am not prepared to say that there can be no satisfactory street car ventilation without them.

To summarize:

1. Bad car air is very prone to cause infections with (*a*) colds; (*b*) influenza; (*c*) pneumonia; (*d*) consumption; (*e*) possibly diphtheria, scarlet fever, and cerebrospinal meningitis.

2. Postal clerks, railroad men, and street car men, and other habitual riders are prone to the bad air intoxications: (*a*) headaches; (*b*) sluggishness; (*c*) flabbiness; (*d*) sleepiness; (*e*) anemia; (*f*) proneness to infections.

3. Jammed, crowded cars are most dangerous.

4. Ventilation should always be through air entering low down, passing over or through radiators and flowing into the car below the seat line, and foul air leaving through the ceiling by ducts arranged around the lights.

5. The air should enter the car at 50° or above.

6. Street cars when heated should not have the temperature pass 55° F.

7. In sleeping and passenger cars the temperature should not pass 65° F.

8. Deck sash ventilation is never satisfactory.

9. The air inlets should be so placed and so screened as to minimize the entrance of cinders and road dust.

10. The inlet ducts should be as short and with as few angles as possible.

11. In sleeping cars and day coaches there should be fans in the inlet ducts. These should run only when the car is standing.

12. Greater uniformity is had in street car ventilation when fans are used to move the air.

The work upon which these conclusions are based has been done by men in the Chicago Department of Health and under the direction of Dr. F. O. Tonney, Director of the Municipal Laboratories.

DIAGNOSIS AND TREATMENT OF OSTEAL TUBERCULOSIS WITHOUT ABSCESS FORMATION.

By BAYARD HOLMES, M.D.,

CHICAGO.

In the winter of 1886-7 Dr. Christian Fenger resected a knee for tuberculosis of the epiphyses of the femur and tibia. The operation was done in a private house and it was my duty as his assistant to prepare an operating room and sterilize instruments and dressing. It was my great privilege to hear him argue with himself for several days previously, making the diagnosis and setting down the indications for treatment. It is to quote one of his expressions of primeval professional verities that this long preamble is undertaken. He said in the most serious judicial and oracular manner, as if translating from deep conviction, "It is a crime to amputate for joint tuberculosis any longer."

During the succeeding twenty-five years surgical diagnosis has made further strides into the jungle of the unknown. The mystery of tuberculosis has been explored and solved. The confusing acceptance to our hypothetical predictions have come under thoroughly understandable laws. Now it is possible to say with equal solemnity and judicial finality, "Typical resection for joint tuberculosis is a surgical apology, if not a professional crime."

The tendency of surgery during the past twenty years has been from desperate adventure to rational opportunity. Drainage of abscesses of the brain, so interesting and awe-inspiring, is now rarely undertaken, because so many antecendent mastoid antrums are obliterated with the hammer and chisel. The dramatic performances of Estalnder and Schede have given way to the simple procedure of resecting an inch or two of rib under a five-minute anesthesia. The drainage of abdominal abscesses and the treatment of general peritonitis are exceptionally undertaken because so many appendices are removed at the first attack of appendicitis and so many gall bladders are evacuated before calculi have produced pressure atrophy necrosis of the wall of the cystic duct. Mammoth ovarian tumors are no longer extracted because little ones are recognized and taken out through an inch and a half opening. Stones are exceptionally removed from the common duct because they are attacked while they are still in the easily managed gall bladder. To drain an abscess of the brain, to resect the chest wall, to drain the periappendiceal abscess, to remove the mammoth ovarian tumor, and, which is the point, to resect the tuberculous joint are all, and each of them, the surgeon's apology for the inefficiency of our general professional service. *The surgeon's opportunity is passed when joint resection is necessary.*

Joint tuberculosis is always a metastatic process. The bacilli reached the joint and bone through the circulating blood.

Joint tuberculosis has two distinct primary anatomical forms: Osteal tuberculosis and synovial tuberculosis.

The curve of frequency of joint tuberculosis has its point of greatest frequency in the second decade of life, but the peak for primary synovial tuberculosis is eight years earlier. The peak of maximum frequency in tuberculosis of males is seven years in advance of that of females. The sexes as might be supposed from the early appearance of the disease are almost equally affected (52:48). Heredity plays an insignificant part in etiology, although Vogel found tuberculosis in the families of 55 per cent. of his 349 cases of joint tuberculosis.

Trauma is often referred to in the history of osteal tuberculosis, but careful consideration of the best studied cases leads one to think that injuries had little etiological significance and gained their prominence only because they first attract attention to an inflamed spot. The acute infectious diseases, grippe, pneumonia, bronchopneumonia, and the whole line of children's diseases play a much larger part by diminishing the resistance of the body through the saturation of the germicidal power of the blood and through the errors of nutrition which follow the indoor confinement, the loss of appetite, and the diminished secretion. The influence of house dwelling, and especially house confinement, is obvious in the retarded peak of frequency in the curves of women.

In order to make my subject manageable, it is restricted to osteal metastasis. The primary focus is in the respiratory or alimentary tract. The patient has long been tuberculous. The diseases may or may not have been recognized. Some one or several of the predisposing factors have diminished the germicidal power of the blood and the tubercle bacilli invaded and are carried through the circulation to many parts of the body. Just as every plant has its habitat on mountain, in valleys, in the woods, or in open marshes, so has the tubercle bacillus its habitat in the human body, even in distinct and limited parts of the bones themselves. Clinical experience and experimental research have shown that the habitat of the tubercle bacillus is in the epiphysis, and in that part of it in which the capillary circulation is most liable to fluctuations in two or more directions. If we take, for example, the epiphysis of the femur, which is supplied with blood from the periostium and from blood vessels entering it at the crucial ligament, and is completely shut off from nutrition from the shaft by the epiphyseal cartilage, then we will note that there are two points in this epiphysis receiving blood from practically every direction, except from the shaft side and the joint side. In this hub the blood streams are apt to flow first one way and then another, thus giving time for a while blood corpuscle containing tubercle bacilli to become lodged permanently in a capillary and thereby setting up a focus of tuberculosis.

Every epiphysis is similarly supplied with blood from variously limited sources and each one furnishes one or more loci which may eventually become foci of tuberculosis. About the knee, for example, there are two such points in the femur, two in the tibia, one or two in the patella, and one in the apophysis of the tibia.

The foci themselves are found in two physical conditions which are of great clinical significance.

and this fact is an added indication for such study of osteal tuberculosis as will lead to its early recognition. In the one case, the focus is composed of a mass of granulation tissue, half a centimeter in diameter or, if longer neglected, still larger size. In the other case the focus is composed of a mass of perfectly firm dead bone, surrounded by a thin wall of granulation tissue containing the tuberculous infection.

In both cases the epiphysis has undergone a most significant and diagnostic vascularization, which is termed osteoporosis, or fatty degeneration of bone. In both cases the periosteum surrounding the epiphysis and even all the other elements of the joint capsule have undergone the same vascularization and have become thick, firm, edematous, and appear to be tender.

If each of these forms of osteal disease are neglected and allowed to take the most fortuitous course, they will each make a perforating channel in the direction of the joint capsule and eventually produce a periarticular abscess in tissues of less hydraulic pressure than the interior of the epiphysis. The materials composing the granulation focus will gradually be extruded into the periarticular abscess by this difference in hemostatic pressure, and when all the tubercle bacilli and all the detritus and all the granulation tissue have been forced out of the cavity in the bone into the cavity in the soft parts, and at last evacuated, recovery of the bone tuberculosis may result. Such a fortunate termination, however, cannot be expected under any circumstance when the focus is of the sequestrum sort. The dead bone will always remain in the epiphysis. It is because this result is so disastrous that I would urge the need of the earliest possible diagnosis and the obliterating operation, which I here propose.

The difficulties of a clinical diagnosis at so early a stage seem at first almost insurmountable, especially when we consider that the patients are frequently children and always in the early decades of life. When the osteal disease comes on in the later decades, the diagnosis is clouded by the very fact of the age of the patient. Not much reliance can be placed upon the negative portion of the history; the fact that there is no injury, no primary infection which would diminish the vitality of the patient is of trifling significance. The onset of pain, especially in the morning and going away with the use of the extremites, the slow onset of loss of function of the adjoining joint, the rigidity and at last the atrophy of the muscles about the joint are much more significant. Such a condition follows any disease or injury in the neighborhood. To determine the tuberculous nature of the affection, we must rely upon all the constitutional and laboratory findings of the disease, and upon the local findings of the osteal focus. These are the tenderness on slow deep pressure with the ball of the thumb immediately over the focus, and later the edema of the overlying periosteum, and the evidence of rarifying osteitis of the epiphysis, which the *x*-ray photograph ultimately shows. In a very few instances the sequestrum focus itself makes a distinct shadow in the midst of the fatty degenerated epiphysis. Great reliance can be placed upon the combination of these local findings with a leucopenia, 4,000 to 6,000, an adequate atrium of infection, a consistent manner of life, and the Pirquet or other tuberculin reaction.

It must not be understood that the diagnosis is to be made at a single sitting. The clinical observations should be continued over a number of weeks. The temperature and pulse reactions, the repeated blood examinations, and the careful local study of the affected part must exclude the less serious and more diffuse infections. It would consume too much time to go into the differential diagnosis, but the hysterical joint, the trophic degenerative process, the gonorrheal periostitis, the affections of arthritis deformans, the albuminose periostitis of Schlange, the syphilitic periarticular diseases, and, in acute cases in children, the pneumococcus infections must all be eliminated by processes that are sufficiently obvious.

During this diagnosis the hygienic treatment should be carried out in the most rigid manner; the patient should be on the best possible diet with all corrective measures used to promote the best nutritive conditions. He should be in the open air and be restrained from exercise as long as there is any fever, and be encouraged to take such exercise as will promote his nutrition. During all this time the condition of the epiphysis should receive the most discrimnating attention. If it gives less trouble, if the rarifying process is arrested, diminished, or disappears the cure may be left to nature, but if the pain, the loss of function, and the periostitis increase, if the sequestrum shows itself in the skiagraph, then a more vigorous method and one which I will illustrate by an example must be considered.

In 1894 a physician brought his sister to me with the diagnosis of a tuberculous knee. She had already been sick for two years and had been on her crutches most of the time. Part of the time the knee had been in a cast. It was evidently a very chronic manifestation as it had appeared first when she was seventeen years old and apparently subsided for two years and then came on again, after an unusual hardship and exposure in the mountains. The pain and loss of function were the prominent symptoms. She had moderate nutrition, but the fickle appetite of a house-kept person. My first investigations led me to discover the primary lesion in the upper part of her left lung. This was apparently an arrested disease, which had been successfully combated by her residence in Colorado. The osteal disease had gone on so long that there was a general periarthritis and some effusion into the joint. A few weeks of massage and elevation of the leg removed this impediment to diagnosis. It then appeared that there was a sensitive point on the inside of the leg just opposite the location of the focus in the epiphysis of the femur and in the adjoining location of the epiphysis of the tibia. These two points of tenderness were consistently present for several weeks. At the end of four months' observation, and at a time when we had fewer means of confirming the diagnosis, I undertook an extra articular évidement of the foci. The operation was done under the strictest antiseptic precautions, the skin incised above the epiphysis, the periosteum reached, and pushed away from the bone and held downward by the retractor so as not to open the joint capsule. Then with a Volkmann sharp spoon the rarefied bone was dug out to the location of the focus. The very rarification of the bone confirmed the diagnosis. After the focus had been removed, which was rather uncertainly distinguished by the difference in density between it and the osteoporotic surroundings, the cavity was filled with sterilized iodoform, a small bone, drain-

age tube placed down to the periosteum, the periosteal flap turned back against it and the skin wound closed, except for the end of the tube. The same operation was done upon the epiphysis of the tibia, and the whole leg placed in a dressing and immobilized with a plaster cast. After five weeks the cast was removed and the bone drainage tube found almost completely extruded, leaving an extremely small tuberculous sinus. This scabbed over and disappeared after a few subsequent dressings. The patient was required to walk with crutches a few days after the first operation and was kept out of doors most of the time. During the two months following the closure of the wound massage and passive motion of the joint were kept up until a relative restoration of its function appeared. Then she was required to walk without crutch or cane.

Six years afterwards I had the privilege of examining this knee and finding the limitation of motion very slight, but the patient had suffered a relapse of her pulmonary disease and was then undergoing treatment for that condition.

In a recent number of the *Lancet-Clinic*, March 12, 1910, I reported a case which had been similarly operated upon fifteen years ago. In that case an *x*-ray picture made of the bone fifteen years after operation showed absolutely no deformity of the epiphysis; the measurements of the knee and the function of the joint had remained perfect during the whole time. I have operated upon patients for a similar osteal focus in the bones above the ankle, about the elbow, at the shoulder, and at the wrist, and have had uniform success. My youngest patients have been less than five years old, and the oldest one was a man forty-five years old with a primary osteal tuberculosis of the olecbronon.

Evidement of an osteal focus before abscess formation should be undertaken when hygienic and dietetic measures have proved ineffectual.

The duration of such preliminary treatment as is necessary to make the diagnosis must extend over months, but should not permit the perforation of the cartilage and the initiation of a synovial tuberculosis, which makes the apologetic operation of joint resection necessary.

92 State Street.

THE TREATMENT OF THE MORE COMMON DISEASES OF THE SKIN.*

By EDMUND LINDLEY COCKS, M.D.,

NEW YORK,

VISITING DERMATOLOGIST, RANDALL'S ISLAND AND HARLEM HOSPITALS; CLINICAL ASSISTANT, N. Y. SKIN AND CANCER HOSPITAL.

The session before the last I had the pleasure of reading a paper on the diagnosis of "The More Common Diseases of the Skin," promising you to take up the treatment at some future time. Of this promise, I was reminded by your worthy President, just two weeks ago, and on account of this short notice, I shall ask your indulgence.

Acute infantile eczema, among the many variegated diseases of the skin, is probably the condition that presents the most pitiful aspect and most urgently appeals to the physician for immediate relief. While promptly responding to suitable management, this dermatosis exhausts not only the strength of the little patient, but severely taxes the patience of physician and attendants, unless a systematic course of treatment is followed. The entire evening might be profitably devoted to the study of this important subject. At the Fordham Medical University two lectures are assigned to this disease. Given a case of infantile eczema, it is necessary to ascertain in the first place whether the patient is a breast-fed or a bottle-fed baby. This question of the milk supply in all its particulars must be minutely inquired into, not taking anything for granted. It is a subject that bears the most detailed investigation, and includes the correcting of faulty conditions on the part of the nursing mother, such as worry, malnutrition, overnutrition, constipation, dyspepsia, abuse of tea, coffee, or beer. Your little patient's sufferings will be further aggravated until these various irregularities have been rectified. Artificially nourished infants must have their milk modified, so as to meet individual requirements. The majority of these bottle babies are too fat, and need a reduction in the supply of cream and sugar. All instructions given to the mother will have to be repeated over and over again. The same remark applies to the local applications. My experience in consultation practice shows that the physician with his professional mind finds almost the same difficulty in remembering directions as do the untrained parents; and surely our nurses are entitled to forbearance when the physician's inability to grasp all the important points is kept in mind. The eczematous baby does not vomit, and this safety valve failing, it does not get rid of an excess of food. The condition is relieved by Phillip's milk of magnesia, half a drachm to a drachm twice daily. At the same time, the remedy acts gently on the bowels, diminishing flatulency and curds, and lessening the frequency of the stools. In case the little patient is nursed at the mother's breast, she should be given a mixture of acetate of potassium, tincture of nux vomica, and fluid of cascara sagrada in the rhubarb and soda mixture.

Treatment.—A principal rule is this: Not one drop of water externally, but water in abundance internally. Sweet oil, or rose water ointment, in gentle topical applications, suffices for the removal of the daily accumulations. If there is a pouring out of serum, a lotion of phenic acid ℥xv, ichthyol ʒi, zinc oxide ʒii, magnesium carbonate ʒii, and lime water ℥iv, should be applied with a piece of gauze or a handkerchief every hour if needed, or until the oozing subsides. In the presence of crust formation, especially on the face, a cap is made of unbleached muslin, with holes cut out for the eyes, mouth, and nose. Then an ointment consisting of salicylic acid gr.iv, ichthyol, ℥xx, zinc oxide gr.xxx, and rose water ointment ℥ii is spread over the outside of the cap; the back of the cap is then placed against the child's face, and the cap is turned outside in. The tape strings sewed to each corner of the cap are now tied. The oozing promptly ceases, the pruritus is relieved, and the patient sinks into his first refreshing sleep. Lesions elsewhere on the body are to be treated after an analogous fashion. Varnishes exclude all the air and hold back the secretions. I am not especially in favor of their use in children. A light splint applied to the flexor surfaces of the arms will prevent the child from scratching.

Eczema ani in the adult is often a sequela of fistula, hemorrhoids, or constipation. In these cases an application just before retiring of very hot water, immediately followed by an ointment of ol. rusci ʒii, in ung. zinci oxidi ʒii often acts like

*Read before the Harlem Medical Association May 4, 1910.

magic. A series of varicose ulcers were treated at the Harlem Hospital by first getting the leg surgically clean, followed by an ointment of scarlet red (2 per cent.), changed once in three days. The effects of this treatment proved little short of wonderful. Eczema in the adult in its different stages must be treated according to the conditions present when the patient first comes under observation. A soothing lotion of calamine and zinc may be all that the case requires. The pruritus may be relieved by an addition of phenic acid. A dusting powder of bismuth, tannin, salicylic acid, and starch may be very acceptable. Dry eczematous patches require a stimulating application, such as ol. cad., pix liquida, or ol. rusci, which are very helpful in relieving the pruritus. These remedies, moreover, are parasiticides and stimulate the parts to a healthy action.

Erythema multiforme and the urticarias are groups of skin diseases most benefited by a general bran bath. All rubbing of the body surface should be avoided, as further increasing the irritation. After this bran bath the patient is placed between sheets without drying, covered lightly, and a lotion of magnesium carbonate ʒii and zinc oxide ʒii in lime water ʒiv is applied freely until the pruritus is relieved. Menthol is sometimes recommended, but in my experience the patient is apt to be chilled by its use. It must be kept in mind that these manifestations are merely the external evidence of an internal derangement. The patient should be treated accordingly. It goes without saying that all opium derivates are to be avoided. The vasomotor complication is relieved by pilocarpin gr. 1/6, hypodermatically; but the patient must be carefully watched, as a severe bronchorrhea may follow. Occasionally, spoiled little Johnnie is brought to you with urticaria lesions almost the size of a cart wheel, and, eliciting the information that Johnnie is allowed to eat of everything, in your righteous indignation you deliver a lecture on dietetics to the mother; but on looking for approval or watching the effect of your harangue you may behold to your discomfiture the deeply impressed parent shaking her finger at her dutiful offspring, and asking him if she has not time and again told him exactly what the doctor is saying now. Such a case looks indeed hopeless and you feel that it is one of love's labor lost. To bring it to a successful issue necessitates a new mother or an inexhaustible stock of forbearance on the part of the physician. In mapping out a diet list in these cases, eggs and peanuts or peanut butter must be particularly avoided.

Scabies, in private practice, is found to be no respecter of persons. Pediculosis, corporis, capitis, and pubis are not so frequently met with. It is advisable in these cases to keep the diagnosis sub rosa, especially in the case of female patients. The correctness of the diagnosis will invariably be questioned, and the patient's confidence will be lost. The parasite of scabies, or the itch mite, is positively destroyed by the following measures: The patient is soaked for half an hour in a hot bath to which have been added tincture of green soap ʒiv, and the same amount of borax, giving particular attention to the webs between the fingers and making vigorous use of nail brushes. He is then dried, and an application of equal parts of balsam of Peru and vaseline is rubbed into the entire body, except the scalp, for ten minutes. After this the patient is put to bed, and the cleansing bath is followed by a restful sleep. The mite does not survive this treatment; soothing applications may still be necessary, however, to relieve the dermatitis due to scratching.

Pediculosis capitis is usefully treated by means of crude oil, one ounce night and morning. A rubber bathing cap is continually worn, and the scalp may be shampooed twice a week. The pediculi are generally killed by the first application, and the nits fail to hatch after the second or third repetition. The nits should be removed by stripping the hairs to which they are adherent toward the scalp. Pediculi pubis are destroyed by beta-naphthol ʒi, saponis viridis ʒii, in vaseline ʒi. Patients suffering from pediculi corporis are cured by a complete change of clothing, plus a bath.

Tinea tonsurans, or ringworm of the scalp, and its sequelæ belong to the most serious skin eruptions of childhood, on account of the extreme contagiousness, keeping the patient out of school, and in fact confining him to his home. At times the affection proves destructive to the hair follicles. The most stubborn case will yield to persistent epilation, preceded by a bichloride shampoo, and followed by the topical application of ung. hydrarg. ox. rubr. ʒii, ung. sulph. ʒi, ung. zinci ox. ʒv twice daily with a stencil brush. The constant wearing of a muslin skull cap is advisable. Ringworm of the body is successfully treated by means of formaldehyde, tincture of iodine, and the above ointment.

Alopecia Areata.—In the treatment of alopecia areata very good results have been accomplished by means of applications of pure carbolic acid. The application is made quickly, not neutralized; postponing the second application until the phenic reaction has subsided. The use of general tonics is indicated in these cases.

Impetigo Contagiosa.—This affection seems to be the source of considerable trouble to the practitioner in regard to its diagnosis as well as to its treatment. It is a skin disease characterized by a discrete eruption, consisting of vesicles which may become pustules as the result of inoculation with pus germs. Antiseptic measures are called for, and the treatment should be attended to by the physician himself. The child is held in the arms of the nurse, and the pustules are opened, or the dry crust is removed, as the case may be. Then the base is cleaned with peroxide of hydrogen, and the parts are dressed with an ointment of ichthyol, 2 per cent., in white precipolate ointment, 2 per cent., to be changed twice daily. In a few days your patient should be well.

Intertrigo.—The secretion of intertrigo, in adults as well as children, is always acid in character, resulting in excoriation. This factor must be taken into consideration for the treatment, and a careful examination be made of the urine, feces, and perspiration. The parts should be separated and a dusting powder kept constantly applied, made up of tannic acid, Bismuth subnitrate, powdered boric acid, and starch, or ichthyol ʒi in the calamine and zinc lotion. If the buttocks are involved, a diaper should be placed under the child and another above it, not to project between the legs and to be changed at once as soon as soiled. All the moist parts must be kept separated.

Eczema seborrheicum, another annoying lesion which especially affects the gluteal region in the infant, promptly responds to a solution of resorcin ʒi, in liquid albolene ʒiv. In adult cases ung. hydrarg ammonatii, full strength, is very serviceable.

Tinea barbæ, or ringworm of the beard, is a dis-

ease the treatment of which is apt to prove very tedious and at times painful. From fifteen to twenty hairs are to be epilated at each sitting. The ung. hydrarg. ox. rub. is to be applied by the physician, if the patient is able to afford it. The relief secured by it is rapid, almost magical. Sycosis nonparasitica does not call for epilation, unless the hair is floating in pus. A 4 per cent. ichthyol solution in equal parts of lanolin and rose water ointment is my favorite prescription.

Tinea versicolor, or liver spot, is due to a vegetable spore. It is treated by soaking the patient in a hot alkaline bath for half an hour, with thorough scrubbing of the parts, followed by drying. A saturated aqueous solution of sod. hyposulphite is applied with friction every day during one week. The patient must be instructed to cleanse the pubic region very faithfully, or a relapse is sure to follow.

Leucoderma or vitiligo is not particularly benefited by any known measures, and little can be done beyond retarding the progress of the disease. Chloasma is the opposite condition, and in these cases the patient may secure cosmetic relief for several months by means of a strong ointment of salicylic acid or the salicylic plaster, which causes an exfoliation of the pigmentary layer. Repeated courses of this treatment may of course be instituted.

Urticaria, dermatitis medicamentosa, erythema multiforme are disfiguring cutaneous eruptions due to the absorption of intestinal toxins and their effect on the vasomotor system. Hence the treatment must be both systematic and symptomatic. All demonstrable causes must be removed, and the intestine be cleaned out. Extreme restlessness on the part of the patient may be treated by tincture of cannabis indica, ten drops every three hours, increasing if necessary, which will relieve both the pruritus and the excitement. Menthol, phenic acid, and liquid albolene are very soothing local applications.

Acne.—Although one of the most stubborn cutaneous affections, acne will yield to persistent and judicious treatment. Hearty cooperation of the patient is the first essential toward a cure. Strict rules are laid down in regard to avoidance of all cakes, pies, or pastries, and salt meats as well as fish are absolutely prohibited. There must be no ice cream sodas or eating between meals. The flabby, indolent, obese patient must be aroused and forced to take an active interest in life. The constipation and general sluggishness of these individuals are greatly benefited by a mixture of potassium acetate ℥v, fl. ext. of casc. sagr. ℥ii, fl. extract of rumex ℥iii, one drachm to be taken half an hour before meals in half a glassful of cold water. Anemic patients should receive the best of food, eggs, milk, cream, rice, farina, hominy, nourishing soups, and meats. Light feeding between meals is admissible. Outdoor exercise must be insisted upon, in spite of the patient's reluctance to cooperate in this direction. My favorite prescription is: R. Ferri citrat. ℥ii, magnesi; sulphatis ℥v, strychn. gr. i, syr. zingiberis ℥i, aq. ℥iv. This is a good tonic, acting on the bowels, and is promptly followed by visible improvement. If the case is one of comedos or pustules, a rapid impression can be made by an application of green soap ℥i, resorcin ℥i, salicylic acid gr. v, rose water ointment ℥ii at night, washed off in the morning, to be reapplied at night, or until a fair desquamation has been obtained. A slower method consists in the expressing of all comedos and incising of the pustules, the bases to be touched with hydrogen peroxide, followed by carbolic acid. The outcome is primary union without a scar. The lotio alba—sulphureted potassium and zinc sulphate—is usefully applied at night, following the employment of hot or cold water, according to the result desired. Slight friction with a towel is very serviceable. It is necessary to keep these cases under close observation, repeating the instructions at each visit until the patient is not only thoroughly familiar with them all, but has become convinced of the advisability of carrying them out.

Psoriasis.—The treatment of this skin disease—the last to be considered to-day, but not the least in order of importance—is both external and internal. The former is preceded by an alkaline bath, and the scabs are then removed while the patient is still in the tub. After he has been carefully dried, an ointment consisting of salicylic acid gr. i, green soap ℥ii, chrysarobin ℥ii, oleum rusci ℥i, and vaseline ℥ii is applied by means of a stencil brush to all lesions below the clavicle. Those above the clavicle are to be treated with the ammoniated mercury ointment. Of late I have been pleased with a solution of ℥ii of chrysophanic acid in chloroform. Each lesion is touched, using absorbent cotton which has been twisted around an applicator. The chloroform evaporates and leaves behind the chrysophanic acid which is covered with a light coat of ichthyol. In this way a varnish is formed which prevents the clothes from becoming soiled. The internal treatment consists in the administration of Sig. potassæ arsenitis, or Fowler's solution in an alkaline medium. Stubborn cases without exception yield to injections twice weekly with arsenic iodide, ten minims of a 1 per cent. aqueous solution at each session. With special reference to the regulation of the diet each case is a law unto itself.

156 West 119th Street.

Study of a Family of Heredosyphilitics.—A Barré and P. Gastel present a study of a family of heredosyphilitics, which has much of interest in it. The disease is manifested in one of the family very lightly, and only the comparison of the history of the other members would have caused the diagnosis to be made in him. In the mother there was only presumptive evidence of syphilis, from the existence of general paralysis. The father was undoubtedly syphilitic. She was pregnant eight times, the first with a child that died at birth. All the other pregnancies gave normal births. The different degrees of infection, each child showing it in some way, are explained by the bilaterality of the infection and the entire absence of treatment in all cases. Tuberculosis was present in two of the children and in the father. To the effect of this taint may be added the extreme poverty of the family. The stigmata were mostly ocular and nervous. One child at the age of eighteen had nervous, otitic, palatine, and ocular manifestations of heredosyphilis. He entered the hospital for meningitis, the other affections not having seemed to merit treatment. All symptoms disappeared under mercurial treatment. In two members of the family only ocular manifestations and in one only very slight ones were shown. The reaction of Wassermann was positive in every member of the family with the blood serum and with the cerebrospinal fluid. Lymphocytosis was positive in only two members of the family. It was the laboratory reactions alone that permitted of a diagnosis of syphilis in one of these patients, in whom the clinical manifestations were almost negative. This shows the value of these reactions in diagnosis.—*La Presse Médicale.*

THE PRESENT STATUS OF THE CANCER QUESTION.

THE second International Conference for the Study of Cancer was held in Paris early in October last, the first of the series having taken place at Heidelberg and Frankfort in 1906. During the interim important committee work has been carried out, the matter of research has been organized throughout the world, and now in this second meeting we are in position to understand something of what has been done along the lines projected during the past four years. The special papers read and the transactions as a whole will naturally be slow in reaching the public. But the *Münchener medizinische Wochenschrift* of November 1 last published von Czerny's inaugural address. This was delivered before a large and distinguished audience of laymen and physicians alike. Official Paris also was largely represented.

Statistics, despite their fallaciousness, were first discussed by the speaker. The disease *seems* to be on the increase among all cultured folk. But certain limited localities report a notable decrease. This discrepancy is highly significant, for it involves the whole subject of the incidence of cancer. Thus we find say a thirty per cent. increase in recent years in certain countries; yet if we consider only restricted localities we may be justified in concluding that the disease is not only on the wane, but actually extinct (for example, in many restricted localities, not a single cancer death has occurred for twenty-five years). Surely this absence of cancer in certain out-of-the way localities cannot be an accident. From such data nearly every theory of cancer might receive support—especially those of contagion, food, soil, inheritance, not to mention many others. Of great significance in the collection of statistics is the anatomical incidence of the disease; but to this is opposed the fact that in localities where cancer is especially prevalent we are likely to find all locations of the disease.

Von Czerny admits the cogency of a parasitic theory of cancer as long as we follow statistics. If we pursue this plan there is as much support of such a theory as in the case of any infectious disease. Aside from the argument furnished by statistics the bulk of the evidence tends to antagonize a parasitic theory. We find a wide line of demarcation between two groups, each of which is histologically and clinically malignant. The former may be described as superficial, external, slowly growing, originating in epidermal tissues—with an antecedent stage of inflammation or irritation—causing local metastases only, and hence largely amenable to prompt surgical treatment. But the other type consists chiefly of deeply placed cancers, attacking the viscera, bones, etc., rapidly growing, and highly disposed to cause metastases and cachexia. Treatment of such cases is impotent. The two types of cancer cannot be sharply separated clinically. Many growths which are technically superficial and epitheliomatous may, according to their location, grow rapidly, and with the aid of their acute local metastases may quickly wear out the patient. Certain growths technically local, but inaccessible because of location, may interfere with life indirectly by causing stricture and the like. In fact what would be termed a relatively mild, localized, and operable cancer on the surface may have the most dire effects if it occur deep in the digestive tube. It may completely interrupt the digestive processes, cause stricture of the digestive tube, and its metastases, even when local, will be of an inoperable and fatal character.

Our victories over cancer through surgical procedures apply purely to one of these general types, to wit, that which is of slow growth and externally located, without tendency to more than accessible metastases. But cancers which come thus to operation represent an insignificant minority. The remainder are made up of neglected operable cancers and those which were inoperable from the outset. Histological distinctions between epithelioma, carcinoma, and sarcoma also fall to pieces in this connection. A most virulent sarcoma may yield to simple remedies. A growth technically epitheliomatous may show high malignancy, etc. All this is well known, trite, and contained in textbooks. But, as v. Czerny repeated with emphasis, in a crusade against cancer as a whole we must never forget these old lessons.

To come back to the original subject, it is well to forget all we know and go back to school. In very recent years it has been shown that with appropriate nutriment cancer tissue may attain huge development. These cultural peculiarities are checked up in part by the rôle played by marked local irritation in ordinary tissues. It must not be forgotten that many irritants may cause the same or a similar effect. Hence a special germ, or any germ at all, might at times cause a phenomenon analogous to cancer proliferation. The most modern experiments seem to assure us that any microorganism may by chronic irritation set up cancer-like growths. That immunizing bodies may be produced seems assured. Cancers tend to form lethal toxins, and such should be overcome by antitoxins. Radium therapy and *x*-ray treatment are alleged to be powerful against many primary cancers. This is the summation, in fact: many agencies may cure localized cancer, but when once the disease has become generalized it is beyond the power of our present resources to overcome.

THE VANISHING INCOME OF THE PHYSICIAN.

It is a melancholy fact that as the cost of living has increased in this country so have the earnings of the medical profession decreased. This phase of the situation was dealt with at some length in an editorial which appeared in the Medical Record, February 26 of this year. The whys and wherefores of the decrease of income of American physicians are fairly obvious and, perhaps, until the causes are removed, it is somewhat futile to discuss the matter. The overcrowding of the medical profession is doubtless the chief cause, and the abuse of medical charity is another cause which must be considered. Furthermore, the effects of modern preventive medicine in lessening disease have reduced the possibilities of earning money by curative and remedial efforts. It is an easy matter to prove that the medical profession in America is overcrowded. In France, which has a population of 37,000,000 or so, there are only 17,000 medical men all told, and in England, with a population of more than 40,000,000, there are about 32,000 medical men, while this country and Canada, with perhaps nearly 90,000,000 people, have more than 120,000 physicians. This proportion is preposterous and the natural consequence is that a considerable proportion of American practitioners have hard work to keep the wolf from the door.

It is not the intention at this time to debate remedies for this parlous condition of things, but the statement is reiterated that pari passu with an increase in the cost of living the physician earns less than he earned some few years ago. There is also another aspect of the case which deserves attention. In all countries the medical man has more difficulty in collecting his just dues than has the member of any other profession or trade. This statement may be applied with greater aptness to America than to other countries. It is more customary here for general practitioners to give credit than for those of England or France, for instance. The entire practice of medicine here is based on the credit system. When a person is sick the practitioner is sent for without, as a rule, a thought of the expense. The physician generally goes as a matter of course. The individual recovers or dies, as the case may be, and when the bill for attendance is delivered, it not infrequently happens either that it is not paid promptly or that attempts are made to evade payment. When a person is ill no trouble or expense is too great to ensure or aid his recovery, the doctor then is his rock of refuge, but when he gets well both his illness and the doctor alike are liable to be forgotten. There are some who even shamelessly evade payment; these are those who in the euphonious and pertinent slang are termed "dead beats."

It may then be taken as proven that medical men are very often the prey of careless or designing patients and it might not be an overestimate to assert that of a general practitioner's annual earnings almost 25 per cent. will never be collected. The physician is precluded to a great extent by the etiquette of his profession from enforcing payment of his dues in the same manner as members of other professions and trades would enforce payment and therefore he would seem to be almost hopelessly handicapped. The most bitter feature of the position is that those least able to bear loss are the ones who are usually mulcted. The city consultant or specialist in surgery or medicine does not lose much by bad debts, or he does not lose so much in proportion to his income as do the hard-working members of the rank and file. Consultant's fees are paid at the office and it is also the custom to pay for big operations at the time or soon after. But the general practitioner must give credit, oftentimes long credit, and as said before there are some who never pay him and do not intend to pay him.

Sulphurous Acid in White Wines.

The subject of pure foods and drinks is one of international importance; it often becomes a matter that affects importations from foreign countries, and the decisions of some of our officials are severely questioned when it is a matter of excluding from this country some of the products of a sister country, which are deemed adulterated according to our pure food laws. A case in point is that of the importation from France of white wines which contain a small amount of sulphurous acid. This, it is claimed by the makers of the wines, is of benefit rather than injury to the consumers, inasmuch as it is added to the wine to prevent certain kinds of fermentation that would injure the taste of the wines and that would also be injurious to the human system. P. Carles, in the *Journal de Médecine de Bordeaux*, for August 21, 1910, gives an interesting explanation of the value of the sulphurous acid in certain fine white wines. They are made when the grapes are very ripe, in fact, somewhat withered and dry, since their fine taste is due to the large amount of sugar contained and developed in drying. Along with this sugar there are a large number of bacteria that invade the grapes, and the addition of the acid stops the action of these bacteria, and thus is of value to the consumer. J. Gautrelet, writing in the *Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, for September 4, 1910, gives the results of an investigation of the effect of this small amount of sulphurous acid on the human body, which was undertaken by a commission presided over by Professor Gayon, director of the Station agronomique et œnologique de Bordeaux. Wiley, in the United States, had investigated the effects of sulphurous acid with his poison squad, and had pronounced it injurious on account of its causing vomiting, burning in the stomach, and general malaise. He made use of capsules of sulphite of soda taken on an empty stomach, which the French investigators claim was not the correct way to conduct the experiment. The Commission kept nine men in a separate dwelling, working in a garden, under the best hygienic conditions, for thirty days. They were given an ordinary diet and the wine to be tested containing the amount of sulphurous acid that is usually found in it was given them to drink with their meals. At the end of the thirty days the urine, blood, etc., being examined daily, it was found that they were still in the best of health, and showed to the most critical examination no diseases of stomach, liver, or kidneys, or diminution of blood corpuscles. Such an

investigation, guarded as it was in every possible way from fraud, and with no possible element of psychic effort in the test, since the men did not know what they were taking nor what it was for, would indicate that small amounts of sulphurous acid in white wines are not injurious, at least not immediately injurious, to the drinkers of it.

The Sense of Smell of the Blind Deaf.

It has generally been believed that the deprivation of one sense tends to increased development of the other senses, renders them more acute, and it is a matter of common knowledge that the blind deaf possess a most penetrating sense of smell, the reason for which is held to be the over-development of that sense. But all our long-cherished ideas are being overthrown almost daily, or rather attempts are being made in that direction. M. Kunz of Illzach-Muhlhausen published a paper some little time ago, which is quoted in the *Annals of the Deaf* for November, 1909, setting forth his view that the destruction of one sense impairs all. William Wade of Oakmont, Pa., writing in the *Annals of the Deaf*, while agreeing in the main with Kunz's conclusions "that the deprivation of one sense is measurably balanced by increased development of the remaining senses is a thorough fallacy," takes exception to the statement 'that the destruction of one sense impairs all.' Wade gives some remarkable proofs from his own experience of the acutely discriminating sense of smell possessed by some blind deaf persons. It has been proven that deaf blind persons do possess a sense of smell which is absent from the normal person, and Wade contends that such persons should be permitted to use this sense as much as they please. It appears that there are individuals who endeavor to prevent the blind deaf from using their preternatural sense of smell because it is considered nasty. The people who object to the blind deaf using their sense of smell for the purpose of distinguishing animals, men, and natural objects of a clean or unclean nature must be hypercritical on the subject of nastiness. Indeed Mr. Wade argues that it may not be a preternaturally keen senses of smell that the blind deaf and seeing deaf possess but that they may have developed a greater concentration of mind on these senses than the seeing-hearing have, and thereby recognize odors imperceptible to others.

News of the Week.

City Death Rate.—For the week ending November 19 the number of deaths in New York City was considerably decreased, being 1,264 or 125 less than for the same week of last year. The rate was 13.77 per thousand of population, as compared to 15.87 in 1910. Pneumonia caused 169 deaths, a decrease of 53, and tuberculosis 155, a decrease of 26. Typhoid fever caused 15 deaths, diphtheria and croup 22, and diarrheal diseases 61. The only increases were in the deaths from heart disease, which numbered 152, from Bright's disease and nephritis, 128, and from violence, 73.

Hospital for the Ruptured and Crippled to Move.—The New York Society for the Relief of the Ruptured and Crippled has applied to the courts for permission to sell its hospital property at Forty-second street and Lexington avenue to the New York State Realty and Terminal Company for $1,350,000. A part of the property will be used for the new terminal of the New York Central Railroad. The society will use a part of the money in building a new hospital in the city and the balance in establishing a convalescent home out of town.

The Holman Association.—The first meeting of this association, which has for its purpose the promotion of rural nursing, hygiene, and social service all over the country, held its first meeting in New York on November 22. Dr. William H. Welch of Baltimore is the president. The association is the outcome of the efforts of Miss Lydia Holman, a trained nurse, who has worked for some time among the mountaineers of North Carolina.

War on Tuberculosis.—The New York State Federation of Women's Clubs in convention at Ithaca recently passed resolutions declaring its unqualified support of the campaign which the State Charities Aid Association is conducting in cooperation with the State Department of Health. The Federation represents a total of 260 clubs with a combined membership of 125,000.

Dr. Kenneth W. Millican, formerly of the editorial staff of the *New York Medical Journal*, sailed for London on November 24 to take a position on the editorial staff of the *Lancet*.

For Medical Research.—The Medical Department of Northwestern University, Chicago, has received a gift of $250,000 from Mr. James A. Patten of that city to be used in establishing a chair for the study of infectious diseases.

Gaynor Hospital Fund.—At a meeting of the trustees of the fund, held on November 25, it was announced that gifts to the amount of $13,208 had been received for the Thanksgiving offering to St. Mary's Hospital, Hoboken. It was decided that the subscription list should remain open until December 1, when the entire amount subscribed will be presented to the hospital.

Hospital Bureau of Standards and Supplies.—The first annual report of this bureau, which has its office at 381 Fourth avenue, New York, covers the work of the seven months ending on September 30, 1910, and shows substantial results in standardization and savings in the purchase of hospital and institutional supplies. The membership is composed of fourteen of the largest New York hospitals, and it is expected that others will join. A non-resident membership, for the benefit of institutions located outside of New York City, is contemplated.

Cholera Reaches Canada.—On the arrival of the steamship *Royal George* at Quebec recently one of the steerage passengers was found to be ill with cholera. As a result all the steerage passengers were detained at the Grosse Isle quarantine station about thirty miles below the city.

Typhoid Fever at the Naval Academy.—Up to November 23 twenty-two midshipmen at the Naval Academy at Annapolis were reported ill with typhoid fever. The source of the infection has been traced, it is thought, to a supply of milk which was received for three weeks when the regular dairyman was not able to supply the full quantity. The use of this milk was stopped on November 9.

Street Disinfection.—In Poughkeepsie, N. Y., a plain is on foot to test the efficacy of disinfection of the streets by sprinkling with a solution of corrosive sublimate.

Hospital Troubles.—Following the suspension of one of their number because of an infraction of the rules, five members of the house staff of the J. Hood Wright Memorial Hospital in New York resigned their positions on November 21 and left the hospital in a body. Only one member of the staff, the house surgeon, remained at his post. The work of the hospital was done by the visiting physicians until new internes could be secured.

In Paterson, N. J., five internes at the General Hospital were suspended from the service on November 24. This action was the culmination of a long series of disagreements between the managers of the hospital and the internes, the latter complaining of the quality and quantity of the food provided for them and alleging lack of cleanliness in the quarters which they occupy.

Diphtheria in Chicago.—Approximately 800 cases of diphtheria were reported in Chicago during November, and the Finance Committee, recognizing the gravity of the situation, voted an extra $10,000 to the Department of Contagious Diseases with which to fight the epidemic.

Ambulance Service Head.—The Rev. Dr. Daniel C. Potter, formerly head of the Division of Charitable Institutions of the Department of Finance, was on November 26 appointed Director of the Board of Ambulance Service of New York. The appointment, which was made by the Board, will not become effective until it is confirmed by the Municipal Civil Service Commission.

Bequest to a Hospital.—By the will of the late Patrick Curran of Philadelphia the sum of $3,000 is bequeathed to the Free Hospital for Consumptives at White Haven, Pa.

To Enlarge a Hospital.—Howard Hospital of Philadelphia is to be enlarged by an addition occupying the space of four adjacent buildings that have been purchased for the purpose.

The Fifth International Congress for the Blind will meet in Cairo from February 20 to February 25, 1911, under the patronage of the Khedive. Eight questions are announced for discussion. 1. When can a person be considered as blind? 2. How to prevent the spread of ophthalmia? 3. Has Esperanto been of any use as a universal language for the blind? 4. What is the best method applicable to all languages of teaching stenography to the blind. 5. What are the best trades and professions for the blind? 6. What are the best games and bodily exercises for blind school children? 7. Can the Braille method be improved? 8. Could the blind be employed in telephone and telegraph exchanges? The Congress will meet only in the mornings and the afternoons will be devoted to excursions to museums and places of interest. The entrance fee is the usual one of 20 francs (or $4), and intending members should write to the Secretary General of the Congress at the University buildings, Cairo.

Tri-County (Mich.) Medical Society.—At a meeting held in Cadillac on November 3 the following officers were elected: *President,* Dr. V. F. Huntley, Manton; *Vice-President,* Dr. R. Broduer, Cadillac; *Secretary and Treasurer,* Dr. W. J. Smith; *Delegate to State Convention,* Dr. S. C. Moore.

The Pee-Dee (South Carolina) Medical Association met at Charleston on November 9. The following officers were elected: *President,* Dr. A. M. Brailsford, Mullins; *Vice-President,* Dr. E. T. Wannamaker, Cheraw; *Secretary-Treasurer,* Dr. J. C. Lawson, Darlington. The next annual meeting will be held in Florence on the second Wednesday in November, 1911.

The Petersburg (Virginia) Medical Faculty at its annual meeting on November 17, elected officers for the ensuing year as follows: *President,* Dr. W. P. Hoy; *Vice-Presidents,* Dr. J. R. Beckwith and Dr. R. A. Gamble; *Corresponding Secretary,* Dr. H. A. Burke; *Secretary-Treasurer,* Dr. W. C. Powell.

Gifts to Preventorium.—The Tuberculosis Preventorium for Children, which last year, after protest from the citizens of Lakewood, N. J., was removed to Farmingdale, has recently received a gift of 64 acres of land at the latter place together with a free lease for twenty-five years of the Windsor stock farm adjoining, comprising 240 acres under cultivation. The gift was made through Mr. Arthur Brisbane by the estate of Albert Brisbane. Mr. Brisbane will present to the preventorium 20 acres of land in addition, from a farm which he has recently purchased. Cows, wagons, furniture, and other accessories are also included in the list. Mr. Nathan Straus has already contributed $50,000 for model buildings to be constructed on the farm, and the Board of Health Auxiliary connected with the Association of Tuberculosis Clinics has subscribed $4,500 to build an additional open shack, for which they will select the children, and which they will support. The institution has for its object the prevention of tuberculosis among children, and will treat only those who have not contracted the disease, but who give evidence of susceptibility. By wise supervision, good food, and pure air it is hoped that many children may be saved.

Rockingham County (Va.) Medical Society.—At the annual meeting of the society held in Harrisonburg on November 9 the following officers were elected: *President,* Dr. J. F. Wright, Keezletown; *Vice-President,* Dr. A. C. Byers, Harrisonburg; *Secretary-Treasurer,* Dr. J. M. Biedler.

Fond du Lac County (Wis.) Medical Society.—The annual meeting of the society was held in Fond du Lac on November 9, officers for the ensuing year being elected as follows: *President,* Dr. G. T. McDougall; *Vice-President,* Dr. P. J. Calvey; *Secretary-Treasurer,* Dr. Flora A. Reed; *Delegate to State Convention,* Dr. S. E. Gavin.

The Ocean County (N. J.) Medical Society.—At a meeting held on November 11, the following officers were elected to serve for the coming year: *President,* Dr. W. G. Lawrence; *Vice-President,* Dr. A. M. Heron; *Secretary,* Dr. W. G. Schauffler; *Treasurer,* Dr. I. H. Hance.

The Late Dr. Ransom.—At a regular meeting of the West End Medical Society, held October 22, 1910, the following preamble and resolutions were adopted: This Society, having learned of the recent death of our esteemed fellow member, Dr. Charles C. Ransom, desires to place on record a formal expression of our appreciation of the great loss resulting to us, both individually and collectively, from his death. Connected by membership with this Society almost from its inception, honored with the office of President, he maintained a never flagging interest in its welfare and actively labored to promote its best interests. His contributions to the Society proceedings were many and always upon a plane of dignified scientific value. A man of culture, of pleasing personality and address, he was

held in high personal esteem by all his associate members. Therefore, be it resolved, that in the death of Dr. Ransom the West End Medical Society recognizes with sorrow and profound regret the loss of a most esteemed member; that we beg to extend to his grief-stricken family our deep sympathy; that a copy of these resolutions be spread upon the minutes, and that the secretary be instructed to furnish a copy to the medical press for publication.

Signed: W. B. Pritchard, M.D.
E. J. Ware, M.D.
A. H. Travis, M.D.

Obituary Notes.—Dr. Samuel Alexander of this city died Wednesday morning of this week at the New York Hospital of gangrenous appendicitis, for which he had been operated on on Saturday. Dr. Alexander was born in New York City on April 2, 1858, and was graduated from Princeton in 1879 and from Bellevue Medical College in 1882, subsequently spending a year at Bellevue as interne. In 1883 he studied in London, Leipsic, and Vienna, and upon his return to America was appointed attending surgeon at Bellevue Hospital. In 1887 he became professor of genitourinary surgery in the Bellevue Hospital Medical College and in 1898 he was made professor of clinical surgery in the department of genitourinary diseases in Cornell Medical College.

Dr. Charles Butler Stiles of Hill View, N. Y., a graduate of the University of Edinburgh in 1887, died at his home on November 19, aged 48 years.

Dr. James Ross Waggener, Medical Director in the United States Navy, a graduate of the Jefferson Medical College in 1872, died at his home in Brookline, Mass., on November 17, aged 64 years. Dr. Waggener, who was retired from active service, served at the Mare Island Navy Yard during the Spanish war.

Dr. Samuel M. Reid of Muncie, Ind., a graduate of the College of Physicians and Surgeons of Keokuk, Ia., died at his home on November 7.

Dr. William S. Chenoweth of Tacoma, Wash., a graduate of the Northwestern Medical College of St. Joseph, Mo., in 1883, a member of the American Medical Association, and the Washington State and Pierce County Medical societies, physician-in-charge of the Fern Hill Hospital, Fern Hill, and a veteran of the Civil War, died at his home on November 1, aged 61 years.

Dr. Stephen G. Cook of New York, a graduate of the Medical Department of the New York University in 1857, a veteran of the Civil War, and a police surgeon in New York from 1873 until his retirement in 1907, died at his home on November 21, aged 78 years.

Dr. William Robert Bross of New York, a graduate of the College of Physicians and Surgeons, New York, in 1881, a member of the New York State and County Medical societies, and medical director of the Equitable Life Assurance Company of New York, formerly Port Health Officer at Port Limon, Costa Rica, and later consulting commissioner on yellow fever in South America, died suddenly at his home in Babylon, L. I., on November 21, of apoplexy, aged 56 years.

Dr. Alvah C. Van Syckle of Hackettstown, N. J., a graduate of the Medical Department of New York University in 1878, a member of the American Medical Association and of the New Jersey State and Warren County Medical societies, at one time president of the latter, and formerly Mayor of Hackettstown, died suddenly of heart disease on November 22 while attending a meeting of the Warren County Medical Society at Hackettstown, aged 57 years.

Dr. George F. Marsden of Red Bank, N. J., a graduate of the Hahnemann Medical College of Philadelphia in 1886, died at his home of stomach trouble on November 22, aged 64 years.

Dr. Thomas Robinson Little of Greensboro, N. C., a graduate of the Medical Department of the University of Pennsylvania in 1900, and a member of the North Carolina State and Guilford County Medical societies, and of the Greensboro Academy of Medicine, died suddenly at his home on November 15, aged 36 years.

Dr. David N. Kinsman of Columbus, O., a graduate of the Medical College of Ohio in 1863, and a member of the American Medical Association and of the Ohio State and Franklin County Medical societies, died at his home of heart disease on November 24, aged 76 years.

Dr. John R. Chatham of Tamms, Ill., a graduate of the Washington University Medical School, St. Louis, in 1873, died at his home on November 14.

Dr. William F. Waite of Kansas City, Kan., a graduate of the University Medical College of Kansas City in 1893, a member of the Kansas State and Wyandotte County Medical societies, and a veteran of the Civil War, died at his home on November 12, aged 63 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEMORIALS TO KING EDWARD.—PROPOSED ENDOWMENT OF TROPICAL MEDICINE AND RESEARCH.—CYSTIC DISEASE OF BREAST.—CANCER OF OVARIES.—ACROMEGALY. — CAIUS QUATERCENTENARY.—GREEK MEDICINE.—MALARIA, MIAN MIR REPORT.

London, Nov. 11, 1910.

Memorials to King Edward have been projected in all directions and everywhere the question has been discussed as to what is the most suitable form in which to commemorate his reign and personality. Considering his deep interest in hospitals and charities not a few towns have decided on an addition to such as the local tribute. London has awaited a report from the committee of a Mansion House Fund started to consider the matter and on Monday the executive reported that they had dealt with no fewer than 164 suggestions. Most of these were obviously impracticable and they reduced them to four, guided by the considerations that the memorial was to be a London as distinguished from an imperial one, that it ought to be such as King Edward would himself have approved and worthy of his country and suitable as an expression of London's devotion to his memory. They decided that whatever else might be added a statue in the metropolis should be erected at a cost of between £50,000 and £70,000. With regard to further extension it would seem that it should appeal to the whole empire. This would rule out three other proposals which found favor, viz., a new bridge and embankment, a museum and a central hall for the London University. I doubt if any of these will kindle enthusiasm; but there is a fourth which has been urged within the last

few days by a very long list of influential men representing a wide range of interests and which, if adopted, would be imperial in scope. That is a scheme for research on tropical diseases and for coping with the protection of life in the tropics. This is of special interest to the profession, and from the point of view of the interest taken by the late king in hospitals for the sick and the prevention of disease would seem a suitable memorial. Moreover it would be beneficial to the numerous races throughout the empire, with its 330 millions living under tropical conditions.

It is true we have a school of tropical medicine in London and another in Liverpool, but it can hardly be argued that they meet in full the responsibility of the country, and they are not due to government but to private support. The Liverpool school owed its origin and maintenance to the munificence of the late Sir Alfred Jones, and it has sent out twenty-one research expeditions to the tropics during the ten years of its existence. The London school also owes its establishment to private generosity, but now gets a government grant of £1,300 —quite insufficient. There is also a bureau for sleeping sickness supported by the government at a cost of £1,200 a year and the university receives £750 to assist work dealing with tropical medicine. The Royal Society has a committee on this subject, but the eminent experts who compose it give their work gratuitously.

The total amount which the British Government has contributed to tropical medicine is paltry indeed considered as an addition to private effort. They should take an example from the United States' action in Havana and in the Panama zone.

Cystic disease of the breast was the subject of an interesting discussion at the first meeting for this session of the Harveian Society. It was opened by Mr. D'Arcy Power who pronounced the state of classification of cystic diseases as chaotic and offered a scheme distinguishing noninflammatory, inflammatory, congenital, and parasitic, each of these having their subdivisions. Mr. Shaw offered another scheme in which he endeavored to retain the terms in common use. Mr. Power in his paper considered the several classes but found those more or less connected with inflammatory changes of more diagnostic interest and more difficult to treat. Chronic mastitis led to an important group of cystic tumors. The cysts might be single and simple or the whole gland might present the appearance of a sponge when examined after removal. The single sometimes had a thick wall and was so deeply placed that it might be mistaken for a solid tumor. It was, therefore, a cardinal rule to incise every breast before amputating it. A mere puncture would not do as it might not find an intracystic growth. The most difficult cases were those of many small cysts resulting from chronic lobular mastitis.

Mr. Shaw showed a series of lantern slides illustrating the appearances (macro- and microscopic) of several varieties of the serous or simple cysts which he held to be due to chronic mastitis. He and other speakers were against puncture. He showed specimens of cancer in the walls of cysts. In many cases solid adenomata projected into cysts and were better called intracystic adenomata.

Mr. W. G. Spencer said little was known as to the pathological development of these growths. The contents of serous cysts seldom corresponded with blood serum. Kanthack regarded papillomata as connective tissue and though this view was not generally accepted it was supported by the fact that these cysts mostly consisted of connective tissue stroma. Circumscribed cysts should not be shelled out but removed with a zone of healthy tissue. If that zone were diseased he excised the breast, leaving the nipple.

Mr. Crisp English said these cysts were almost always secondary to mastitis and in all doubtful cases exploratory incision should be made. He did not believe the ordinary form predisposed to malignant disease.

Mr. Gask said when the condition called for operation the whole breast should be removed, for a partial excision did not free the patient from neuralgic pain and in certain cases carcinoma followed.

Mr. Clayton Greene remarked on the similarity of adenoma, fibroma, and interstitial mastitis, suggesting an inflammatory origin. As to its relationship to malignant disease he had observed two classes—one with large cysts, two or three in number seldom more, the other when the whole breast was riddled with cysts. The latter should be always operated on. The former he had not regarded as dangerous, but after this discussion he was inclined to revise his opinion.

At the Medical Society of London cancer of the ovary was the subject of a paper by Mr. Bland Sutton. This he regards as always secondary, or, at any rate, he is convinced that primary carcinoma of this organ remains unproven. Many cases thought to have arisen primarily in the ovary were metastatic. In cancer of the stomach, cecum, or gallbladder, the cancer cells permeated the muscular and serous coats and found their way into the peritoneal cavity and were conveyed by the peritoneal fluid into the recesses of the pelvis or lodged on the ovaries, Fallopian tubes, and uterus. He thought when these cells implanted themselves on a normal ovary, a solid tumor resulted, but if they fell on the walls of an ovarian cyst they quickly grew into formidable masses. Primary cancer of the Fallopian tube was very malignant and operative treatment rarely resulted in enduring success. If the ostium of the tube remained open cancerous particles were poured out, cornucopial fashion, into the pelvis and soiled the organs and tissues. Implantation on the walls of an ovarian cyst was no rarity. In the last eighteen months he had had seven such cases, the primary foci being: in the stomach 2 cases; in the hepatic flexure of the colon 1; sigmoid flexure 1; uterus 1; Fallopian tube 1; undetermined 1.

At the annual meeting of the Royal College of Surgeons to be held next Thursday, the report, already in type, will be presented.

Professor Arthur Keith gave a demonstration at the college last week on acromegaly. After mentioning the increase of size and the signs of this first noticed by the patients, such as the necessity for larger gloves, boots, collars, etc., Mr. Keith said that since Marie drew attention to the disease in 1886, above 400 cases have been reported. He estimated that there are probably fifty or more at present in London. It has been suggested that the prototype of Punch was a subject of acromegaly but that diagnosis was wrong, said the professor, for though the nose, jaw, chin, and dorsal hump favor it, the small hands, thin lips, and good teeth are against it.

There is no example of acromegaly in the British Portrait Gallery or in the National Gallery, but one of Rowlandrous caricatures is an example. The

pituitary body was usually enlarged in the disease and its secretion evidently concerned in regulating and coordinating the growth of various parts of the body. A study of the effects of overgrowths of this gland will perhaps furnish a key to many of the factors which determine the physical conformation of the body, said the professor, and lead to the establishment of physical anthropology on a scientific basis.

In connection with this subject I may quote a case shown on the 27th ult. at the Liverpool Medical Institute by Mr. C. G. Lee. It was that of a man of 32 who had recovered from diabetes insipidus and then developed a marked increase of adipose tissue with optic atrophy. His weight had increased from 11 stone 7 pounds to 13 stone 10 pounds, but this seemed to be only due to fat, as there were no signs of acromegaly. Skiagraphy showed enlargement of the sella turcica and Mr. Lee attributed the symptoms to diminished function of the pituitary body.

At the meeting of the Royal College of Physicians the president reported that he and other officials were entertained at Caius College, Cambridge, on the occasion of the 400th centenary of Dr. Caius, and this hospitality was returned by inviting the Master and Fellows of Caius to the Harveian oration and banquet. Their portrait of Glisson was also presented to Caius. The president also reported that the medical staff of Guy's Hospital had offered to present to this college a portrait of Sir Samuel Wilks. This was accepted by the meeting with acclamation and the thanks of the college directed to be returned. The audited accounts for the year were adopted and other formal business transacted.

The Fitzpatrick lectures at this college for 1910 were delivered on the 3d and 8th of this month by Sir Clifford Allbutt who took for his subject Greek Medicine in Rome.

In writing of malaria last week I referred to the Mian Mir Committee's Report. It seems, however, that this must be received with considerable reserve pending full criticism from Ronald Ross who has meantime published in the *Lancet* a summary of his objections to its statements. The object of the experiment was said to be to test the doctrine that malaria can be banished by mosquito reduction at little cost anywhere. But this proposition in its bare statement is laid down by no one. What Ross taught was that mosquito reduction was easy under very favorable circumstances. It appears now that these did not exist at Mian Mir, and as to cost the government's allowance was absurdly insignificant —only a few pence a head being officially held to be more than could be devoted to mosquito reduction. Considering the monetary cost of the soldier in India to the mortality and invaliding from malaria it would seem that striking medical and preventive work must be the most inexcusable extravagance.

Tuberculous Cavities in a Nursling of Three Months.—Collet and Delachanal detail the history of an infant of three months of age, who had a healthy mother, but a tuberculous father, which died of miliary tuberculosis with meningitis, and in whom there were found *post mortem* two cavities in the right lung which were entirely independent of the bronchial glands. The child died with the symptoms of an acute pulmonary trouble, with intense dyspnea, cough, and vomiting. The bronchial glands on the right side were caseous. There were no ulcerations in the intestine, which the author takes to mean that the tuberculosis was not from drinking tubercular material, but came by inhalation. The cavity seemed to have been formed by a rapid pneumonic process, not by a slow fibrocaseous one.—*Lyon Médical.*

(From Our Special Correspondent.)

THE ISOLATION HOSPITAL IN TORONTO—NEW MEDICAL OFFICER OF HEALTH FOR TORONTO—MEDICAL INSPECTION OF SCHOOLS IN TORONTO—ANNUAL REPORT OF THE PROVINCIAL BOARD OF HEALTH OF ONTARIO—THE GENERAL HOSPITAL, TORONTO —ADDITION TO ST. MICHAEL'S HOSPITAL, TORONTO—INFANT MORTALITY IN ONTARIO—DR. LOUIS WICKHAM OF PARIS IN TORONTO—PUBLIC HEALTH CONFERENCE IN OTTAWA—SPEECH BY DR. CHAS. A. HODGETTS—GRADUATION OF NURSES AT THE SICK CHILDREN'S HOSPITAL, TORONTO—ACUTE POLIOMYELITIS IN ONTARIO—APPOINTMENT OF A LAY SUPERINTENDENT TO ORILLIA ASYLUM.

Toronto, November 15, 1910.

The Isolation Hospital in Toronto has been the subject recently of much discussion both in medical and lay circles. An inquiry was held a few weeks ago into its management, and although no definite conclusion was reached, it was decided that more stringent control should be exercised over the institution. The evidence given at the inquiry was quite conflicting, the majority of the medical men who were examined as witnesses declared that all reasonable care was taken to avoid the spread of infection, while many of the lay witnesses stated that the authorities were careless in the extreme. However, the evidence of non-medical persons must always be taken with a grain of salt in such cases, as people generally seem ever to be prejudiced against any attempts to curtail the freedom of themselves or families even if these be in the interest of the whole community. There can be little doubt that if isolation hospitals are to efficiently fulfill the purpose for which they have been established, the regulations laid down must be stringently carried out. Dr. Charles Sheard has again resigned the post of medical officer of Toronto, to which he had been reelected but two or three months ago. Dr. Charles Hastings, a well known practitioner of Toronto, has been appointed to the vacant position. Dr. Hastings has been an earnest worker in the field of public health for many years and is an enthusiast for clean milk and especially for pasteurized milk. A new departure has also been made by the Toronto City Council in connection with the Board of Health by the appointment of Dr. G. G. Nasmith, late chemist to the Provincial Board of Health, to the post of bacteriologist to the city Board of Health. The city Board of Health will now have for the first time a fully equipped department of bacteriology and in charge of the same a thoroughly competent man.

The medical inspection of schools in Toronto is likewise a new departure. Two inspectors were appointed a short time ago, one of these being a lady doctor. The appointment had just been made when a bolt from the blue was launched by the lady. In a long letter which she addressed to the daily papers, she complained that her hands were so tied by the methods of control that her work was practically of no avail. She argued that as in New York, the medical inspection of schools should be in the hands of the Board of Health and that the medical inspectors should be given a considerable amount of power and authority. The City Fathers of Toronto were not of the same mind and reprimanded Dr. Helen MacMurchy for publishing the letter and decided that matters should be left *in statu quo*.

The annual report of the Ontario Board of Health for 1909 has been issued recently. Among other subjects of interest it contains full reports on the Howard-Bridge ozone system of water purification as installed at Lindsay, Ontario. Dr. Nasmith made the chemical and general report and concluded that the system installed at Lindsay was an absolute failure so far as purifying the water was concerned and Dr. Geo. R. Philip, who made the bacteriological report, came to a similar conclusion.

Dr. Chas. A. Hodgetts, late chief health officer of Ontario, writes in the report an instructive article on the growth of the tuberculosis movement in Ontario and describes the erection of two sanatoria for the treatment of tuberculosis, one in St. Catherines and the other in Ottawa.

Tenders for the principal buildings of the Toronto General Hospital have been accepted and, weather permitting, the work of construction will proceed as rapidly as possible. A large addition is being made to St. Michael's Hospital, which, when completed, will nearly double the capacity of that institution. Infant mortality in Ontario and in Canada generally is larger by far than conditions would seem to warrant. In 1907 the mortality in England and Wales under one year of age was 117.62 per 1,000 births; in 1900 the mortality in Ontario under one year of age was 132. In 1907 the number of deaths in Ontario was 33,502 and the infant mortality was 29 per cent. of this amount. In Quebec the infant mortality is even higher and the death rate of infants born of French-Canadians in Montreal is so high that the authorities have become seriously alarmed. It is a somewhat curious coincidence that in Great Britain, in which more than three-fourths of the inhabitants live in large cities, the infantile mortality is considerably less than in the United States and in Canada in which the great majority of the population live in far less crowded localities.

At the end of September Dr. Louis Wickham of Paris gave an address on cancer treated by radium in the Hall of Physics of Toronto University, illustrated on the screen by specimens chosen from among his patients. Dr. Wickham is not one of those who claims that radium is a specific or in the nature of a specific for cancer. He is very modest in his claims and only argues that in certain forms of cancer radium acts beneficially and that it is, at any rate, a valuable adjunct to the knife.

Dr. Chas. A. Hodgetts, who is now medical adviser to the Canadian Commission on Conservation, delivered an address at the Public Health Conference held in Ottawa in the second week of October in which he urged the creation of a federal department of health to cooperate with the various provincial health departments. After referring to the pollution of water which is so prominent a feature in the causation of disease in the United States and in Canada, Dr. Hodgetts declared that it required some other authority than provincial, viz., that of the federal government, to solve international and interprovincial sanitary problems. The conference recommended the establishment of a federal council of health to deal with larger questions of disease prevention by the federal and provincial governments in cooperation. It was also recommended that a federal laboratory be established for the purpose of experimental work, to manufacture serums and antitoxins, and generally to supply aids in fighting disease as well as to prove of value in education. The conference urged that both federal and provincial governments should encourage still further the establishment of sanatoria for the care of consumption, particularly among the poorer classes.

Representatives of the health departments of the various provinces and federal government officers, at a meeting held October 13, organized the Canadian Health Association. The object of the association will be to interest the public in the spread of information relating to matters affecting the public health. Officers were elected as follows: *Honorary President,* Sir James Grant, Ottawa; *President,* Dr. J. A. Starkey, McGill University; *Treasurer,* Dr. George D. Porter, Toronto; *Secretary,* Major Lorne Drum, Ottawa.

In connection with the Sick Children's Hospital, Toronto, is probably the most magnificent nurses' home in the world. This beautifully fitted building was erected by Mr. John Ross Robertson, the proprietor of the *Evening Telegram.* On October 14 the graduating exercises took place at this building, when twenty-two nurses were presented with diplomas. There are at the present time in the training school fifty-seven nurses, while one hundred and fifty applied for admission during the year, fifty of whom were accepted. Acute poliomyelitis which has been more or less prevalent in several districts of Eastern Ontario seems now to have disappeared. Hamilton was the center of the epidemic, if it might be so called, and in that city there were many deaths among infants and some deaths among adults. The appointment by Sir James Whitney of a lay superintendent to Orillia Asylum for the Feeble Minded gave rise to much adverse discussion among medical men and in lay papers of opposing politics. It has been pointed out that although it is generally the custom in the United States and in Canada to have medical superintendents of hospitals and of institutions for the insane, in Great Britain such superintendents are almost always not medical men but good business men. It is argued there that medical men are not, as a rule, good business men, and furthermore, that it is not well that the entire control of a hospital should be in the hands of medical men. Although friction has occurred in Great Britain between the laymen of the hospital boards and the medical staffs, on the whole the British system of hospital control is said to work satisfactorily. It is far more economical than in either Canada or in the United States.

The Technique of Arthrotomy. C. F. Painter and A. P. Cornwall.
Some Cases of Sudden Death During Pregnancy and the Puerperium. H. G. Myrick.

Atresia of the Vagina.—W. P. Graves states that this condition is either acquired or congenital. In the former instance the majority of cases are the result of a plastic gonorrheal vaginitis acquired before the age of puberty. Adhesions take place usually at the junction of the anterior and middle third of the vagina. Acquired atresia of the vagina also occurs in adult women and may be the result of adhesions forming after a vaginitis following severe lacerations at childbirth, in which case atresia occurs higher up and may involve the cervix. Senile vaginitis is not an uncommon cause of atresia. Symptoms are not ordinarily manifested until puberty, when men-

strual blood accumulates behind the adhesive membrane and makes a tumor. The operation for atresia is attended with considerable danger of fatal sepsis. In the operation for acquired atresia, after the septum has been incised and the contents of the space beyond have been removed, there should be a thorough cleansing of the parts. The edges of the septum should then be trimmed flush with the walls of the vagina. All scar tissue should be removed so as to prevent a future contraction. When the septum has been completely cleared away it will be found that there remains a denuded area which extends like a ring around the inner circumference of the vagina. The mucous membrane of the upper portion of the vagina should then be drawn down and approximated to that of the lower portion by interrupted catgut sutures. Such an operation should restore perfectly the normal caliber of the vagina and should not be followed by a tendency to the development of a stricture. The use of antiseptic douches twice or three times daily should be begun the day after the operation and should be kept up until the discharge completely disappears. In congenital atresia the following technique has been based upon the operations of Burrage and Abbey. Through a superficial transverse incision made just below the urethra, the bladder and rectum are slowly dissected apart with the finger. The forefinger of the left hand should be kept in the rectum and some blunt instrument like a urethral dilator should be held in the bladder by an assistant. In this way an artificial opening can be made of the exact proportions of the normal vagina. The next step is to line this cavity with a pouch of skin made up of flaps turned in from the surrounding parts. To accomplish this the two labia minora are dissected off, from above downward, in such a manner as to leave a pedicle sufficiently large to furnish good circulation. The two surfaces are then split apart so that two paddle-shaped flaps remain. There should then be dissected from the inner side of the thigh two similar flaps which have their bases at the two lower corners of the artificial opening. All four flaps are then sewed together over a glass form. Before the flaps are sewed together several catgut sutures, with the ends left long, should be placed in the vault of the artificial cavity. When the skin pouch has been nearly completed, the glass form is removed and the catgut sutures are brought out through the skin pouch. The pouch is then inverted and the sutures are tied in such a manner that the pouch fits snugly into the artificial cavity.

Cancer of the Scrotum.—R. M. Green presents copious extracts from the early writers on this condition, which has also been known as chimneysweep's disease. This was first described in 1775 by Pervicall Pott.

Mikulicz's Method of Increasing Peritoneal Resistance.—Prof. E. De Paoli states that he has practised this method in all cases in which celiotomy had been performed. It consists in the injection of nucleinate of sodium, which causes a pronounced hyperleucocytosis and also serves to measure with precision the natural powers of resistance of the patient who is about to be operated upon. If after the injection there is a satisfactory hyperleucocytosis this is the proof that the powers of resistance are sufficient; if, on the contrary, hyperleucocytosis does not follow injection of the drug, one knows that the means of defense against infection are decidedly lowered. In the first case one may operate with confidence; in the second one should abstain from operating, if possible, until the patient is in a better condition. Bacteriological studies of the blood of patients before and after the injection of nucleinate of sodium have shown an increase in the bactericidal power of the blood serum with reference to the culture of the *Bacillus coli*. This result is very remarkable because it serves to show how the drug must act in protecting the peritoneum against the germ very commonly found in septic peritonitis. The method finds its chief application in cases in which there is danger of postoperative sepsis, as in operations on the intestinal tract, and also in those cases in which the conditions for perfect asepsis are lacking, for instance, when one cannot operate in a well-appointed hospital. It is probable that the method will not prove of great advantage in those cases in which the abdominal lesion is not in the digestive tract, provided always that asepsis is perfect; in these cases, of course, sepsis is quite unusual in any event.

The Technique of Arthrotomy.—C. F. Painter and A. P. Cornwall continue their discussion of this subject, particularly with reference to the treatment of infectious arthritis in female patients.

Sudden Death During Pregnancy and Puerperium.—H. G. Myrick states that among the chief causes of sudden death in pregnant and puerperal women are cardiac disease, embolus, cerebral hemorrhage, grave intoxication, as eclampsia, and hemorrhage from various sources, placenta previa, rupture of the uterus, ectopic gestation, or abortion. The author details three of her own cases as follows: cardiac disease, eclampsia, and cerebral hemorrhage

What is the Direct Cause of the Seizures of Epilepsy? N. P. Levin
Reveries of a Young Practitioner. F. M. Bell.

Nervous Affections in Relation to the Adjustments of the Eyes.—G. T. Stevens presents the results of his study of this subject with reference to epilepsy. He states that his later experience has led him to believe that idiopathic epilepsy is, in a great proportion of cases, the result of the condition of tilting of the meridians of the eyes which he has called declinations, and for some years past his efforts toward relief of these cases have been directed toward the correction of this defect. Although such a correction is sometimes extremely difficult and demands much patience and infinite care, the results have been on the whole most satisfactory.

Pathogenesis of the Toe Phenomenon.—A. Gordon concludes on the basis of experiments made upon patients under the anesthetic influence of chloroform, as studied by Marinesco, that the toe phenomenon is the most sensitive of all the cutaneous reflexes, disappearing even before the corneal reflex. The most important evidence in favor of its encephalic origin lies in its absence in complete transverse lesions of the cord at the level of the cervical or dorsal segments. He states that any involvement of the cerebrospinal motor pathway is therefore expressed in the toe phenomenon. But whether the latter is a spinal or encephalic reflex must be decided in favor of the latter in view of the previously mentioned Marinesco's and others' observations with hemiplegics and paraplegics under chloroform in view of the appearance of the reflex shortly after the onset of hemiplegia, finally and mainly in view of its absence in cases of total compression of the cord which means total suppression of encephalic influence on the spinal cord which contains a center for the extensors of the toes.

Extramedullary Spinal Cord Glioma.—D. Inglis, T Klingman, and M. Ballin report a case of this condition in which the early and seemingly complete restoration of function in the cord after removal of the tumor established at least the physiological integrity of the cord. The course of the disease was that of a slowly progressive segmental

lesion in the earlier stage of development unilateral, giving the clinical aspect of the Brown-Séquard symptom complex. The characteristic pain, distinctly localized, due to nerve root irritation, was prominent from the very beginning and at no time seemed the diagnosis of a spinal tumor doubtful.

Administration of Ether.—A. D. Young states that because the margin between complete anesthesia and a fatal dose of chloroform is so narrow he believes that ether is the only general anesthetic that should be used. All the armamentarium an anesthetist needs is a hypodermic syringe, morphine and atropine, inhaler, ether, and a couple of small towels. Thirty or forty minutes before beginning the administration of ether the patient should be given a hypodermic injection containing one-sixth grain of morphine and 1/120 grain of atropine. The patient should never be moved after being anesthetized until the operation is completed. The practice of anesthetizing in the patient's room should be abandoned, as moving to the operating room may tend to awaken him and cause vomiting, and, in addition, the anesthesia will last just that much longer. There is no sign by which one may learn when the patient is ready. One must be guided by the amount of ether used and by the breathing of the patient. When the respiration is deep and regular, accompanied by slight snoring, the patient is usually ready, but not always. However, the surgeon may now begin, and if there is slight resistance on the patient's part a few more breaths will have him completely under. The author has investigated many of the elaborate forms of apparatus advocated by various men, and believes they possess no advantages over the simple wire mask which should be covered with gauze, eight to twelve layers in thickness, according to mesh. This covering should never be thick enough to in the least interfere with the respiration.

Anesthesia Dangers.—L. D. Frescoln reports two cases of anesthetic shock occurring in patients anesthetized with chloroform for forceps delivery. He concludes that before giving an anesthetic one should choose a good inhaler to prevent interference with respiration; keep the mouth free from mucus; remove false teeth or other foreign bodies; have oxygen ready for emergency; sometimes it is well to begin by using atropine and morphine before giving chloroform and atropine before ether; he prefers ether in cases with heart disease or kidney trouble and chloroform in pulmonary cases if one or the other must be given.

Local Anesthesia.—L. F. Watson believes that local anesthesia should be selected whenever a choice of anesthetics is possible, because of the greater safety and comfort afforded the patient. To those using the cocaine method the advantages are apparent and the field continually enlarges as the technique improves. The importance of local anesthesia has never been sufficiently appreciated in America, due probably to inexperience in the method and a certain deep rooted fear of poisoning traceable to the days of strong cocaine solutions. The strong solutions are equally or more dangerous than general anesthesia, while the weak solutions are the safest of all methods of analgesia. Success in the use of local anesthesia depends on patience, an intimate knowledge of sensory nerve distribution, and special training in the method. The technique of the injection is always delicate; it varies with each region, each operation, and in each patient. The technique must be learned with a knowledge of its application and adaptation to each individual case. Because of the slower appearance of complete anesthesia with the weaker solutions, surgeons that begin operating as soon as the injection is finished will often fail with local anesthesia. This can be employed in any part of the body where the nerve supply can be controlled. With a proper selection of cases the majority of surgical operations can be performed under local anesthesia. A one-fifth per cent. cocaine solution is used for the skin and nerve trunks; elsewhere a one-tenth per cent. solution is employed.

Dose of Stovaine in Spinal Analgesia.—M. Salmon states that it has been found that the changes which take place in blood pressure during spinal anesthesia are very marked and important. There is a marked fall of blood pressure, and this to a certain extent bears some relation to the amount of drug used and the level at which it is injected. That the dose can be gauged by the blood pressure readings at once becomes evident if one but reflect for a moment upon the mechanism concerned in the maintenance and regulation of normal blood pressure, namely the continuous activity of the vasomotor system whose center is located in the medulla.

Tonsil Forceps.—H. M. MacWhinnie describes a new instrument for grasping the tonsil, consisting of a three-catch locking device arranged so that greatly hypertrophied tonsils as well as the submerged forms and stumps, when once accurately engaged, may be securely held.

Cause of Epilepsy.—N. P. Levin assumes that vascular phenomena precisely similar to those occurring in asthma and agioneurotic edema, occur in the brain with each epileptic seizure. If sudden exudations can occur from the vessels of the skin, bronchi, or intestines, they may also occur in the viscera and in the brain. The violent symptoms occurring during an epileptic fit are explained by the sudden increase in the intracranial pressure entailed by this exudation within the unyielding walls of the skull. As soon as the pressure within the cranium has readjusted itself the symptoms pass off. The author suggests that possibly a decompression operation as practised by Cushing, would be of service in this disease. To remove a good section of the cranial vault is such a simple procedure that it is worth trying on many epileptics. By removing a portion of the unyielding skull and substituting instead an expansile diaphragm in the shape of the scalp one will allow of quicker adjustment of intracranial tension, and thus, perhaps, diminish the frequency or severity of epileptic seizures.

The Young Practitioner.—F. M. Bell contributes an article interspersed with humor and philosophy, on the early years of waiting in the physician's practice. He states that the conquest of disease comes not by intuition but by earnest labor. Reticence, indecision, and lack of self-confidence are three of the greatest obstacles to success, and it is these failings which are wont to make the young practitioner seek paths of ease and irresponsibility. Just as long as he shirks responsibility, so long will he remain a nonentity in the medical world.

Operative Treatment of Fractures.—A. F. Jonas discusses the open method of treating simple fractures. He states that experience has shown that with open operation the external retention and fixation appliances must be of the same design and must be applied with the same care as

in cases in which no incision is made. He formulates the following rules: 1. All fractures that can be adjusted manually and can be fixed in a position that will insure a good functional result, even though the Röntgen rays indicate a lack of perfect end-to-end approximation, are to be treated by the closed method. 2. In all fractures with a marked deformity, such as overlapping, angulation, lack of contact of fractured surfaces, when it is apparent that union will not take place, an open operation is done. 3. In all cases in which there is an interposition of soft structures or loose bone fragments an open operation must be done. 4. All compound fractures are treated by operation if the broken ends do not fall into easy apposition. 5. All depressed cranial fractures are cases for an open operation. 6. All spinal fractures showing symptoms of compression are cases for an open operation. The Röntgen ray must be employed whenever possible to aid in a proper estimation of the extent and location of the fracture. It must determine whether bone approximation is sufficient after the fixation appliance, internal or external, has been applied. Having determined at the earliest possible moment that manipulation is fruitless to replace the broken bones, an immediate operation should be done before the physiologic rarefying process has begun, or at least before it is very far advanced. Regarding technique, nothing is introduced into the open wound that has touched the skin. Finger contact is avoided. All parts of the wound are handled with sterile instruments. In all cases in which an open operation is found necessary three forms of material are used to insure bone coaptation, viz., the silver plates of Sick, bronze-aluminum wire, and chromic gut: the latter only to reinforce the metallic appliance.

Gastroenterostomy for Non-Malignant Diseases.—J. D. Dunham reports the results of analysis of 48 cases of gastroenterostomy for ulcer of the stomach. There were 15 deaths. He draws the following conclusions: 1. Hyperchlorhydria as a symptom of chronic gastric ulcer is inconstant and should be disregarded. 2. Perfect recovery may occur when atony of the stomach has existed before the development of ulcer and motor insufficiency persists. 3. Many of the fatalities cited in his report would have been averted had the family physician made a diagnosis before serious complications had developed. Forty patients in his series of cases gave a history of ulcer covering five years or more before the diagnosis was made. 4. Pylorectomy offered a better prognosis for recovery in 5 of the fatal cases. Three of the patients were lost by fatal hemorrhages from the ulcer area, and 2 died as a result of carcinomatous transformation of the pyloric ulcer. 5. The legitimate field for gastroenterostomy in benign diseases of the stomach is a chronic ulcer near or below the pylorus, with stenosis.

Bloodletting in Children.—H. Stern sketches the history of bloodletting, especially in the nineteenth century and the advocacy of its use in children by certain authors in the later years of that century. The opinion prevails among most of those who have contributed to the subject since the revival of bloodletting in the beginning of the nineties of the last century that early age *per se* offers no specific contraindication to this procedure. The author gives a table of the amount of blood that can be safely extracted at different ages, but says that bloodletting in children is distinctly contraindicated in chronic hydermia and in cachectic conditions. It goes without saying that general depletion is a much more energetic measure in children than in adults and the infant needs every drop of blood as soon as the acute condition demanding depletion has subsided. The author believes that bloodletting in proper cases is probably the most potent single remedial measure that one possesses, and he wishes to arouse interest in the clinical study of this old remedy under modern conditions and modern means for observation.

Submucous Resection.—R. M. Nelson has devised the following method for prevention of perforation in submucous resection of the nasal septum. After making the first incision through the mucous membrane down to the cartilage, and separating the membrane from it as far back as necessary, instead of cutting through the cartilage at the same line of incision followed in going through the membrane, the cartilage is carefully cut through from one-eighth to one-fourth inch posterior to the incision through the mucous membrane. The rest of the operation is done after the usual methods. At the close of the operation, instead of the cartilage being cut off flush with the incision through the mucous membrane, there is left a projecting ledge of cartilage extending from one-eighth to one-quarter of an inch posteriorly from the line of this incision. In bringing the raw surfaces of mucous membrane together this projecting ledge of cartilage is found not only to be completely covered over, but also to appear to aid very materially in holding the edges of the wound in close apposition, acting somewhat as a natural splint.

Blood-Vessel Anastomosis.—V. D. Lespinasse, G. C. Fisher, and J. Eisenstaedt describe the use of magnesium rings for blood-vessel end-to-end anastomosis. The physical qualities of magnesium include its solubility in saline fluids and the body fluids and the non-toxic character of the products. The authors describe the technique, in which several methods are employed, each of which is described. The method of repair of a longitudinal slit in a blood-vessel is also described. The period in which the magnesium rings are absorbed varies from 80 to 100 days for complete absorption. There is nothing inside the lumen of the vessels after the operation is completed, and if trauma to the intima is avoided and the vessel washed free from all clots and not tied tightly enough so that the rings cut the intima where it bends outward to form the flange, thrombosis will not occur. Secondary thrombosis, such as occurs in the Payr operation, is impossible. Primary stricture cannot occur if the vessel is accurately measured and a proper sized ring is at hand with which to make the anastomosis. Secondary stricture has never occurred in any of the experimental operations. Primary hemorrhage could not occur and there is no danger of embolus unless there is thrombosis. The following principles must be kept in mind in making blood-vessel anastomosis with magnesium rings: 1. The vessel must be accurately and cleanly dissected. 2. All wound hemorrhage and oozing must be checked. 3. All clots must be removed from the ends of the blood-vessel. 4. A proper sized ring must be used. 5. The rings must be tied together under more than six-pound pressure. 6. Traumatism to the intima behind the line of union must be avoided absolutely. 7. Gentleness and accuracy in all manipulations are absolutely essential. 8. Perfect asepsis must be maintained. The authors believe that the operation is well within the skill of the average surgeon, is safe, certain, and easy, and should be done in all wounds of the large vessels, both venous and arterial, and in all false aneurysms and arteriovenous aneurysms. Under these conditions, a short piece of vessel, including the lesion, can be removed and an end-to-end anastomosis made.

Achlorhydria Hæmorrhagica Gastrica.—J. T. Pilcher states that there is a definite entity presented in the stomachs of some patients suffering from various intraabdominal and extraabdominal pathological conditions, which is characterized by the absence of hydrochloric acid and the presence of occult blood. This condition is probably effected through the agency of a reflex nerve stimulation inhibiting first the production of free hydrochloric acid to only a moderate degree. This so modifies the inhibiting factor of the gastric juice that the necessary conditions for the growth of pathogenic bacteria are furnished, chief among which are to be reckoned the streptococci and colon group, which are present in striking numbers. These direct

irritants, either themselves or in conjunction with a primary irritative factor, *e.g.* gallstones, appendicitis, pancreatitis, etc., perpetuate the pathological process until there is an achlorhydria produced. It is most probable that to the ulcerative erosion following this irritation the presence of blood may be ascribed. In the 100 stomachs examined at operation atrophy was never present, nor was there, except in one case, any evident insufficiency of the pylorus. There is a general symptomatology accompanying this condition which is very suggestive. The test meal recovered is indicative of the pathological process in the stomach. There were indications in but seven cases observed that there was no secretion from the stomach mucosa. In others the presence of mucus, the biuret reaction, and coagulation after activation would tend to show that there was still a moderate degree of enzymatic action. The cases are therefore not "achylia gastrica." Proof of the etiological factors has been deduced from the prompt and permanent recovery of the patients operated on. The condition is so common, approximately one in every fifteen stomach cases in which the patients were examined, and the indication it gives of irritation in other organs is so firmly established, not to mention the potential factor for future trouble which it itself contains, that it merits more frequent consideration in the study of possible gastric conditions.

Hebosteotomy as an Aid to Delivery.—C. W. Barrett presents this paper which was reported in the MEDICAL RECORD, Vol. 78, page 37.

Influence of Perigastric Lesions on Gastric Secretions.—M. J. Lichty describes his observations, which were reported in the MEDICAL RECORD, Vol. 77, page 1073.

Treatment of Poliomyelitis.—A. L. Skoog states that when the diagnosis is made and prodromal symptoms can be treated there is no objection to the moderate use of laxatives, and one of the most important therapeutic means is rest. Lumbar puncture may be of value therapeutically as well as for diagnosis. Hexamethylenamin may be used in the treatment of these cases. It is probably best to give the drug in as large doses as is safe for a period of a few hours and then to discontinue it for about twenty-four hours. His practice is to give from 0.12 to 0.24 grams to a child from two to four years of age, giving a dose every hour until three doses have been given, then giving no more until the following day at the same hour, when the course is repeated. This repetition may be employed as long as the acute symptoms persist. Thus one suddenly loads the body with the chemical and then allows a short period of rest. One might give from 3 to 8 grams of the drug to the adult during a daily three or four hour period of its administration. During the past months he has used this method in five cases in the prodromal stage. Three patients recovered without any paralysis, one died, and another, whose case was of the foudroyant type, developed paralysis. Hexamethylenamin has also been given to a few children in families in which there was a fear of others acquiring the disease. In patients suffering from much pain and hypersensitiveness he has used the salicylates, of which aspirin was found most agreeable to children, and he has also obtained relief by applying heavy cotton dressing to the involved extremities. Partial immobilization may have been a factor in producing the results obtained. In his practice he employs isolation of patient and sterilization and disinfection of articles and excretions.

Metastasis and Tumor Immunity.—P. Rous states that the conclusion seems justified that resistance to tumor growth can no longer be considered to depend primarily on a failure of the host to provide a stroma and vascularization for the neoplastic cells. Both may be provided by the resistant host, and yet the tumor dies. Whether the lymphocytes or some factor unknown is responsible for this result has yet to be investigated.

Laryngeal Signs of Tuberculosis.—C. L. Minor finds that the symptoms of early laryngeal tuberculosis are limited in number and not as valuable as the signs. The earliest is usually a mere weakening of the voice, which may appear long before hoarseness is noted. Next to this he would note a sense of dryness in the throat followed by a localized tickling or pricking. Pain on swallowing is not usually an early symptom in his experience. The subjective symptoms, however, are relatively unimportant as compared with the objective signs. He has not found pallor of the mucous membrane often as an early sign, and he believes that catarrh with hyperemia is usually the first sign, though it is not diagnostic. It is only when it becomes unilateral and persistent that it becomes really suspicious. An obstinate patchy catarrh confined to one cord is highly suspicious, and in a patient whose lungs are tuberculous may be safely counted as tuberculous itself. Next to this he would note as significant a grayish wrinkling of the posterior commissure, which he thinks is the commonest early finding, but it is not diagnostic. The earliest real diagnostic symptom is a table-like elevation of the mucous membrane in the posterior commissure, and this is pathognomonic. This tends to break down into ulcers and, with their abundant granulations, they may pass for tuberculomata. Next as a site of early changes is the vocal process, the posterior insertion of one cord or the body of the cord itself, where ulcers tend to appear which may be scattered along the edge. He finds some involvement of the arytenoid region very early in the disease, localized congestions or thickenings. Thickening of the aryepiglottic folds is a more advanced change, but when present is pathognomonic. Another early change, though a rare one, is the protrusion of a small point of red granulation beneath the anterior commissure, and when seen its diagnostic value is great. In the therapeutics of this stage the author insists first on absolute rest of the voice, not allowing even whispering; next, the avoidance of all irritants, especially smoking, and third, cleanliness; fourth, the use of astringents. He warns untrained physicians against resorting to endolaryngeal applications with the cotton-tipped laryngeal sound in cases of ulceration.

Antityphoid Vaccination.—G. B. Foster states that protective inoculation against typhoid fever was instituted in the United States Army in March, 1909, and over 12,000 persons have been inoculated up to October 1, 1910. About one-seventh of the personnel of the regular army have now been vaccinated, and a regulation requiring the vaccination of all recruits and all those presenting themselves for reenlistment would result, within three years, in a regular army practically immune to typhoid fever. Furthermore, in the event of hostilities, should the vaccination of the reserve army—militia and volunteers—be made compulsory before mobilization, it is reasonable to prophesy that the medical history of our land forces in past wars, as regards the incidence of typhoid fever, would not repeat itself.

On Chronic Bronchitis and Emphysema as the Result of Acute Pneumonia. S. West.
Aortic Regurgitation. W. Broadbent.

Greek Medicine in Rome.—Sir T. Clifford Allbut, in the second lecture on this subject, discusses the doctrine of the pulse, the ancient conceptions of sexual generation, the influence of pneumatism on medicine, the hygienic and therapeutic doctrines of the pneumatists, and the eminent physicians of this period.

Multiple Myeloma.—O. T. Williams and E. R. Evans report a case of this condition associated with the presence in the urine of "Bence Jones" protein. The patient was a collier thirty years of age, who for several months had had feelings of weakness, pains in the chest and between the shoulders, and anorexia. He emaciated rapidly and developed a prominence on the right fifth rib. Later there developed rigidity of the upper dorsal spine, retraction of the head, extreme muscular weakness with marked emaciation of the thenar and hypothenar eminences of the hands. The spinous ligaments between the last cervical and first dorsal and between the latter and the second dorsal vertebræ were far less resistant than in any other part of the spine, and pressure over this region caused pain which was local and not referred to any other part. The urine showed the characteristic reactions of Bence Jones protein. A little later, spontaneous fracture of several ribs and of the sternum occurred. The left sternoclavicular joint became disorganized. The patient lost the use of his legs completely, and also all sensation below the level of the loin. There was loss of control of both micturition and defecation, and in a short time death ensued. The protein found in the urine of this case gave on most occasions the characteristic reactions of the Bence Jones protein. The reactions of the protein varied from time to time. On all occasions when a thorough examination was made the protein yielded a phosphorus-free carbohydrate-containing radicle. The percentage of sulphur in the protein was found to be different on two occasions. This variation was found to be synchronous with an alteration in the output of ethereal sulphuric acid. A possible explanation of these findings is that the chondromucins of the bones and tendons are broken down in different degree at various stages of the disease. A piece of rib two inches long containing a myelomatous tumor was examined microscopically. This demonstrated conclusively that the tumor was not only a true myeloma, but was also practically identical with the plasmocytic type of growth already described.

Malignant Disease of the Testis.—R. Howard states that the question of a radical operation for malignant disease of the testis has come more and more to the front in recent years. In other parts of the body the operations for malignant disease have been progressively elaborated until it is an axiom that extirpation of the growth, with the lymphatic glands the part drains into and the intervening lymphatics, is the only radical form of operation, and that this should be done in all cases. In the case of the testicle, however, the deep situation of the involved lymphatics and the important structures which lie near them have appeared to negative the usual operative procedure, and surgeons on the whole have been content to perform castration and to trust that the lymphatics are not already infiltrated. The very few cases that escape subsequent recurrence in the glands show on what feeble grounds this hope rests, and a radical glandular operation appears to be the more urgent as local recurrence in the scrotum is rare. The author reports a case of sarcoma of the epididymis and testicle occurring in a ten-year-old boy. The latter had complained of a painless swelling of the left testis that had been present for ten weeks and that was increasing in size. The case was perhaps a fortunate one as a first operation in that it occurred in a thin boy, but that a truly radical operation on the lymphatic area in malignant disease of the testis is possible could not be disputed. In fact, the operation went a step further than Jamieson and Dobson's ideal operation, in that it cleared the whole of the external iliac artery and vein, instead of the upper third only, and their dictum that the operation "is exceedingly difficult and dangerous, if not impracticable," does not hold good in boys, at any rate.

Intravenous Medication in Pulmonary Tuberculosis.—J. McElroy reports good results in three cases of pulmonary tuberculosis in which he employed intravenous injections of chinosol with formaldehyde. Fifty c.c. of a 1 to 2,000 solution of formaldehyde plus a 1 to 4,000 solution of chinosol were injected into the median basilic or median cephalic vein—the usual precautions being taken—and this was repeated daily, the strength being gradually increased.

Operative Treatment of Papilloma of the Bladder.—J. W. T. Walker states that two probable and important causes of recurrence of vesical papillomata are the incomplete removal at the time of the operation and the implantation of fresh papillomata during the operation.

Chronic Bronchitis and Emphysema Resulting from Pneumonia.—S. West alludes to the serious nutritive changes in the lung associated with and following pneumonia. The signs of bronchitis associated with pneumonia in its acute stage have a different significance according as they have preceded the attack of pneumonia or developed in the course of it. Where the pneumonia is subsequent—*i.e.* occurs in the course of bronchitis—the association of the two affections is awkward but not necessarily of very grave significance. Where, on the other hand, the physical signs of general bronchitis develop in the course of the pneumonia they indicate not a mere bronchitis or complication of the pneumonia but pulmonary failure, a very serious condition and almost necessarily fatal. True emphysema frequently follows pneumonia as the result of atrophic changes in the alveolar walls.

Aortic Regurgitation.—W. Broadbent states that dilatation and hypertrophy of the heart are carried to a greater extent in aortic regurgitation than in any other valvular disease. The systolic blood pressure is very high but the diastolic is low. The pulse is the most important factor in estimating the amount of regurgitation.

Four Cases of Pneumonic Plague.—H. P. Sleigh describes these cases that recently occurred in the County of Suffolk, England. True to description, the disease had picked out two very dirty households. Three nurses who attended to the sick escaped infection. The incubation period was definitely five days. Prodromal symptoms were not well marked. All the patients complained of being "not well" a few hours before the onset of illness; and in one case—that of the child—there was vomiting. The invasion was sudden, and in one case at least the illness was ushered in by a rigor. All complained of severe frontal headache. The features were drawn, the expression vacant, and mental ineptitude was well marked. The temperature was high from the commencement, the thermometer registering 105° in two of the cases and 103° in the other two within a few hours of the onset of the illness, and remained high till within twelve hours of death, when in each case the temperature fell a couple of degrees. Respirations in all four cases were quickened from 30 to 40 per minute. In only one case was there definite lobar pneumonia; in two there were evanescent patches, and in the fourth no signs of pneumonia were detected. The case with definite pneumonia had no expectoration at any time of the illness; the other three had thin dark blood-stained expectoration. The pulse in all cases was feeble and fluttering, and ranged from 120 to 140 per minute. The tongue in each case was red at tip and edges, but the dorsum was covered with a thick

yellowish fur. In two of the cases there were vomiting and diarrhea. The spleen in one case at least was enlarged, but no other glandular enlargement was detected. In the child there was delirium, but in the others consciousness was unimpaired till the end, and in one case the patient gave thoughtful and intelligent instructions within ten minutes of her death. It was at once recognized that this was a highly contagious disease, so that prompt measures to isolate contacts were adopted. From specimens of sputum and blood taken from the last three cases the *Bacillus pestis* was ultimately discovered in all the specimens, but this was not demonstrated till too late to administer serum treatment. Investigation showed that many rats in the neighborhood were dying from plague.

The Recent Plague Cases in Suffolk.—H. H. Brown contributes his own description of the same cases described by H. P. Sleigh in this issue.

Radium Therapy in Eye Disease.—A. Lawson and J. M. Davidson state that they can endorse more fully now the opinion that radium is likely to prove of great service, both in the treatment of external diseases of the eye and in those of the eyelids. The results are in many ways most encouraging, and the field of utility for radium in eye disease has widened considerably since the time it was first shown to be a specific for rodent ulcer. The cases selected for treatment are divided into four groups, as follows: 1. Ulcerations of the cornea. 2. Non-ulcerative acute inflammations of the cornea and sclerotic. 3. Affections of the lids. 4. Corneal scars.

Serum Anaphylaxis.—A. K. Sloan reports a case of diphtheria in which a second attack followed six weeks after the initial seizure. The chief point of interest in the case was the occurrence of sudden collapse after the injection of serum at the onset of the second attack. At the time the cause of this was a mystery. In the light of further knowledge, however, and for the following two reasons, the author has no doubt that the grave condition was due to serum anaphylaxis: (1) The collapse occurred within two hours of the injection without other apparent cause and while the child was lying quietly in bed; (2) the collapse was accompanied by the almost simultaneous appearance of a marked serum rash of the urticarial type. Apart from the twenty-four hours' urgent illness following the injection, the author thinks that the prolonged febrile period thereafter and the slow convalescence were chiefly due to the serum phenomena. It is of the greatest moment from a clinical point of view that one should know more about the exact conditions under which the phenomena are likely to occur. This is specially important in view of the fact that foreign serums are now being put to such diverse uses. Anti-diphtheritic serum in addition to being used as a curative agent in diphtheria, is used as a prophylactic agent for the same disease, is recommended as an antituberculosis measure (Montgomery Paton), is used by some for asthma, and finally (a special serum) is used by a Paris physician for the treatment of diphtheritic paralysis. The latter proceeding, in view of the possibility of anaphylaxis occurring, would suggest itself to one as being specially open to objection when one remembers the weak condition of many patients suffering from diphtheritic paralysis.

Internal Secretion of the Generative Glands.—Münzer begins a serial article which, from the very bulk of its detached information, is very much unsuited for abstraction. The subject differs somewhat from that of mere castration, as far as theory goes, but the phenomena induced in the economy by castration are due purely to the removal of certain cell groups in the interstitial tissue of the testicle and ovary. The relationship first noted is that between the cells just mentioned and the tegumentary structures, which appears to be very intimate. The author obtains his material from castrated animals of many species and from castrated men and women. The latter are readily obtainable from the clinic, but the male castrates are represented chiefly by eunuchs and members of a certain religious sect. The body of data secured is much larger than was formerly available and the individual cases vary greatly, whereas formerly they were placed in a few types. To return to tegumental changes in man. Recent writers state that human castrates look younger after the operation, but there is a larger and older literature which states that the very converse is true. A woman whose badly diseased ovaries are removed might for a time at least look younger and fresher. The reporters do not state how long these changes last. Those who have studied the Russian castration-sect state that the castrate looks either younger or older than he is. A withered, yellowish skin is, doubtless, sufficiently common in male castrates. There seems little doubt that the generative glands preside over the development of the tegumentary structures, so that their removal signifies an arrest of development. The result of such arrest seems to depend largely on the particular quality of the individual skin, the age of the subject, etc. But whether the patient looks younger or older, there are common symptoms present. The skin is abnormally thin, pale, etc. According to the circulation of the patient the complexion might seem lighter, the color higher, etc.; or in a darker, sallow skin the latter would be merely pale and yellowish. The great distinction between the complexions in health could hardly be without influence after castration. The writer, however, does not base any types upon these so that, for all we know, a sallow person may become more youthful looking and one of blooming appearance may look older as a result of castration. This is, in fact, directly stated of the male religious castrates. The marked loss of energy in both human and animal male castrates is believed to rest on a direct relation between the generative glands and the muscles, a certain loss of muscular tonus resulting. In an economical sense this loss, of course, represents a gain. The castrates have less muscular power, but the very loss enables one to use them for draft purposes, etc. This change in muscularity makes the flesh of certain animals more tender; but there is no universal law at work here. Thus the capon is by no means always a castrated cock, but one that has been crammed by force feeding. Skeletal growth seems also under the control of the internal secretions to some extent. Eunuchs are notable for their size, and castration of women for osteomalacia is distinctly curative. The earlier castration is done, *i.e.* during the period of tegumentary, muscular, and skeletal development, the more marked are the results. Many data are on record in regard to the skeletal changes in castrated animals, and those in savage races of men. Those who mature early sexually are usually very short of stature. The pelvis of a castrate, man or animal, is said to assume the female type, but otherwise there is no movement in this direction. The atrophying effect of castration or the arrest of development in either sex on the other genital organs has been abundantly studied. The effects of castration on the growth of the hair are complex. The head hair is not disturbed or may be increased. Women may develop a beard after castration, while men lose theirs. But hair anomalies are so common that the majority of them do not appear to depend on disturbance or removal of the generative glands.

Prevention of Epilepsy, Idiocy, and Psychopathy by Treatment of Nurslings and Young Children.—Thiemich discusses a possible connection between bottle-fed

and breast-fed infants in respect to relative cerebral development. Examination of the best endowed and efficient school children often shows a superior development of the head while the converse is also true. But too many exceptions occur to justify the setting up of laws. The author proposes to discuss only the disturbances of nutrition which affect mental development, leaving the effects of infectious disease to Hoppe. The subject leads into many bypaths, and the conclusions of the author as to his department may be stated: Of great importance for epilepsy is the elimination of an alimentary factor; or, in other words, there is not sufficient evidence to show that infantile convulsions and the so-called spasmophilic diathesis are forerunners of epilepsy. On the other hand, there is a marked connection between alimentary traumatisms during the first year and imbecility, as well as neuropathy, in general. There is reason to believe that a full diet of good breast milk prolonged a sufficient length of time might be of considerable prophylactic value. Such a diet, with general hygiene, should lead to a strengthening of the organism, with incidental normal quality of cerebral functions. Hoppe, discussing the possibility of preventing the sinister effects of infectious diseases upon the cerebrum of the nursling, states that some cases of meningitis, polioencephalitis, etc., appear to be directly due to measles and scarlatina. Some of the earliest cases of epilepsy seem to be due to infectious disease. There is little to be said of tuberculosis at this time of life. The bulk of Hoppe's article is therefore bound up in the effects of hereditary syphilis, which may be made responsible for a number of cerebral lesions. Suspicious cases may be treated as syphilitic (the authors make no reference to the claim that 606 is contraindicated in nurslings). Studies like the preceding are naturally weakened by omission of all considerations of antenatal pathology, but the authors are openly dealing with the born child only.

Pulmonary Tuberculosis and the Muscles of the Chest.—This antiquated subject has received considerable attention for the past twenty years or more, new problems arising from time to time which concern the walls of the chest in connection with the intimate nature of the *habitus phthisicus*. Fischer seems to confine himself to the state of the muscles directly over a tuberculous focus. The muscle first shows a state of paresis, which is best demonstrated by testing its mechanical excitability, the latter being increased. The primary condition is followed by degenerative atrophy. The only way of explaining these phenomena is that they are due to the absorption of the tuberculous toxin.

Successful Treatment of Pyorrhea Alveolaris.—Sachs, a practising dentist, writes this article in the interest of the medical practitioner. The condition is purely local, and due to local irritation. It is aggravated by numerous constitutional disorders which may represent a predisposing element, but is common enough in the most healthy subjects. The treatment is complicated, and varies with the duration and general state of the individual. Any constitutional disorder must be removed and the patient's health brought to the highest possible point. All local disturbances due to dead tissue and granulations must be removed, including salivary calculus, etc. Lactic acid 50 per cent. should be introduced into the alveoli. The teeth should be kept clean and, as a preventive measure, one must remove all fresh deposits of lime, which are generally promptly infected. The presence of fresh infection is shown by strong pressure over the alveolus, which is followed by a drop of pus. The measures used at first for combating the disease are, in fact, to be continued for at least a year. When all signs of pus have disappeared for several weeks the patient may be well, but it is mostly a matter of months, for considerable time is required for Nature to fix firmly the loosened teeth. Only in desperate cases does the author resort to reimplantation and bridgework, which often fail outright and may even aggravate the condition.

Deutsche medizinische Wochenschrift.

November 10, 1910.

Vaginal Operative Methods in Obstetrics.—Jung sums up his article as follows: Bossi's rapid and powerful dilatation with his dilator must be rejected, save in cases where the cervix is effected and regular strong pains are taking place. The method should never be used in a primipara, and no one should resort to it save a skillful and experienced obstetrician. Placenta prævia furnishes a strict contraindication. Metreurysis is the best resource for the gradual hastening of labor, and for placenta prævia with living child. Colpohysterotomy is the best resource for the placenta prævia centralis, but can be used only in the clinic. Metreurysis is the best way to cause premature labor. In placenta prævia with dead child combined version is the best resource. Whenever immediate delivery is necessary colpohysterotomy is indicated if the pelvis is normal. If the woman cannot be taken to the hospital metreurysis should be employed as an emergency measure. Dührssen's deep cervical incision is too bloody an operation to be done outside the clinic. The indications for typical cesarean section and Porro's operation are those usually given.

Treatment of Laryngeal Tuberculosis.—Schroeder tabulates his own experience as follows. He refers naturally to early cases. The patient should be in an institution and the kernel of the treatment is treatment of the patient, for the larynx usually improves with the improvement of the lungs and general state. When fever or complications are present these must first be treated. In certain cases with definite indication the various operative resources may be employed. Results from tuberculin treatment are dubious.

Treatment of Cancer of the Upper Third of the Esophagus.—Pernice, first discussing a cancerous stricture at this point, or rather a stricture suspected of being cancerous, would make a trial esophagotomy; but should the patient chance to be still vigorous would continue the intervention to radical operation. He would use Kocher's incision with two longitudinal incisions dropped from either end. If the cancer is found to have involved parts of the respiratory system these would have to be removed as well, and before attacking the esophagus. The stump of the trachea must be sutured to the skin, if it has been necessary to remove the larynx, etc. The mediastinal pouch must also be tamponed before removing any tissue. After extirpation of the diseased esophagus the lower extremity must be sutured into the skin as far as possible from the tracheal opening; that is the latter occupies the upper, while the former occupies the opposite angle of the wound. The upper stump of the esophagus is sutured completely submucous. Small, frequent meals must be given at once.

Subcutaneous Infusion in Eclampsia.—Fränkenstein believes that the known injurious effects of the saline infusion in kidney diseases eliminates it from the treatment of eclampsia. He suggests various substitutes without much seeming confidence, since any kind of infusion is dangerous if there is danger of cardiac collapse. Instead of the normal saline infusion may be substituted the infusion of 4 per cent. sugar solution.

Treatment of Myomata with Röntgen Rays.—Schnidler, who has recently published a monograph on this subject with some favorable results, has since added others to his list and now believes that these results justify the advice to the practitioner to subject his patient to treatment with the rays before surgical removal. Especially does he give this counsel in severe cases in which the prognosis of recovery under surgery is not good.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynecology.

Stated Meeting, Held October 27, 1910.

Dr. S. M. Brickner in the Chair.

Congenital Transverse Septum of Vagina Complicated by Pregnancy.—Dr. Max Rosenthal presented a woman, 23 years of age, who had consulted him three weeks after her marriage because of an irritation of the external genitals, a bad discharge, and pain in coitus. Examination showed an eroded and injected introitus. The vagina was about one and one-half inches long and formed a pouch in which there were no traces of the fornices. At the apex of the sac was a small opening which scarcely admitted a probe. The uterus could not be felt distinctly through the vagina. He had the impression that the cervix lay just above the opening of the sac. Three weeks after first seeing her she again presented herself and her symptoms indicated that she had become pregnant. They had therefore to deal with a pregnancy complicated by a congenital partial atresia of the upper part of the vagina. Neugebauer in his monograph on congenital and acquired stenoses and atresiæ of the vagina mentioned 57 cases of congenital transverse occlusion of the vagina and Brickner, six or seven years ago, published four similar cases in the *Zeitschrift für Geburtshülfe und Gynäkologie*. Several theories had been advanced to explain these malformations. Transverse partitions of the vagina were found normally in the chimpanzee and some regarded these deformities as atavistic manifestations. This anomaly might also be accounted for by an invagination of the Wolffian duct into the duct of Müller after the formation of the genital cord. Perhaps the most likely explanation was some irregularity of absorption of the Müllerian ducts during that part of embryonal life when these ducts became absorbed to form the vagina. According to Neugebauer Cesarean section had to be resorted to in 56 cases in which this deformity existed, including 28 Porro operations. In one of Brickner's cases he was able to effect a delivery by the natural passages by simply making crucial incisions into the membrane which presented in front of the protruding head. Inasmuch as pregnancy had supervened before he had decided upon what plan to pursue in order to correct the deformity he had decided not to interfere for the present, as he did not care to risk inducing an abortion by surgical manipulations and he had further decided that an excision at the present time might result in stenosis from the cicatrization of a circular wound, which might be an even more impassable barrier than the present condition. He intended to wait until labor set in and act according to indications.

Dr. Simon Marx said that during the past twenty years he had seen three cases of a similar nature. In one case the vagina was one and a half inches in length and the cervix could be felt behind it. He inclined to the belief that it was a transverse hymen. When this patient became pregnant and went into labor the septum stretched out; an incision made into it permitted the baby to promptly appear. In another case labor was practically normal. In a third case the transverse partition was torn, the vagina and perineum were torn, dissecting the vagina entirely away from the rectum.

Dr. James N. West reported an instance of transverse septum of the vagina in a woman who had aborted at the third month. She had retained secundines and it was necessary to curette her. The vagina was so narrow that it was impossible to introduce a speculum. So he divided the septum and introduced a clamp on each side, suturing them in place with catgut. He then curetted her. She made an uneventful recovery.

Dr. S. M. Brickner believed that the patient presented by Dr. Rosenthal had a congenital malformation of the vagina, a condition which he had met with about twenty-five times. In all the cases they were able to demonstrate some vestiges of the hymen. The condition itself presented nothing of importance until the woman became pregnant. In speaking of the etiology of the condition he referred to some anatomic work and what he had found in the whale, sheep, and other animals. He demonstrated upon the blackboard the different transverse septa as they appeared in different animals. They acted as barriers to the seminal fluid. These transverse septa represented he thought a reversion of type.

Dr. Rosenthal said that his first impression was that he was dealing with an imperforate hymen. The cervix could be felt on top of the opening. This was in all probability a congenital transverse septum of the vagina.

Large Fibroma of the Ovary with Twisted Pedicle.—Dr. Louis Friedman reported this case, an Italian girl nineteen years of age. She had begun to menstruate at the age of sixteen. Two years ago menstruation stopped for ten months, when it again became regular. About six months previous to her admission to the hospital she had noticed a hard mass in the abdomen. She was taken with sudden colicky pains, which were not relieved by morphine; she vomited several times and had some temperature. On admission to the hospital she had a pulse of 158 and a temperature of 104.2. The entire abdomen was rigid; there was a tender mass in the McBurney region and evidence of some fluid in the abdomen. The symptom complex was presented of an appendix abscess with peritonitis and the usual Kammerer incision was made. The tumor proved to be a fibroid of the right ovary with a pedicle twisted one and one-half times. The pathologist's report was read which showed the growth to be a pure fibroma of the ovary, measuring 22 x 14 x 12 cm.

Dr. Robert T. Frank said that such tumors required operation because they were so often followed by massive ascites. Even in cases of comparatively small fibroma of the ovary, attention would be called to the condition because of the marked ascites.

Dr. H. D. Furniss reported the case of a girl, seventeen years old, who had a growth which was diagnosed dermoid of the ovary. It was found to be a fibroma of the ovary. There was about one pint of free fluid in the abdomen.

Puerperal Pyonephrosis.—Dr. Ralph Tousey reported this case, a woman, forty-four years of age, who had always enjoyed good health up to the time of the birth of her second child, twenty-four years after the birth of the first. The child was born without instruments, but the placenta did not come away readily and was manually extracted an hour later. On the fifth day post partum there was a sudden rise of temperature of 103° F., and the uterus was explored without finding any retained potions of the placenta or membranes. The bladder was catheterized and from this time there was slight bladder discomfort and increased frequency of micturition. Five weeks after labor these symptoms became more marked and the health of the patient began to fail. Three months after labor she had a gnawing pain in the left lumbar region. Blood examination showed a low hemoglobin percentage and a high leucocyte count. At the end of four months after labor the woman had lost thirty pounds and passed urine hourly by day and by night with vesical tenesmus. The left kidney was painful, tender, and presented a fluctuating tumor reaching to the navel, and pushing the enlarged spleen toward the median line. The right kidney was palpable but not tender. The urine from the bladder and from the left kidney was full

of pus, but without casts or kidney elements. *Staphylococcus pyogenes aureus* was alone present. The cystoscope showed a general cystitis without ulceration. Treatment with urotropin, abundant fluids, bladder irrigations with boric acid lessened the discomfort. At operation an incision was made over the fluctuating tumor and several pints of creamy pus evacuated from the pelvis of the left kidney. Slight adhesions to the descending colon were separated and the pelvis and an abscess in the cortical portion of a kidney were drained with rubber tubing; gauze drainage surrounded the mass and the wound was partly closed. Relief from all disease symptoms was immediate, the temperature only once rising above 100° F. The tube was removed on the tenth day, the tumor mass disappeared, and the urine gradually approached normal. After eight weeks in bed the patient regained her health and strength. Urotropin and abundant fluids were continued. At present, four months after operation, the patient had a granulating wound one inch long with a urinary fistula through which leaked a half ounce of urine daily. The bladder urine still showed a slight trace of pus.

Toxic Hematoporphyrinuria, Complicating Septic Perforation of the Uterus with Peritonitis.—Dr. S. Wiener reported the case of a woman, twenty-five years of age, admitted to Mount Sinai Hospital on July 31, 1910, after having taken repeated doses of saffron for the purpose of inducing abortion, and after having used hot vaginal douches, inserting a hard rubber tube about six inches. This was followed immediately by severe abdominal pains and bleeding; the blood passed was bright red. The general condition of the patient on the morning of her admission was poor, facies anxious, pale, and lips cyanotic. The eyeballs were icteric, tongue dry, temperature 102° F. Pulse was 124, regular, soft, and compressible. The white blood cells were 15,000 and polynuclears 87 per cent. The abdomen was lax and tympanitic in the upper half, while the lower half was rigid with dulness on percussion. Tenderness extended over the entire abdomen, but was most marked in the iliac regions. The cervix was soft and admitted the tip of the finger and the uterus was enlarged to the size of a two months' pregnancy. A small quantity of port-wine colored urine was obtained by catheterization and aroused a suspicion of injury to the bladder. Urinalysis showed no red blood cells, no hemoglobin, a few granular casts, amorphous urates and a trace of albumin. The reaction was acid. A further specimen showed the presence of hematoporphyrin. The patient was operated upon and eight ounces of fluid blood was found in the abdomen. All the visible peritoneum was injected and on the posterior surface of the uterus there were two small irregular perforations. A panhysterectomy was done. Both tubes and ovaries were intensely congested; the ovaries were cystic and the corpus luteum of pregnancy was found in the right ovary. Murphy irrigation was started and camphor and morphine injected hypodermically. The pulse and general condition grew worse; the lips and extremities at first were deeply cyanotic, then of a remarkable purplish black hue. The patient sank into coma and died. Autopsy was refused and a blood culture taken *intra vitam* was negative and there was no growth in the tube inoculated with peritoneal fluid. It was a difficult matter to say to what extent the drug toxemia contributed to the fatal issue. The peculiar discoloration and the rapid onset of coma seemed to indicate that the immediate cause of death was saffron poisoning and not peritonitis. The hematoporphyrinuria must be attributed to the ingestion of saffron. The cases of saffron poisoning reported by Garrod and Corvey which Dr. Wiener reviewed showed blood in the intestines and in the stomach, and in Ferraris' case the urine was reported as "bloody." Garrod had shown that intestinal hemorrhage might give rise to hematoporphyrin.

Dr. Max Rosenthal said that saffron had first been used as a coloring matter in the making of bread. Some years ago there appeared a report of a large number of cases in which death was due to saffron which had been taken to procure abortion.

Four Cases of Ureteral Calculi.—Dr. H. D. Furniss reported these cases. He stated that his reason for bringing them before the section was because they gave very different clinical histories and for this reason were instructive. They taught that renal calculi might exist with few, if any, of the typical text-book symptoms.

Case I.—Mrs. H., aged fifty-seven, whose previous history was negative, experienced pain in the left renal region for the first time a year before Dr. Furniss had seen her. The pain did not radiate to the front, upward, nor downward, nor was it referred to the opposite side. It lasted twelve hours, during which time there was no frequency of urination; but a month later she began to be troubled with frequent micturition. Physical examination revealed nothing abnormal except a small elongated mass in the region of the left ureter, to the left and behind the cervix. The two ureteric orifices were alike but a catheter inserted into the left met with an obstruction three-quarters of an inch up. A radiograph showed a shadow at this place. The patient refused an operation.

Case II.—Mrs. E. R., aged fifty-three years, whose history was negative, had been in good health until five years ago, when she began to have attacks beginning with lassitude followed by a sensation of lameness in the outer side of the right thigh. There was pain in the right renal region which radiated to the front and downward along the course of the ureter. Then followed frequency of urination. After about twelve hours the patient was relieved of the pain, but was prostrated for a week. The day following the attack the urine was quite turbid. These attacks had occurred at intervals of from eight to ten weeks. An attempt was made to catheterize the ureters and an obstruction was met with three and one-half inches from the vesical orifice. A radiograph showed two shadows at this point. The urine flowed only from the left ureter. The patient was operated upon and made a good recovery.

Case III.—This woman, forty-one years of age, gave a history of an instrumental delivery, puerperal fever, phlebitis of both legs, after which she had attacks of pain, associated with temperature, in the right kidney region during a period of three years, which terminated after the discharge of a large amount of pus through the bladder. Two months after this she began to have pains in the left kidney region associated with nausea and temperature. During attacks the urine would be clear, but between attacks pus was found constantly. During the past year each attack had become more severe. There was no frequency of micturition except at night. Catheters were passed easily to the pelvis of the kidney on both sides. The urine from the right kidney was clear, while that from the left was turbid from the presence of pus. A radiograph showed the presence of two stones in the pelvis of the left ureter. A radiograph taken with the bougie inserted showed that the bougie passed them.

Case IV.—Mrs. L., twenty-six years of age, whose previous history was negative, was four months' pregnant, had severe crampy pains in the left lumbar and inguinal region lasting for eighteen hours. She was ill with the pain and temperature for a week; after this she had pain in both inguinal regions. Three weeks after her labor she passed an oval stone, experiencing pain only when the stone passed the urethra. Three weeks later she passed another stone and had some frequency of urination before the pain. Cystoscopy showed a normal bladder. The catheter in the left ureter was obstructed three inches up the ureter. Radiographs showed that there were two stones in the left kidney, a stone in the left ureter opposite

the transverse process of the third lumbar vertebra, two stones in the pelvic portion of the left ureter, and a stone opposite the transverse process of the third lumbar vertebra in the right ureter. The urine from the right side was clear, while there was a moderate amount of blood from the left.

The Value of Local Treatment in Gynecological Cases.—Dr. JOHN VAN DOREN YOUNG read this paper in which he expressed the opinion that the value of local treatment of gynecological cases, in both private and hospital practice, was much underestimated by surgeons and was not fully appreciated by the physician in general practice. It was his object in this paper to bring out discussion which might more clearly define the dividing line which separated those cases which should receive local treatment and those which were amenable only to operative procedures. At present there was danger of expecting too much from surgery; it was the combination of surgery and local treatment that gave the best result. Dr. Young divided local treatment into three groups: The first, hygiene and general care; the second, treatment applied directly to the affected parts; and the third, treatment which might be carried out by the patient in her home. Under the first head Dr. Young emphasized the importance of proper hygiene, clothing, exercise, proper sleeping quarters, dietary, and especially the care of intestinal toxemia and constipation. If the general health was neglected little could be expected even from a most skillful operation. Tonics looking toward the improvement of the appetite, digestion, and anemia were most important. He had obtained very satisfactory results from the use of glycerophosphate of soda in fifteen grain doses in a glass of hot water one hour before meals, combined with calomel one tenth of a grain, and with three grains of soda every four hours. He urged the importance of sleeping in a well ventilated room or outdoors, if possible. The mental conditions and surroundings should also be taken into consideration as they often had a decided influence on the progress of the case. In considering the second head, local treatment, Dr. Young called attention to the importance of taking a careful history and stated that the examination should be made on a proper examining table with the patient properly prepared, bowels and bladder emptied, corsets removed, and all waist bands loosened. Inspection of the external genetalia should be made first, followed by digital examination, examining the right side of the pelvis with the right hand and the left side with the left hand. Dr. Young outlined the routine treatment which he carried out in both private and hospital practice as follows: The external genitalia were cleansed by a boric acid solution and dried. If an acute inflammatory condition was present the same solution was used on a cotton swab and the vaginal canal was cleansed. Crude pyroligneous acid was then applied to the external genitalia and to the vaginal canal. The speculum was then introduced and the cervix cleansed with boric acid solution and crude pyroligneous acid applied up to the internal os. Iodine was applied to the cervix ulcerations and carbolic acid and iodine where a more active agent was required. Pure carbolic acid or the actual cautery might be used. Cysts of the cervix were punctured. Tampons were of actual value and might be divided into alkaline, antiseptic, specific antiseptic, hygroscopic, and hygroscopic with analgesics. He recommended the use of ichthyol 10 to 20 per cent. in glycerin, also 10 to 20 per cent. in boroglyceride. The combination of boroglyceride with ichthyol, iodine, carbolic acid, and hydrastis had given him excellent results. Pipe clay with glycerin or combined with glycerin and ichthyol he used as a serviceable supporting tampon. His method of tamponade was to apply the medication upon absorbent cotton and to hold the cotton in place by tampons of lamb's wool. Applications, either by applicators or syringe, might be made in the uterine cavity with great advantage. Irritant applications should be intermitted if the treatment was frequent or the vaginal mucosa would be damaged. Electricity had its advantages. All treatment, vaginal or intrauterine, should be carried out with surgical precautions. In discussing the third factor in local treatment, those measures which the patient could carry out herself, Dr. Young mentioned the douche, which should be given in the recumbent posture, from two to twelve quarts being used at a temperature of from 100° to 120° F. As so frequently used the douche was valueless. He advised rest after taking a prolonged douche. Postural treatment might be advantageously carried out by the patient to rest an anteflexed and anteverted uterus by assuming the Trendelenburg position. In cases of retroversion rest upon the face or the knee-chest position would often give relief. Dr. Young was sceptical in regard to tampons and suppositories introduced by the patient herself. The cases in which local treatment was of value might be outlined as follows: Inflammation of the external genitalia, infections of the urethra and bladder, many conditions of the rectum and anus, inflammatory and infectious conditions of the vagina, cervix, and endometrium, erosions, ulcerations or cystic degeneration of the cervix, cervical stenosis, uterine and pelvic congestion, local peritonitis, tubal infection, retroversion, and the inoperable uterine prolapse in elderly patients. Local treatment had a field both as preparatory to operation and for the relief of postoperative conditions.

Dr. SAMUEL BANDLER called attention to two or three points which he said had been impressed upon him as being important in the treatment of cases other than operative. He believed that drugs applied locally or in douches much above the external or internal os were not very effective. Their action upon the higher areas was purely a mechanical one. It should be remembered that water at a certain temperature would produce anemia, while at another it would produce hyperemia. One should bear in mind the mechanical principles involved and bring about an anemia or a hyperemia according to indications. Dr. Bandler said that he was a great believer in electricity in nonoperative cases. With this agent one could produce anemia or hyperemia according to his wants. Another factor which was of great value was the substitution of gauze for cotton for vaginal packing. He rarely used cotton tampons as they were not valuable in supporting the uterus. Where operation was not urgent the patient should be prepared for it beforehand. He had adopted the principle of applying postoperative treatment before the operation.

Dr. JAMES N. WEST said that if there was any condition in which local treatment was of value it was in diseased conditions of the cervix. It was very important that the cervix should be treated before operation. A cervix filled with small cysts, erosions, etc., to such an extent that amputation seemed necessary, was many times relieved of the diseased condition and then operation became a matter of simple trachelorraphy, which retained fecundity. With regard to the treatment of retroversions, Dr. West recalled several instances in which the retroverted uterus was in the hollow of the sacrum and abortions occurred about the third month in each case. In two of these cases operation was refused and by packing the vagina to support the uterus and hold it above the pelvic brim until the natural enlargement of that organ from the growth of the fetus kept it up had enabled the women to go to term. It was surprising to note the relief that could be afforded patients with inflammatory conditions or retroversions. When he assisted Dr. Emmett at the Woman's Hospital they had used lamb's wool for packing, and cotton only for medication. Such tampons could remain in the vagina two or three days without irri-

tating the patient at all and there was no odor. He had applied argyrol, silver nitrate, and other medicaments to the interior of the uterus, but never got satisfactory results. He felt that local treatment so far as inflammatory conditions were concerned was limited to the cervix, the vagina, and the vulva.

Dr. JOHN O. POLAK said that it was surprising how little the general practitioner knew about the introduction of the pessary at the present time. Unless properly placed the vagina would not tolerate this foreign body. Dr. Skene had suggested that the vagina should have preliminary treatment before the pessary was introduced. If tolerance was once obtained it was amazing how long a patient could wear a pessary without discomfort. He agreed with what had been said in regard to intrauterine applications. They did no good. In gonorrheal cases nature in time would kill the gonococcus inside the uterus. He had followed cases with pus tubes for years, five or ten, and then opened the abdomen and found them intact. Every tube containing the gonococci did not always form a pyosalpinx. The douche worked well in cases of leucorrhea, especially when a dilute one-half to two per cent. lactic acid solution was used.

Dr. CHARLES GARDNER CHILD called attention to the vagueness of the description in text books as to how to make applications through the vagina and to the vagina. The proper method was to have the patient in the knee-chest position, retract the perineum, with the finger or speculum, and when the vagina bulged out from the in-rush of air to make the application. The only field for the use of a pessary was in displacements with a freely movable uterus and one which was replaceable. The less tamponing that was done the better for the patient. The vagina should always be prepared before the introduction of the pessary.

Dr. ROBERT T. FRANK said that there were two classes of cases which were particularly difficult to treat, especially in dispensary practice. The first class consisted of those young women who developed rectocele and cystocele with leucorrhea after child-birth. While an operation would relieve the condition it was contraindicated because if the woman had more children the operation would be nullified. The second class consisted of those cases of diseased adnexa in which pains were comparatively slight and the acute stage of the disease passed, but in which malpositions were present. Tamponing and other mechanical measures relieved these patients to a certain extent. Frequently when these patients came to operation a more radical operation was found necessary than had previously seemed to be indicated. In these two classes of cases medical treatment was very unsatisfactory but was, nevertheless, preferable to operative interference in young women.

Dr. SOLOMON WIENER spoke of another form of local treatment, the use of the hot-air cabinet. This treatment relieved pain. Two applications of twenty minutes each were often made, after which patients would state that pain was much relieved.

Dr. JOHN VAN DOREN YOUNG said that he had seen many patients at the clinics for whom something should be done; it seemed a pity not to try to help them. Dr. Young commended the interesting nonoperative gynecological work that Cabot of Boston had done.

The Small Cystic Ovary.—Emile Forgue and Georges Massabuau state that the cardinal symptoms attributed to the microcystic ovary are pain, hemorrhage, and general nervous symptoms. Many sclerocystic ovaries do not cause pain. Others are accompanied by inflammatory symptoms due to pelvic peritonitis and adhesions, and it is the removal of these ovaries that brings relief of the pain. There are also small, free ovaries that are very painful, and their removal brings with it little relief. Hemorrhage seems to be caused much more frequently than pain by the sclerocystic ovary.—*Revue de Gynecologie.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June, 1910.

ANATOMY.

Answer any ten questions on this paper, but no more.

1. Describe the coccyx. Name the muscles attached to it.
2. Describe the ileocecal valve. What is its function?
3. Give the coverings of a femoral hernia from within outward.
4. Give the minute structure of the kidney.
5. Describe the inferior radio-ulnar articulation.
6. Describe the suprarenal glands. State their function. What would be the effect of their removal?
7. Describe the glands and villi of the intestines.
8. Give the foramen of exit, the distribution, and the function of the oculomotor nerve.
9. Where does the glossopharyngeal nerve rise, and what structures are supplied by this nerve and its branches?
10. Locate and describe the lymphatics of the front of the thorax.
11. Give the origin, course and branches of the temporal artery.
12. Name the principal centers of organic function in the medulla oblongata.
13. Locate the respiratory center.
14. From what portions of the cortex cerebri do the arm, face and leg receive their motor impulses.
15. What would be the effect of a transverse section of (*a*) the anterior root, (*b*) the posterior root of a spinal nerve?

PHYSIOLOGY.

Answer any ten questions on this paper, but no more.

1. What is blood pressure?
2. Name six factors that influence it.
3. Compare woman's and cow's milk.
4. State the functions of the facial nerve.
5. What kind of digestion occurs in the duodenum?
6. Where do the products of digestion actually get into the blood?
7. What is a proteid?
8. Name the ductless glands and give their function.
9. How is the bodily heat maintained?
10. What is muscular co-ordination, and by what centers is it controlled?
11. What disturbances would follow ligation of the renal arteries?
12. What is the actual cause of death when induced by asphyxiation, and where is the damage localized?
13. Compare voluntary and involuntary muscle. State one exception to the general rule of their differences.
14. State the properties of pancreatic juice.
15. Compare physiologically, mucous, serous, and synovial membrane.

CHEMISTRY.

Answer any ten questions on this paper, but no more.

1. Discuss arsenic and mention its properties, uses and compounds. Give antidote for poisoning by arsenic.
2. Name three elements in the potassium group, with their symbols and atomic weights.
3. Give the symbol and quantivalence of sulphur. What are the principal oxygen compounds of sulphur? In what form is it used as a germicidal and disinfecting agent?
4. (*a*) State the normal reaction of urine. (*b*) To what is it due? (*c*) State the variations in normal specific gravity. (*d*) What pathological conditions are indicated by a very high or a very low specific gravity?
5. Give the chemical formula and derivation of acetic acid. Mention the most important acetates.
6. Give the names and formulas of three gases used for producing general anesthesia.
7. What are enzymes? Mention those of animal origin and where found.
8. Give test for the detection of bile in the urine.
9. Which are the principal opium alkaloids and with what acid are they combined in opium.
10. What is cholesterin? In what pathological condition is it found?
11. Give the chemical formulas and common names of magnesium hydrate and magnesium sulphate.
12. (*a*) What is tartar emetic? (*b*) What are the symptoms of poisoning by tartar emetic?
13. (*a*) What is hemoglobin? (*b*) In what pathological condition is hemoglobin found in the urine?

14. (*a*) What is the ammonium radical? (*b*) Give chemical formula of the ammonium compound contained in aromatic spirit of ammonia.

15. (*a*) Give the source and chemical formula of common salt. (*b*) How are chlorides chemically recognized in urinary analyses?

MATERIA MEDICA AND THERAPEUTICS.

Answer any ten questions on this paper, but no more.

1. Name (*a*) the source, (*b*) the preparation, and (*c*) the effects of ergot.

2. Differentiate the symptoms of atropia and morphia poisoning.

3. (*a*) By what drug, and (*b*) by what method may local anesthesia be induced?

4. Explain the theory of the action of antitoxin.

5. (*a*) Mention five preparations having antiseptic properties; (*b*) give adult dose of each.

6. Describe (*a*) the method of administration, and (*b*) the results to be accomplished by the hot pack.

7. State (*a*) the source, (*b*) the action, and (*c*) the therapeutic uses of strychnia.

8. (*a*) What remedies may be used in septic condition of the alimentary canal? (*b*) Give dose of each.

9. Outline a dietary in (*a*) chronic rheumatism, and (*b*) chronic interstitial nephritis.

10. Write a prescription for any ailment in which iodide of potassium may be used.

11. Specify (*a*) three official preparations of aconite; (*b*) adult dose of each.

12. Give (*a*) the source, (*b*) the physiological action, and (*c*) the infantile dose of santonin.

13. (*a*) Prescribe in proper form for diarrhea in a child four years of age; (*b*) explain the action of each ingredient.

14. Give (*a*) the therapeutic uses, and (*b*) the adult dose of terebine.

15. Define (*a*) alteratives, (*b*) antipyretics, and (*c*) mydriatics.

HISTOLOGY—PATHOLOGY—BACTERIOLOGY.

Answer any ten questions on this paper, but no more.

1. Describe the rôle of uric acid in gout.

2. Give etiology of valvular heart disease.

3. How does aortic insufficiency affect the circulation of the blood?

4. Define anemia.

5. Define immunity.

6. Describe a microscope and such accessories as you would use in histologic work.

7. Describe preparation of objects for microscopic examination.

8. Describe the cell body.

9. Describe the process of mitotic cell division.

10. Define chromatolysis.

11. What are bacterins?

12. What is the effect of an injection of bacterial vaccine?

13. Describe preparation of and varieties of culture media.

14. Give technique of making plate cultures.

15. Give method of examining sputum for detection of tubercle bacilli.

PRACTICE OF MEDICINE.

Answer any ten questions on this paper, but no more.

Differentiate:

1. Acute pericarditis and acute endocarditis.
2. Apoplexy and acute alcoholism.
3. Cancer and ulcer of stomach.
4. Chancre and chancroid.
5. Diabetes and acute glycosuria.
6. Epilepsy and hysteria.
7. Hemoptysis and hematemesis.
8. Intestinal and hepatic colic.
9. Organic and functional heart disease.
10. Pneumonia and pleurisy with effusion.
11. Pyelitis and cystitis.
12. Scurvy and purpura.
13. Typhoid fever and acute tuberculosis.
14. Edema glottidis and retropharyngeal abscess.
15. Cerebral concussion and cerebral compression.

OBSTETRICS AND GYNECOLOGY.

Answer any ten questions on this paper, but no more.

1. Give a comparative description of the virgin uterus and the uterus after child-bearing.

2. State procedure in case the head refuses to engage the pelvic brim.

3. How may rupture of the uterus complicating delivery be recognized? How should such a condition be managed?

4. Under what circumstances during labor may obstetric anesthesia become advisable? Mention an appropriate anesthetic for this purpose and describe the method of its administration.

5. What may cause delay in the second stage of labor? How should such a condition be managed?

6. What are three most dangerous forms of uterine hemorrhage?

7. Outline your treatment of the foregoing types of uterine hemorrhage.

8. Describe toxemia of pregnancy and state what may be done to prevent or to relieve this condition.

9. Under what circumstances is induction of abortion permissible and how is it safely performed?

10. Name the varieties of salpingitis and give briefly the etiology and diagnosis.

11. What are the causes of pelvic abscess. Describe method of surgical treatment.

12. Mention the causes and state the management of cystitis in the female.

13. Mention the prodromal symptoms of puerperal eclampsia. Describe the management of puerperal eclampsia.

14. Give the causes, diagnosis, and treatment of prolapse of the ovary.

15. What is ophthalmia neonatorum? How prevented? How cured?

SURGERY.

Answer any ten questions on this paper, but no more.

1. Give diagnosis and treatment of intracapsular fracture of the femur.

2. Give technique of posterior gastroenterostomy.

3. Etiology and treatment of senile gangrene.

4. Give causes, symptoms, and treatment of phlebitis.

5. Mention the causes of non-union of fractures.

6. Give causes, diagnosis, and treatment of abscess of the liver.

7. How would you treat a penetrating wound of the trachea?

8. Describe acute suppurative osteomyelitis of the tibia.

9. Gonorrheal arthritis; diagnosis and treatment.

10. Differentiate between fracture of the neck of humerus and subcoracoid dislocation.

11. Discuss etiology of thrombosis.

12. Symptoms and treatment of acute pancreatitis.

13. Diagnosis of floating kidney.

14. Mention the conditions that may necessitate amputation of an extremity.

15. Etiology and treatment of cystitis.

HYGIENE AND MEDICAL JURISPRUDENCE.

Answer any ten questions on this paper, but no more.

1. Describe the methods usually employed for the sterilization of drinking water.

2. (*a*) What conditions of soil tend to promote health? (*b*) What conditions tend to impair health?

3. State (*a*) the main source of infection in tuberculosis; (*b*) what personal hygienic measures may be employed to prevent its spread? (*c*) what disinfectants and what method of application will tend to prevent house infection?

4. Outline in detail the precautions that should be taken in the treatment in scarlet fever to prevent the spread of the disease.

5. What diseases spread by infection from person to person?

6. What temperature should be maintained in the sick room in the treatment of (*a*) croup, (*b*) pneumonia, (*c*) typhoid fever?

7. Name the diseases regarded as quarantinable.

8. Define food and name two which are in themselves complete or perfect foods.

9. What are the legal obligations between physician and patient?

10. What are the essentials of a thorough medical examination of an applicant for life insurance?

11. What constitutes expert medical testimony?

12. Name the post-mortem signs external and internal of recent drowning.

13. In signing a certificate of insanity what facts relating to the patient should be recorded?

14. Define a wound in its medicolegal sense.

15. In witnessing a will what facts should satisfy the physician as to the mental competency of the testator?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June, 1910.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 87; or Gray's "Anatomy" (1908), page 65.

2. See Cunningham's "Anatomy" (1909), page 1077; or Gray's "Anatomy" (1908), page 1315. The *function* of the ileocecal valve is to prevent the contents of the large intestine from passing backwards into the small intestine.

3. *The coverings of a femoral hernia from within outward* are: Peritoneum, subperitoneal areolar tissue, septum crurale, crural sheath, cribriform fascia, superficial fascia, and skin.

4. See Cunningham's "Anatomy" (1909), page 1138; or Gray's "Anatomy" (1908), page 1426.

5. See Cunningham's "Anatomy" (1909), page 282; or Gray's "Anatomy" (1908), page 317.

6. See Cunningham's "Anatomy" (1909), page 1213; or Gray's "Anatomy" (1908), page 1437. The *function* of the suprarenal glands is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body. *Removal* of both suprarenals causes death very soon; removal of one suprarenal is not necessarily fatal.

7. See Cunningham's "Anatomy" (1909), page 1062; or Gray's "Anatomy" (1908), page 1300.

8. The oculomotor nerve leaves the skull through the sphenoidal fissure, and is distributed to the levator palpebræ superioris, rectus superior, rectus inferior, rectus internus, and obliquus inferior muscles of the eye. It is the *motor* nerve of these muscles.

9. See Cunningham's "Anatomy" (1909), page 689; or Gray's "Anatomy" (1908), page 1066.

10. See Cunningham's "Anatomy" (1909), page 923; or Gray's "Anatomy" (1908), page 807.

11. See Cunningham's "Anatomy" (1909), page 809; or Gray's "Anatomy" (1908), page 612.

12. The special centers located in the medulla oblongata are: (1) Center for mastication, (2) for secretion of saliva, (3) for sucking, (4) for deglutition, (5) for vomiting, (6) for voice, (7) center for expression, (8) cardiac centers, (9) respiratory centers, (10) vasomotor centers.

13. The respiratory center is situated at the tip of the calamus scriptorius, in the gray matter in the floor of the fourth ventricle.

14. The *motor areas* are located and arranged on the cerebral cortex, immediately in front of the fissure of Rolando. At the upper part of the convolutions in front of this fissure are areas connected with the movements of the lower extremities; then from above downward are located the centers for movements of the shoulders, arms, wrists, fingers, face, lips, tongue, and larynx and pharynx.

15. Transverse section of the *anterior root* of a spinal nerve causes loss of motion and degeneration of the peripheral portion of the anterior root fibers; the sensory fibers of the posterior root are not affected.

Transverse section of the *posterior root* of a spinal nerve causes loss of sensation and degeneration, which latter differs according as the section is made on the proximal or peripheral side of the ganglion. If the section is made between the cord and the ganglion, degeneration only occurs in the piece severed from the ganglion, but connected with the cord. If the section is made beyond the ganglion, degeneration occurs in the fibers peripheral to the lesion.

PHYSIOLOGY.

1. *Blood pressure* is the pressure of the blood against the walls of the blood vessels, due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance of the capillaries.

2. In addition to the three factors just mentioned in Question 1 are: (4) The frequency of the heart beat, (5) the quantity of blood in the circulation, (6) vasomotor influences.

3. Human milk contains less proteids and fats and salts than cow's milk, and at the same time contains more sugar and more water.

4. The facial nerve is the motor nerve of the muscles of expression, also of the platysma and the buccinator; it also supplies the muscles of the external ear, the stylohyoid, and the posterior belly of the digastric. Through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands.

5. In the *duodenum*, proteids, fats, and starches are digested.

6. The products of digestion get into the blood: (1) In the portal vein, and (2) where the thoracic duct enters the venous circulation, at the junction of the left subclavian and internal jugular veins.

7. A *proteid* is a complex organic substance, of unknown constitution, composed of carbon, hydrogen, oxygen, nitrogen, and sometimes containing also sulphur, iron, or phosphorus. It has distinct chemical properties, and is the chief constituent of muscles, glands, nerves, blood, lymph, and serum. It is indispensable to all animal and vegetable life.

8. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, cocygeal, pituitary, and pineal glands. The *function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin. The *function of the thymus* is not settled; it is said: (1) To be a blood forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity. The *function of the thyroid* is not definitely settled; (1) it has some trophic function; (2) it is supposed to antagonize toxic substances; (3) it produces an internal secretion. The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body. The *function* of the *other* ductless glands is unknown. They all, or nearly all, furnish an internal secretion.

9. The heat of the body is *maintained* by the thermotactic centers in the brain and cord, keeping an equilibrium between the heat gained or produced in the body and the heat lost. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord. *Heat is given off from the body* by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

10. By *muscular co-ordination* is meant the harmonious working of various related muscles to produce a definite result. The *centers* are in the cerebellum and spinal cord.

11. Ligation of both renal arteries is fatal.

12. The actual cause of death in asphyxia is paralysis of the respiratory center by the prolonged action of the venous blood. The damage is chiefly found in the right side of the heart, the pulmonary arteries, and systemic veins, all of which are gorged with venous blood; the left side of the heart, pulmonary veins, and systemic arteries, are empty.

13. *Voluntary muscle* is under the control of the will; *involuntary* is not. *Involuntary* muscles have alternate periods of rest and activity, or are characterized by rhythmicality; involuntary muscles are also characterized by peristalsis. *Voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is non-striated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated.

14. The *pancreatic juice* is a viscid, alkaline fluid. It contains four ferments: Trypsin, which converts proteids into proteoses and peptones and afterward decomposes them into leucin and tyrosin; amylopsin, which converts starches into maltose; steapsin, which emulsifies and saponifies fats; and another ferment which curdles the casein of milk. It also contains: Leucin, tyrosin, xanthin, soaps, chlorides of potassium and sodium, phosphates of calcium, sodium and magnesium, sodium carbonate, and water.

15. *Mucous membrane* lines those parts which communicate with the exterior of the body; it contains glands, basement membrane, connective tissue support, blood and nerve supply, and epithelium.

Serous membrane lines closed cavities (except peritoneum in the female); it contains a basement membrane and endothelial cells, but no glands.

Synovial membrane is in connection with joint and tendons, and has no glands, but a basement membrane with connective tissue cells.

CHEMISTRY.

1. Arsenic has symbol As, atomic weight of 75, molecular weight of 300, valence of three or five, generally occurs in combination with sulphur; is a brittle, crystalline solid, or an amorphous powder, insoluble in water. It is poisonous. If pure it has no odor or taste. It is used in the manufacture of fly poison, rat poison, shot, pigment and fireworks. Its chief compounds are: Hydrogen arsenide; arsenic trichloride; arsenic trioxide, and pentoxide; arsenous, arsenic, metarsenic, and pyroarsenic acids; arsenic bisulphide, trisulphide, and pentasulphide. The antidote is freshly prepared solution of ferric hydroxide.

2. Lithium, Li, 7; Sodium, Na, 23; Potassium, K, 39.

3. Sulphur, symbol S, quantivalence 2 or 6. Principal oxygen compound: Sulphur dioxide SO_2, and trioxide SO_3. The yellow sulphur is generally used as a disinfecting agent; it is burnt, thus forming the oxides of sulphur.

4. (*a*) Acid; (*b*) acid sodium phosphate; (*c*) about 1015 to 1025; (*d*) *very high specific gravity* may denote: Diabetes mellitus, glycosuria, heart disease, and acute fevers; *very low specific gravity* may denote: Albuminuria or Bright's disease.

5. Acetic acid, CH_3COOH. It is produced by the dry distillation of wood. *Most important acetates:* Ammonium, iron, lead, potassium, and zinc.

6. Chloroform, $CHCl_3$; ether, $(C_2H_5)_2O$; nitrous oxide, N_2O.

7. *Enzymes* are hypothetical substances, produced by living cells, and capable of causing definite chemical changes in certain substances. Their chief characteristics are: "(1) They are capable of causing change in a large amount of the materials upon which they exert their specific actions, while they themselves remain unaltered. (2) Prolonged contact with alcohol destroys the activity of most enzymes. (3) For each there is a definite temperature at which the action is most energetic; and all are destroyed at 75 to 80 degrees. (4) Each produces its best action only in a medium of a certain reaction. (5) Their action is hindered by accumulation of their products."—(Witthaus' *Essentials of Chemistry.*)

Animal enzymes: Ptyalin, in saliva; pepsin, in gastric juice; trypsin, amylopsin, and steapsin, in pancreatic juice; glucase and lactase in the intestinal mucus; thrombase, in the blood.

8. Test for *bile:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

9. *Principal opium alkaloids:* Morphine, narcotine, papaverine, codeine, narceine, and thebaine. These alkaloids are in combination with meconic, lactic, and sulphuric acids.

10. *Cholesterin* is a monoatomic alcohol of unknown constitution. It is found in biliary calculi.

11. Magnesium hydrate, $Mg(HO)_2$, milk of magnesia; magnesium sulphate, $MgSO_4$, Epsom salt.

12. (*a*) *Tartar emetic* is antimonyl potassium tartrate. (*b*) *Symptoms of poisoning:* "These are seldom delayed more than half an hour. Nausea, violent and continual vomiting, burning pain in stomach and bowels, with an acrid, burning sensation in the throat, are usually the first symptoms. Then purging, intense thirst, feeble, rapid pulse, cramps in legs, and general lowering of the temperature, with great prostration, follow. The coldness extends even to the internal organs. The bowels become tympanitic. The spinal centers are greatly depressed. The urine is generally increased, but sometimes diminished or suppressed, and may be bloody and passed with difficulty and pain. Delirium and convulsions may precede death, or the patient may sink into coma, or die from exhaustion."—(Riley's *Toxicology.*)

13. Hemoglobin is a very complex, organic substance, which forms the coloring matter of the blood, and is the oxygen carrier; it contains iron. It is found in the urine in Blackwater fever.

14. The ammonium radical is NH_4; it has never been isolated, but it enters into several compounds. Ammonium carbonate, NH_4HCO_3, is contained in aromatic spirit of ammonia.

15. (*a*) NaCl; obtained from rock salt, sea water, or salt springs. (*b*) Chlorides are recognized in the urine by the addition of a few drops of nitric acid, and then a solution of silver nitrate; a white curdy precipitate is produced.

MATERIA MEDICA AND THERAPEUTICS.

1. Ergot. *Source:* The sclerotium of claviceps purpurea. *Preparations:* Fluidextract, extract, and wine of ergot. *Effects:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative; it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

2. In poisoning by *atropine*, the pupils are dilated, the pulse is rapid, and respiration is increased; in poisoning by *morphine* the pupils are contracted, the pulse and respiration are slowed.

3. (*a*) Local anesthesia may be produced by cocaine. (*b*) See Rose and Carless' "Surgery" (1908), page 1318; or Da Costa's "Surgery" (1908), page 1047.

4. *How* antitoxin produces immunity and effects cure is not known, but *theories* deduced from observed facts are as follows: "As the various pathogenic bacteria produce the causative toxins of their respective diseases, so the organic cells of the body, reacting under the stimulus of the poisons thus introduced, immediately proceed to elaborate defensive bodies, which if produced in sufficient quantity will neutralize the effects of the toxins. Residual antibodies remaining in the blood after recovery render the animal immune for a time against the disease. The immunizing and curative effects obtained by the injection of the blood serum of an immunized animal into the circulation of another animal are due either to direct chemical neutralization of the toxins themselves by the antibodies so introduced (Behring, Kitsato), or to a particular influence exerted by the antibodies upon the living cells of the orgamism which, being affected in two opposite directions, remain neutral to the disease (Buchner). Some authorities hold that these results are due to the conjoint action of leucytic and chemical forces. Ehrlich's side-chain theory assumes that every toxin contains toxophore molecules having direct toxic action, and haptophore molecules which combine the toxophores with a similar combining group of molecules in the tissue cell of the attacked organism. The tissue cell molecules being destroyed by the toxophores, a rapid and profuse regeneration of similar molecules occurs in side chains, and these molecules overgrowing are carried into the circulation, becoming the antitoxin, which acts by combining with the haptophores of newly arrived toxin, using up their combining power before they can reach the tissue cells."—(Potter's *Materia Medica*, etc.)

5. Mercuric chloride, dose gr. 1/20; mercuric iodide, dose gr. 1/20; silver nitrate, dose gr. 1/5; creosote, dose ♏v to xx of the carbonate; and salicylic acid, dose gr. vij.

6. The hot-pack "is used, not only to cause sweating and so relieve the patient of poisons and fluid in renal diseases, but also to relax muscle spasm and to relieve nervous excitement and nervous insomnia. It is particularly efficacious in the nervous insomnia of severe chorea in children.

"A bed is prepared by covering it with a rubber blanket. Over this is placed a dry woollen blanket. A large, heavy blanket is now dipped in very hot water and then wrung out, and the naked patient quickly wrapped in it, the dry blanket being folded over him after several hot-water bottles have been placed alongside the patient. Finally the sides of the rubber sheet are drawn around and over the patient and an ice-cap placed on the head. A thermometer should be placed in the mouth every half hour, and if the patient's temperature becomes febrile (101°) he should be taken out of the blankets and rubbed dry."—(From Hare's *Practical Therapeutics.*)

7. Strychine. *Source:* Strychnos nux vomica, and strychnos ignatia. *Action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis stimulates the vasomotor centers, and so raises arterial tension; it stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes. *Therapeutic uses:* For indigestion, intestinal torpor, heart disease, pneumonia, amenorrhea, dysmenorrhea, paralysis, impotence, and as a cardiac and respiratory stimulant.

8. *Gastrointestinal antiseptics:* Carbolic acid, dose gr. j; creosote, dose ♏xij; guaiacol, dose ♏vij; salol, dose gr. x; resorcin, dose gr. iij; thymol, dose gr. vij; silver nitrate, dose gr. 1/5; sodium sulphocarbolate, dose gr. xij; betanaphthol, dose gr. vj; salicylic acid, dose gr. xij.

9. (*a*) "In the dietetic treatment of chronic rheumatism, especially if the patient is anemic, animal food cannot be excluded, but the basis of the diet should be farinaceous food with a few fresh green vegetables. Fish, eggs, and fowl may be eaten, but dark meat is not desirable. Sweets and alcoholic beverages should be omitted, and all foods should be plainly cooked and eaten in moderation."—(Thompson's *Practical Dietetics.*)

(*b*) See Osler's "Practice of Medicine" (1909), page 700.

10. ℞. Potassii iodidi 3iij.
Syrupi sarsaparillæ q. s. ad 3ij. ℥.
Signa: Take one teaspoonful after each meal.

11. Aconite, gr. j; fluidextract of aconite, ℥j; tincture of aconite, ℥x.

12. SANTONIN. *Source:* Santonica, flower heads of Artemisia pauciflora. *Action:* Anthelmintic to round worm and thread worm. *Dose for an infant:* Gr. ⅛-¼.

13. ℞. Olei ricini, 3j.
Sig. Take at once.

Its action is to remove the irritating material in the intestinal canal. This can be followed by other treatment if necessary.

14. TEREBINE. *Therapeutic uses:* For cough, emphysema, dyspepsia, phthisis, chronic bronchitis, bronchiectasis. Dose, ℥vij.

15. *Alteratives* are remedies which modify the nutritive processes, and so promote metabolism. *Antipyretics* are agents which reduce body temperature. *Mydriatics* are agents which dilate the pupil of the eye.

HISTOLOGY—PATHOLOGY—BACTERIOLOGY.

1. See French's "Practice of Medicine" (1907), page 925; or Osler's "Practice of Medicine" (1909), page 398.

2. See French's "Practice of Medicine" (1907), pages 572, 576, 580, 583, and 588; or Osler's "Practice of Medicine" (1909), pages 796, 802, 804, and 808.

3. See French's "Practice of Medicine" (1907), pages 574 and 584; or Osler's "Practice of Medicine" (1909), pages 793 and 798.

4. *Anæmia* is a condition in which there is a reduction in the quantity of the blood, or of the number or hemoglobin contents of the red corpuscles.

5. *Immunity* is non-susceptibility to disease, or the power of resistance of cells and tissues to the action of pathogenic microorganisms.

6. See some good text-book on Histology or Microscopy.

7. The object is first placed in some fixing fluid, then it is washed, then hardened by immersion in alcohol, then treated with some clearing agent, then placed in paraffin; it is then ready for the section cutter. After the sections are cut, the next process is staining, after which the object is ready for examination.

8. See Cunningham's "Anatomy" (1909), page 8.

9. See Cunningham's "Anatomy" (1909), page 9.

10. *Chromatalysis* is the disintegration of the coloring matter or chromatin of a cell, or the breaking down of the nucleus of a cell when the latter dies.

11. *Bacterins* are bacterial vaccines.

12. After bacterial vaccines have been injected into the tissues, there is first of all a diminution in the amount of opsonin in the serum; there is no appreciable rise of temperature; the patient complains of malaise, and local lesions may become temporarily worse. Then additional opsonin is made and turned into the serum, the opsonic index rises, fever diminishes, the patient feels well. This is followed by a slight diminution of all these latter symptoms, and a position of equilibrium is reached. Later, there is a period of decline.

13. See French's "Practice of Medicine" (1907), page 1212.

14. See French's "Practice of Medicine" (1907), page 1214.

15. The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minues, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue

PRACTICE OF MEDICINE.

1. In *endocarditis:* The murmur is soft, not harsh; it is systolic or diastolic; it may be transmitted; it is heard loudest at definite points; it is not followed by signs of effusion; the apex beat may be strong.

In *pericarditis:* The murmur is harsh; is not in connection with the heart sounds; is heard loudest at the base of the heart and over the precordium; is followed by (or accompanied with) signs of effusion; the apex beat is generally feeble.

2. In *acute alcoholism* the coma is not usually absolute; there may be an odor of alcohol on the breath, the patient can generally be aroused by shouting in his ear; there is no paralysis; the pupils are normal or dilated; respiration is practically normal; the pulse is first rapid and later feeble, and the skin cool. In *apoplexy* there is generally paralysis of the head and upper limbs, and in left-sided lesions there may be aphasia; the pulse is slow and full; the respirations are at first slow, regular, and stertorous, later on becoming of the Cheyne-Stokes type.

3. *Cancer of stomach* does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; there is progressive emaciation; severe anemia and cachexia are also present.

Ulcer of stomach is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

4.

CHANCRE.	CHANCROID.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

5. See French's "Practice of Medicine" (1907), page 943.

6.

EPILEPSY.	HYSTERIA.
1. No apparent cause.	1. Cause, emotional.
2. Sudden and rapid onset.	2. Onset gradual, usually after some mental excitement.
3. Aura generally present.	3. Globus hystericus or palpitation.
4. Consciousness lost.	4. Consciousness generally preserved.
5. Pupils generally dilated.	5. Pupils normal.
6. Tongue often bitten.	6. Tongue never bitten.
7. Patient very liable to hurt himself.	7. Patient not liable to hurt himself; may injure others.
8. May be involuntary bladder and bowel discharges.	8. Never.
9. Of short duration.	9. Duration longer.

7. See Osler's "Practice of Medicine" (1909), page 489.

8. See French's "Practice of Medicine" (1907), pages 813 and 852.

9. In *organic* heart disease the murmurs are due to stenosis or incompetency of one or more of the valves of the heart.

In *functional* heart disease the murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

10. See French's "Practice of Medicine" (1907), pages

172 and 698; or Osler's "Practice of Medicine" (1909), page 652.

11. See French's "Practice of Medicine" (1907), page 908; or Osler's "Practice of Medicine" (1909), page 706.

12.

SCORBUTUS.	PURPURA HÆMORRHAGICA.
Occurs in those subject to lack of vegetable food and to bad hygiene.	No such etiological relationship.
Definite antecedent symptoms: weakness, impaired circulation, etc.	Antecedent signs slight or absent.
Onset slow.	Onset sudden.
Gums spongy, swollen, and bleeding; teeth loose.	Gums often bleeding but not swollen.
Severe muscular pains.	Less marked.
Brawny infiltration of lower extremities.	Not present.
Hemorrhages from mucous membranes not as a rule profuse.	Hemorrhages from mucous membranes often so severe as to prove fatal.

—(From Schamberg's *Diseases of the Skin.*)

13. See French's "Practice of Medicine" (1907), pages 101 and 104; or Osler's "Practice of Medicine" (1909), pages 93 and 299.

14. See French's "Practice of Medicine" (1907), pages 646 and 718; or Osler's "Practice of Medicine" (1909), pages 444 and 598.

15.

CONCUSSION OF THE BRAIN.	COMPRESSION OF THE BRAIN.
Unconsciousness is incomplete; patient can be made to answer, though it may be briefly, and in simple words.	Complete unconsciousness; may scream into patient's ear at the top of the voice, but will receive no answer.
Special senses, though greatly blunted, are not abolished.	Special senses entirely suspended.
Power of movement not destroyed; if the position of a limb be changed the patient will resist or bring it immediately into the original position.	Complete or partial paralysis; in most cases hemiplegia.
Respiration is quiet and feeble.	Respiration full and noisy.
Pulse feeble, frequent, and intermittent.	Pulse full and slow, and sometimes laboring.
The stomach sickens and rejects its contents.	The stomach is insensible to any impression; no nausea or vomiting.
The feces may be discharged incontinently, as may also the urine, though not usually.	Bowels are torpid, and the bladder incapable of emptying itself, though the urine may escape by overflow.
Deglutition little impaired.	Deglutition difficult or impossible.
Pupils variable, though generally contracted; the eyelids somewhat open.	Pupils variable, though generally much dilated, and the eyelids closed.
Temperature of the body less than natural.	Temperature almost natural, a little below the normal standard.

—(From Treves' *Manual of Surgery.*)

1. OBSTETRICS AND GYNECOLOGY.

VIRGIN UTERUS.	UTERUS OF MULTIPARA.
The cavity is of normal length—about two and a half inches—and normal (triangular) in shape.	The cavity is increased in length—three inches or more, and is oval in shape.
The cervix is small, hard, and cartilaginous, and of the same length as the body.	The cervix is large and soft; it is nearly one inch in length, while the body of the uterus measures nearly two inches.
The external os appears as a transverse slit or pinhole orifice with smooth edges.	The external os is irregular and its edges are fissured.
The uterine sound shows that the sides of the cavity of the body are convex inward.	The sides of the cavity of the body are convex outward.
The uterus is normally anteflexed.	The axis of the uterus is apt to be straighter, or the uterus may even be retrodisplaced.
There is more or less flattening of the anterior and posterior uterine surfaces.	The contour of the body of the uterus is more rounded, while its diameters are increased.
The fundus is nearly flat.	The fundus is convex.
The internal os is closed.	The internal os is partially patulous.

—(From Dorland's *Obstetrics.*)

2. Empty the bladder and rectum; determine if there is a faulty presentation, as bregma, brow, or face. Measure diagonal conjugate and height of symphysis, and determine the true conjugate. If this latter measures less than 2¾ inches in a simple flat pelvis, or 3 inches in generally contracted pelvis, the contraction is absolute, and only cesarean section or craniotomy is possible. Ascertain by palpation whether there is serious disproportion between head and pelvis. Malpresentations must be corrected with one hand in vagina pressing upward on the fetal anterior portion of the presenting part, and if possible drawing down in the occipital pole, aided by external manipulation. Press the head downward into the pelvis; this maneuver may be aided by Walcher's position. If there is marked disproportion, cesarean section and craniotomy must be considered. If disproportion is apparently not insuperable, rupture the membranes just after the acme of a pain, when the cervix is fully dilated, keeping the patient in Walcher's position. If the head thereupon engages during the next few pains, allow spontaneous delivery, or aid with forceps if necessary. If the head still refuses to engage, apply axis-traction forceps in Walcher's position, tentatively; if unsuccessful, perform podalic version by combined or internal method. If membranes have already ruptured, note whether there is marked retraction ring. If not, podalic version is proper, subject to limitation of slight disproportion; but if the uterus has retracted markedly, forceps, and that failing, only cesarean section, symphyseotomy, or craniotomy is admissible.—(From Scott's *State Board Obstetrics.*)

3. See Williams' "Obstetrics" (1909), page 837; or Hirst's "Obstetrics" (1909), page 597.

4. ANESTHETICS are used in labor to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum when many sutures are required.—(From King's *Obstetrics.*)

And see Williams' "Obstetrics" 1909), pages 321 and 663; or Hirst's "Obstetrics" (1909), page 320.

5. See Williams' "Obstetrics" (1909), page 660; or Hirst's "Obstetrics" (1909), page 439, etc.

6. Postpartum hemorrhage, hemorrhage due to placenta prævia, and that due to premature separation of placenta.

7. See Williams' "Obstetrics" (1909), pages 821, 815, and 808; or Hirst's "Obstetrics" (1909), pages 587, 577, and 585.

8. See Williams' "Obstetrics" (1909), page 507; or Hirst's "Obstetrics" (1909), page 263.

9. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerin, water, or some other fluid. For description of method, see Williams' "Obstetrics" (1909), pages 381 et seq., or Hird's "Obstetrics" (1909), page 799.

10. SALPINGITIS. *Varieties:* Acute and chronic; catarrhal and purulent. *Etiology:* Septic infection, gonorrhea, menstrual congestion, taking cold at the menstrual periods.

Diagnosis: Pain in ovarian region; fever; rapid pulse; local tenderness; pain on moving, walking, defecation, coitus, and during menstruation; menorrhagia and sterility; the enlarged tube may be palpated by vaginal examination.

11. Pelvic abscess. *Etiology:* Pelvic cellulitis, rupture of tube (in ectopic gestation or pyosalpinx), pus from neighboring tissues, gonorrhea. *Treatment:* The abscess should be opened and drainage instituted, generally through the vagina. And see Williams' "Obstetrics" (1909), pages 863 and 888.

12. Acute cystitis. *Etiology:* Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold. *Treatment* includes: Rest, administration of plenty of cold water or milk, diuretics, bland and mild food, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

13. See Williams' "Obstetrics" (1909), pages 525 and 541; or Hirst's "Obstetrics" (1909), pages 630 and 635.

14. *Prolapse of ovary:* "Downward displacement without displacement of the tubes and uterus may result from prolonged congestion, inflammation, subinvolution, elongation, and stretching of the ligaments, or violent strain. The symptoms are constant and severe pain, which is increased by movement and at the menstrual period, nausea and indigestion, headache, and nervous disturbances. Bimanual examination reveals enlargement, tenderness, and the abnormal position of the ovary. In uncomplicated cases the ovary may be restored to its proper position by directing the patient to assume the knee-chest posture for ten minutes two or three times daily, or the infundibulopelvic ligaments may be shortened through an abdominal incision. Pelvic congestion will require the use of saline laxatives, hot vaginal douches, the application of iodin to the cervix and vaginal vaults, and the use of glycerin tampons. Diseased ovaries should be removed and uterine displacements should be corrected."—(Gould and Pyle's *Pocket Cyclopedia.*)

15. *Ophthalmia neonatarum* is an infectious, purulent inflammation of the conjunctiva in the new-born. It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc. The *treatment* is: (1) *Prophylactic:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. By boiling and filtration. *Two types of water filter:* (1) Those which aim at acting chemically on the water as well as straining off the grosser suspended impurities; (2) those which act mechanically, having pores sufficiently fine to strain off all microorganisms. 1. The first type have a filtering medium of carbon (charcoal), or iron. Such filters strain off the grosser suspended impurities and make the water more palatable through aeration. The best, when new, slowly oxidize organic matter, lessen hardness, diminish nitrites and ammonia, and increase nitrates. They do not remove disease germs; but may, after a few days' use, increase the number of bacteria. 2. The second type provides bacteriologically pure water, but has no effect on the chemical constituents in solution; its pores are so fine as to strain off all microorganisms. Of this class are the Pasteur-Chamberland filter of unglazed porcelain, and the Berkefeld filter of infusorial earth. They should be occasionally sterilized by heat; to obtain rapid filtration pressure is necessary; muddy water should have the grosser impurities removed by a preliminary filtration.

2. "The healthiness of a soil depends chiefly on the following factors: (1) Considerable slope and permeability, so that water runs off readily and regularly, rendering both the soil and the air above it dry; (2) vegetation not excessive; (3) absence of organic emanations; (4) purity of water supply."—(Notter and Firth.)

3. (*a*) Sputum; (*b*) hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily spongebaths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*) (*c*) The sputum should be burnt; the house should be disinfected with formaldehyde.

4. See French's "Practice of Medicine" (1907), page 324.

5. Typhoid, typhus, influenza, cerebrospinal meningitis, pneumonia, diphtheria, whooping cough, mumps, scarlet fever, measles, chickenpox, smallpox, gonorrhea, syphilis, erysipelas, tuberculosis, yellow fever, leprosy.

6. (*a*) About 70° F.; (*b*) about 65° to 70° F.; (*c*) about 65° or 68° F.

7. *Quarantinable diseases:* Cholera, yellow fever, smallpox, plague, typhus, leprosy, diphtheria, scarlet fever, measles, mumps, chickenpox, erysipelas. For *length of time*, see index in French's or Osler's "Practice."

8. Food is material which when taken into the body is capable of being absorbed and then replenishes the tissues which have been consumed in the metabolism of the body. Two complete or perfect foods are milk and eggs.

9. The physician is not bound to attend a case, but having accepted he cannot leave without giving sufficient notice to enable the patient to procure another physician; the patient, however, can dismiss the physician when he chooses. The physician undertakes to use proper skill, care, and judgment in diagnosing and treating the case, and also to give full instructions as to how the patient may be best cared for. The patient undertakes to allow the physician ample opportunities to make his diagnosis, to give him all information in his power, to obey instructions, and to pay a proper fee. The physician is not allowed to divulge anything that he learned while in professional attendance, provided such knowledge was necessary to the successful conduct of the case.

10. The physician should record the assurer's answers to the questions designated by the company. He then examines the assurer with regard to actual present conditions (pulse, heart sounds, chest development, respirations, murmurs, condition of tongue, urine, rupture; traces of paralysis, syphilis, jaundice, gout, rheumatism, dropsy, and any other point indicated by the company).

11. In *expert* testimony, the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can be done only by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

In *ordinary* testimony the witness testifies to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

12. In *death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as gooseskin, and, if the body has lain upwards of twelve hours in the water, that of the hands and the feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained) composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from aphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.—(From Quain's *Dictionary of Medicine.*)

13. The following "scheme" is suggested by Frederick Peterson. I. "*Physical condition:* (1) Height, weight, nutrition, circulation, pulse, temperature. (2) Cranial measurements. (3) Stigmata of degeneration. (4) Condition of heart, lungs, alimentary canal, genitourinary organs. (5) Reflexes, pupillary and tendon. (6) Condition of cranial nerves. (7) Motor symptoms—paralysis or morbid movement, gait. (8) Common sensory symptoms—paresthesia, hyperesthesia, anesthesia. (9) Special sensory symptoms—sight, hearing, smell, taste, field of vision. (10) Speech disorders—stammering, syllabic articulation, paretic speech, motor or sensory aphasia, agraphia, apraxia, verbigeration. (11) Sleep. (12) Expression, gesticulation, attitude.

II. "*Psychic condition:* (1) Mode of speech—accelerated, retarded, mute, incoherent. (2) Conduct—Does patient care for his person and dress? Does he attend to his ordinary duties? Is he excited and active, or depressed and quiet? (3) Illusions or hallucinations? (4) Mood—Is the fundamental mood depressed, exalted, irritable, changeable, apathetic? (5) Ethical feelings—What is the state of his moral conceptions and judgments? (6) Attention—Does the patient note what goes on about him, etc? (7) Memory—Weakened or increased as regards long past and recent events. Test mathematical, geographical, and historical knowledge. Test dates, ages, and names of members of family, the events of the past few days, etc. (8) Idea-association—Is there apraxia or parapraxia? Does the patient orient himself as to place, time, and objects and persons about him? Is the flow of ideas accelerated, retarded, or incoherent? (9) Judgment—How does he explain his own morbid condition and his relation to his surroundings? What does he busy himself with now, and what are his plans and purposes for the future? (10) Delusions and imperative ideas."

14. A wound (in the medicolegal sense) is defined as any injury or lesion which has been caused by mechanical or chemical means.

15. In absence of strong evidence to the contrary, it may be assumed that the testator is quite sane. If the will is clear in language, intelligible, and written in the absence of the beneficiary (so as to preclude undue influence), the testator was probably sane. .....

Medicolegal Notes.

Prohibition of Sale of Opium by Retail.— A druggist was prosecuted under the Kentucky statute, Section 2630 (Russell's St. §5067), for selling at retail, not on a physician's prescription, a quantity of opium, with the knowledge that it was intended for smoking purposes or for habitual use. The statute provides that no person shall sell at retail certain poisons to any person without satisfying himself that such poison is to be used for legitimate purposes, and not on a physician's prescription. He was convicted, and appealed. It was agreed that the appellant was a retail druggist; that he sold the opium to the purchaser for the purpose of allowing the latter to smoke it; that it was not sold on a physician's prescription; that it is a poison, destructive to adult human life in quantities of five grains or less. The offending charge was that the appellant sold the drug by retail without a prescription to a person addicted to the use of it; and, this being so, the sale was not made for a legitimate purpose. A reversal was asked upon the ground that the statute is invalid because of uncertainty in not defining with sufficient precision the words "retail" and "legitimate purposes," and because it makes an arbitrary and unreasonable discrimination in excluding from its provisions manufacturing chemists and druggists selling by wholesale, and has the effect of depriving the appellant of his ability and property without due process of law. With regard to the appellant's first objection it is well settled that a penal statute creating an offense must be sufficiently plain and exact to enable persons of ordinary intelligence to understand its provisions. The appellant argued that the legislature should have defined the meaning of the words "retail" and "legitimate purposes," so that a druggist might know what quantity would constitute a sale by retail, and what would or would not be considered a sale for legitimate purposes. The court held, however, that it would be absurd to say that a person who had intelligence enough to conduct a drug store did not know when he was selling a drug by retail, and there ought not to be any difficulty in understanding the meaning of the words "legitimate purpose" as used in the statute. If he does not know or has any doubt about the legitimate purposes for which the drug may be used he must in good faith exercise reasonable care to find out the purpose for which it is bought. Whether or not this degree of care is used is a question of fact to be determined, if put in issue, from the evidence. On the trial the commonwealth introduced a number of physicians to show that the sale of opium for smoking purposes or to an habitual user of the drug was not a sale for legitimate purposes. Their testimony was objected to, but was held to be admissible, since the words "legitimate purposes" when applied to a sale of drugs or poisons by druggists have a technical meaning that may not be clearly known or understood by courts or jurors. The court also held that the failure of the legislature to place in this statute restrictions around the sale of opium or other drugs by wholesale did not leave it open to the objection that it is discriminatory, arbitrary, or unreasonable. The purpose of the act was to correct the evil following the illegitimate use of opium and other drugs usually bought at retail, and all persons within its scope were treated exactly alike.—Katzman v. Commonwealth, Kentucky Court of Appeals, 130 S W. 990.

Revocation of Licenses for Advertising Ability to Cure Chronic and Incurable Diseases.—The Arkansas Acts 1909, p. 637, authorizing the State Board of Medical Examiners to revoke a license to practice medicine on certain specified grounds has been held not to be invalid, as depriving a licensed physician of his property without due process of law. And that section of the statute authorizing revocation of a license for publicly advertising special ability to treat or cure chronic and incurable diseases is not invalid because of indefiniteness. Chronic and incurable diseases are specifically named and discussed in medical works, and are known to physicians possessing a sufficient knowledge of their profession to practice medicine; the word "chronic" being the antithesis of "acute," and a "chronic and incurable disease" being generally understood to be one of long standing and unyielding to treatment. It was held that the State Board's action in consulting standard medical works naming and discussing chronic and incurable diseases would not be to use them as evidence, as contended by the plaintiff, who sought to enjoin it from interfering with his practice, but rather as an aid to the memory and understanding of the members of the board.—State Medical Board of Arkansas, v. McCrary, Arkansas Supreme Court, 130 S. W. 544.

Malpractice in Application of X-Rays.—A patient sued a physician for damages for malpractice, alleging that he negligently, carelessly, and unskillfully applied the *x*-rays to the plaintiff's hand, and also caused the hand to be exposed to the rays eight or nine times, and for such length of time as to cause the skin and other tissues of the hand to be severely burned. It appeared that the plaintiff, who was a machinist, while working at his trade, sustained a supposed scratch in the palm of his hand. Later a red spot, about the size of a half dollar, appeared in the center of the palm. The plaintiff's evidence showed that he consulted the defendant about it and was told by him that he had dry tetter, or eczema. He employed the defendant to treat him and the defendant commenced to do so by applying a salve to the spot. The treatment, by various applications, was continued for more than a year without relief. The defendant then told him he would have to use the *x*-rays on the hand, that this would cure him and would not interfere with his work. The *x*-ray treatment was applied. The defendant told him to hold the palm of his hand about half an inch from the energized tube. He exposed the plaintiff's hand to the rays nine times in eleven days, each time directing him to hold his hand about half an inch from the tube. The exposures varied from 10 to 35 minutes. After the eighth treatment the plaintiff complained to the defendant that his hand was burning and paining him and afterward the defendant gave him another treatment of 10 minutes' duration. Plaintiff claimed that his hand became badly swollen; that the defendant scraped the skin until he got it nearly all removed from the palm; and that he scraped the hand to remove the parts which appeared to have been burned or cooked by the *x*-ray; that he suffered great pain and could not sleep nights, although the defendant administered 25 drops of laudanum. The hand was exhibited to the jury, showing that the injuries had resulted in a "claw hand." The defendant testified that the hand was exposed the number of times claimed, but that it was protected except over the spot to be treated, and that the hand was placed not closer to the tube than six inches, and the plaintiff was cautioned to keep it at that point. A number of physicians and surgeons testified that the *x*-ray at the time (1902) was a proper treatment for injuries such as the plaintiff had. Their testimony showed that the proper treatment was to place the hand at from six to twelve inches from the tube, and to leave it thus exposed for different periods of time to be determined from the result of the treatments. The witnesses were agreed, therefore, that if the hand was treated as claimed by the plaintiff the defendant was guilty of negligence, and if it was treated as claimed by the defendant he was not guilty of negligence. Under these circumstances the court held that the issue was plainly for the jury, who in the court below returned a verdict for the plaintiff for $5,583.33 damages. Although the plaintiff's evidence as to the manner ofapplying the *x*-rays stood alone and that of the defendant was corroborated by two other persons the plaintiff was also corroborated by some of the physical facts in the case. The expert testimony tended to show that, if the hand had been treated with the *x*-ray as defendant claimed it was, there was not much likelihood of it being burned as it was. The court considered that the plaintiff's case was supported by substantial evidence. It was held that the circuit court judge had properly declared the law defining the duty of a physician in charging that where one holds himself out to the public as a physician, the law implies a promise that he will use reasonable skill and diligence in the treatment of those employing him and that a physician need not exercise extraordinary diligence or care in treating a patient, but only reasonable care, and that he is not responsible for errors of judgment or mistake in matters of doubt.—Hales v. Raines, Missouri Court of Appeals, 130 S. W. 425.

Medical Opinion Evidence May Be Given Without Stating Facts.—An insanity expert, like any other medical expert who has made the proper professional examination of his patient, may express an opinion, though he may not yet have stated the scientific facts or external symptoms upon which it is based. But the party offering him as a witness may require him to specify in detail the observations upon which the opinion is based, so as to show the strength of the opinion. And the opposite party, in cross-examination, may call for the observations and probe the underlying facts to the fullest extent for the purpose of affecting the strength of the opinion. The jury are entitled to the facts on which an insanity expert bases his opinion, if these are sought by the prosecution or the defendant.—People v. Faber, New York Court of Appeals, 92 N. E. 674.

I. ELECTRIC SLEEP AND ANALGESIA BY MEANS OF FREQUENTLY INTERRUPTED DIRECT CURRENTS APPLIED THROUGH CLOSED WIRED CIRCUITS.

II. ELECTRIC SLEEP IN PATHS OF DISPLACEMENT CURRENTS: UNIPOLAR AND WIRELESS METHOD. ANIMAL MYOGRAM EXPERIMENTS.*

(A PRELIMINARY COMMUNICATION.)

BY LOUISE G. ROBINOVITCH, B. ès L., M.D. (Paris),

MEMBER, NEW YORK ACADEMY OF MEDICINE; MEMBER, AMERICAN MEDICAL ASSOCIATION; FOREIGN ASSOCIATE MEMBER, MEDICO-PSYCHOLOGICAL SOCIETY OF PARIS.

THE distinction between electric "sleep" and "analgesia" is one of degree and will be explained below. The history of brain electrization is given in our thesis.[1] A brief history of electric "sleep" and "analgesia" follows below.

In 1890 d'Arsonval found that high frequency currents above 2,500 and not over 10,000 periods per second caused a certain degree of anesthesia. In 1892, or earlier, Dr. Hutchinson of Providence, R. I., found that induction currents frequently interrupted with the ribbon vibrator that he had invented caused anesthesia.† In 1901 Mlle. Pompilian, director of the laboratory at the Boucicaut Hospital, Paris, produced anesthesia in frogs by subjecting them to induction currents frequently interrupted by means of a revolving wheel with twelve insulated segments designed by herself.‡ In 1902 Professors Leduc and Rouxeau experimented with direct currents interrupted by means of a revolving wheel designed by them. This wheel had four insulated segments.§ There were two contact levers; one lever was fixed and the other adjustable. By changing the relative position of the movable lever it was possible to change the period of the passage of the current. One-tenth of the entire period during a revolution was found to be the most favorable condition for producing what they called electric "sleep" or "anesthesia."

In 1905 we found, while working in the laboratories of these two professors, that an induction current obtained by an induction apparatus in which the primary coil was run by means of a frequently interrupted direct current, 6,000 times per minute, period 1/10, produced deep anesthesia in rabbits. While working out the details of the physiology of electric "anesthesia" we pointed out the dangers of using induction currents on animals[1], especially when the head was included in the circuit. In 1906 we presented researches into the blood pressure, temperature, respiration and duration of electric "sleep," as well as studies of the effects of the two polarities and of various electric currents.[1] In 1907-1908 we perfected the interrupter, general instrumentation and technique of application.[2] In 1909 we pointed out that a certain degree of analgesia and sleep could be obtained in rabbits with currents generated by a Vreeland oscillator, the preferred form of current being a pulsating one.[3]

December, 1909, we found that "sleep" could be produced by unipolar and even by wireless methods in paths of displacement currents. In 1910 Dr. F. M. Law of New York and ourselves obtained myogram traces showing muscle-nerve reaction in paths of displacement currents both by the unipolar and wireless method. After we had registered these myogram traces, Dr. Law found a valuable reference to Professor B. Danilevsky's remarkable experiments on muscle-nerve reaction in the vicinity of powerful electromagnetic fields.[4] In our experiments we worked in the vicinity of very feeble displacement currents.

The first physiological researches into electric sleep, or anesthesia, were made by Dr. Rouxeau, Professor of Physiology, Nantes, France.[5] The detailed physiologic researches into this sleep and anesthesia were made by us in Professor Rouxeau's laboratory. We were the first to utilize this anesthesia in laboratory surgery; we made the first announcement of this practical application in animal surgery July, 1906, before the jury of our Paris thesis.[1] Professor Raymond presiding. To eliminate the muscular rigidity caused by the earlier models of interrupter, we perfected the wheel interrupter in every detail and pointed out the danger of using the city current, alternating, rectified, ordinary wet battery, and all sorts of irregular currents.[6] We were the first to apply electric sleep and anesthesia in clinical work, in Dr. Mangan's service, Bureau of Admission, Ste.-Anne Asylum, Paris,[7] January 25, 1910, electric analgesia was applied by us locally to a patient at the St. Francis Hospital, Hartford, Conn., Dr. M. M. Johnson amputating the great toe of one foot and the great, second and

*Read in the Section of Pathology and Physiology of the American Medical Association, at the sixty-first annual session, held at St. Louis, Mo., June, 1910. This is part of a paper read under the title "Electric Anesthesia and Electric Resuscitation After Heart Failure under Chloroform or Electrocution." The part on resuscitation will be published in the *Journal of the American Medical Association*.

†Verbal information given by the manufacturers of coils with the ribbon vibrator.

‡Personal communication. According to Mlle. Pompilian, her paper appeared in the Comptes rendus de la Société de Biologie. We found two models of her wheel in two different firms of instrument makers in Paris; one wheel had some twelve insulated segments and two contact levers; the other had less segments.

§Professor Rouxeau did not know of the existence of Mlle. Pompilian's models when he designed this wheel.

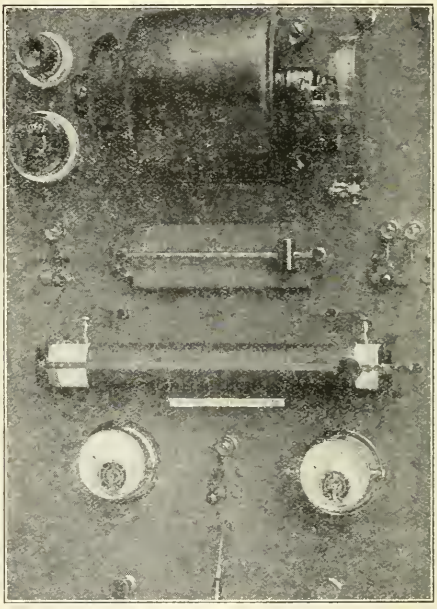
third toes of the other. The operation was published in the MEDICAL RECORD, April 23, 1910.*

Electric Source and Technique.—At this late date, when we present to you myograms showing muscle-nerve reaction by unipolar and by wireless methods in paths of displacement currents, it seems tame and crude to speak of reaction of living tissue under the influence of wired and closed circuits. But pending further investigation of our findings and practical application of wireless electricity for producing sleep in man, we may once more go over the matter dealing with currents in wired circuits in relation to sleep and analgesia, as we have applied it in clinical work as well as in animal and in human surgery.

None but storage batteries of large capacity, 100 to 200 amperes, should be used.[6] The current used for the patient and the motor should come from two separate sources. The current to be used for the patient is connected with the inlet binding posts of a graphite rheostat. A wire potentiometer should not be used because it brings troublesome inductance into the circuit, as is explained in myograms Nos. 1, 2, 3 and 4. The current is interrupted on the negative pole; this pole is connected as follows: a wire connects the outlet binding post of the potentiameter (negative pole) with the wheel interrupter, a milliamperemeter, a switch, and finally a resistance box (Wheatstone bridge or any graded resistance). The other binding post of the potentiameter (positive) is connected directly with the bridge. The resistance put into the circuit is from 300 to 500 ohms. The resistance represents the patient or the animal. The circuit is then closed by means of the switch. A voltmeter is connected in shunt, all the other instruments are in series. Now, the wheel interrupter is put in a position allowing the passage of the direct current without interrupting it (the wheel is not revolving).

*In view of this history of electric "sleep" and "analgesia," with interrupted direct currents it is to be regretted that the *Journal of the American Medical Association* states editorially, January 15, 1910, p. 211, that Drs. Tait and Russ were the first to apply the "current to practical surgical work," the practical surgical work of these physicians, according to their own account in the same journal, November 13, 1909, having consisted of pricking patients with the point of a pin, and of having made "an extensive skin incision for a phlegmon of the hand." The same editorial states that "prior to their work the problem had been studied principally from the physiologic point of view by Leduc," who, according to this editorial, is professor of physiology, and whose experiments we are said to have repeated. Apparently inspired by this authority, the *Post-Graduate*, March, 1910, also remarks editorially that Professor Leduc is professor of physiology, etc. In justice to this professor, and to Professor Rouxeau, both of whom have shown us every courtesy in promoting the progress of our personal researches into the practical applicability of electric sleep and analgesia to animal and human surgery as well as in clinical work, we wish to be allowed to state that Dr. Leduc is not professor of physiology, but of physics; that he has never manipulated any physiological instruments, and that he has never performed any surgical operations on animals subjected to this sleep; that, consequently, we could not have repeated his experiments either as regards the physiology or the surgical application of the anesthesia. The two California physicians certainly do not make any claims of priority in this matter; in a friendly conversation both stated to us frankly that they knew our works "by heart," because of frequent consultation while repeating our experiments on the surgical application of the "current." It is to be regretted that these two physicians speak of the bad results they have obtained, but do not point out the causes responsible for their bad results, as we explained these causes to them in our opening discussion appended to their paper. With our method and apparatus we never caused any untoward symptoms either in man or in animals.

The voltmeter indicates, say 40 volts; the milliamperemeter indicates, say, 20 milliamperes. Now the wheel interrupter is made to revolve by means of the motor, say, 1500 to 2000 times per minute. Whatever the amperage is while the wheel is in-interrupting the direct current, it is your aim to regulate the period of the passage of the current so as to have it pass only one-tenth of the time, nine-tenths being lost. This is accomplished by changing the position of the adjustable contact lever in relation to the fixed lever on the wheel, while the latter is revolving. Keep on adjusting the movable lever until the milliamperemeter that registered 20 milliamperes when the wheel was stationary now registers only two milliamperes, while it is revolving. The period of the passage of the current is now one-tenth. The period is of the utmost importance in this work and should be regulated every time before an experiment is commenced.* Now reduce the current to zero with the potentiameter, break the circuit by opening the switch, take out the bridge and substitute for it an animal or a patient. The wheel is made so that it can interrupt the current from 6,000 to 12,000 times per minute, according to the speed of its rotation.



The author's latest model of apparatus for obtaining frequently interrupted direct currents for electric sleep and analgesia. Exclusion of inductance from the circuit intended for the patient is one of many details improved in this model. The rheostat controlling circuit for patient is made of graphite.

It is dangerous to use any other current than that indicated above. Alternating, induction, rectified, or currents supplied by ordinary wet batteries are dangerous for this work. See our thermometric, myographic, and manometric experiments with induction currents.[1] Irregular direct currents are equally dangerous. Dr. Brewer's bad results, obtained while repeating our experiments in animal

*A leading firm in New York has constructed, under our direction, an interrupter with a fixed period of the passage of the current. See figure

surgery, were caused in part by the irregular current generated at the College of Physicians and Surgeons; laundries and elevators are run by power taken from the same main line as is that supplying the laboratories. The current is markedly uneven and we demonstrated its unevenness in this

Myogram No. 1.—Direct current interrupted with metronome forty times per minute. Current from two "dry cells" controlled with wire potentiometer in the circuit. Current so small that the meter does not register it. Muscle nerve preparation in damp chamber. M, reaction at make of circuit by metronome; B, reaction at break of circuit by metronome; I, reaction caused by inductance. Last part of trace shows irregular effect of inductance that is increasing.

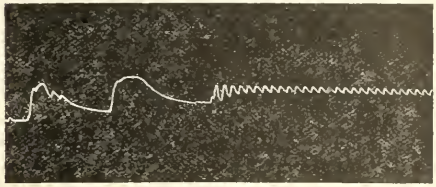
college, at a meeting of the New York German Medical Society, January 3, 1910. Unsuitable apparatus combined with such a current accounts for death and convulsions in animals, especially when too high amperage is used through error. Correct technical construction of the apparatus is of utmost importance.

Application in Dogs.—The fur is shaven on the head and over the loins. The head electrode is 9 x 9 centimeters, made of zinc, covered with absorbent cotton, wet in a 7 per 1000 salt solution of water. A similar electrode, 15 x 20, or 25 cts., is fastened over the loins. The negative pole is connected with the head electrode. It is dangerous to apply the positive pole to the head.[1] The positive pole is connected with the electrode over the loins. The current is at zero. The wheel is revolving, causing either 6.000 or 7.000 interruptions per minute; when the current is turned on; period of the passage of the current, one-tenth.

The interrupted current is turned on slowly, gradually, by means of the potentiameter. The animal begins to react vigorously and attempts to dislodge with its forepaws the head electrode when the meter registers one milliampere or thereabout. More current is turned on, and the animal makes a supreme effort to escape; still more current is turned on; when the meter registers about 2 milliamperes the animal falls on its side, there is evacuation of the bowels and emptying of the bladder; if the animal has milk in the breasts the milk spurts for a few seconds. In pregnant animals abortion

Myogram No. 2.—Muscle nerve preparation in lamp chamber. Current used for electric "sleep" and "analgesia" (direct, interrupted 6,000 times per minute, period 1/10). Current turned on gradually with wire potentiameter until reaction is seen, then current remains same during whole trace. Current so small that meters do not register it. The irregularity of muscular contraction is caused by inductance of the wire potentiometer.

may take place within from a few hours to a day after the experiment. The current is decreased a bit, say, to 1.5 milliamperes; the animal may attempt again to raise itself; the current is increased again to some 1.7 milliamperes, and the animal remains in a condition of muscular relaxation and in apparently comfortable position. If there are signs of uneasiness the current is increased again to 2 milliamperes, and the animal is ready to be operated upon. As a rule, it is useless and dangerous to increase the current above 2 milliamperes, because muscular rigidity is caused by currents



Myogram No. 3.—Consists in two parts: First part is irregular caused by inductance. This inductance was regulated by the operator until the registered muscular contraction of the same muscle resembled in form the wave form of a vibrating tuning fork. The direct-current was interrupted with a metronome 204 times per minute. If the trace is correctly interpreted, a muscle in an electric circuit with inductance acts as a capacity, and the proper tuning of this capacity to the inductance is indicated in this myogram, in its second part, showing equal reactions during make, break and inductance.

above 2 milliamperes when applied centrally in dogs. Besides, respiratory and cardiac disturbance and even difficulty may be caused by a current above 2 milliamperes. Only in rare cases is higher amperage necessary for dogs, as high as 2.5 or even 3 milliamperes; but these exceptions are about one in a hundred animals.

Consciousness is not abolished and hearing is preserved during this condition. The eyes are open and vision seems to be good. The animal may lift its head from time to time and even make an attempt to raise itself; but it falls on its side again and remains quiet. If let alone the animal closes its eyes and falls into a sleep; but if a surgical operation is performed on it the animal keeps its eyes open all the time; but there is apparently no reaction to pain; there is no sudden withdrawal of the limb operated upon even when the tissues are being torn; sudden withdrawal of the limb would be expected if pain were caused by cutting with the knife or by tearing of the tissues. The sense of touch seems to be preserved with from 1.5 to 2 milliamperes, and the animal may stretch out its limb slowly while the tissues are being touched or torn. Sometimes it is necessary to regulate the amperage during the operation, increasing or decreasing a fraction of a milliampere above the initial 1.5 or 1.7 milliamperes. It is possible that when only 1.5

M B

Myogram No. 4.—Taken with a graphite rheostat and shows total absence of inductance. A direct-current was interrupted with a metronome, 204 times per minute; reaction was recorded only with makes and breaks of the circuit. M, make; B, break.

milliamperes of current are sent through the body centrally, pain is not completely abolished, but it is sufficiently so to make it possible to operate on the animal without causing it to react in any way indicative of pain. When properly managed the animal never whines or shows any signs of distress.

The operation is generally bloodless. This condition is in accord with our manometric studies, showing increased blood pressure, apparently due to vasoconstriction. As soon as the wound is closed and the current turned off the animal arises to its feet

M B

Myogram No. 5.—Unipolar method. Reaction at make and break of direct-current feeding field coils. At break of current reaction is more marked than at make. M, make; B, break.

and does not show any resentment; it cheerfully accepts a piece of cheese or sugar offered to it.

During the last four years we have used this analgesia instead of ether and chloroform in all our laboratory surgery; we have performed hundreds of operations, but have never had any untoward accidents happen to animals as a consequence of this analgesia.

Application in Man.—Professor Leduc was the first man who submitted himself to electric sleep, Professors Rouxeau and Malherbe applying the current; but the experiment was not pushed far enough to produce complete anesthesia; 35 volts and 4 milliamperes were used centrally. In our work we distinguish between electric sleep and analgesia. We produce electric sleep in patients suffering from insomnia by applying to the forehead the negative electrode shaped to the forehead and the positive electrode to the palm of the right hand. The current is turned on slowly, gradually, some five minutes being consumed in turning on ¾ of a milliampere. Currents above this amperage are not liked by patients. When this amount of current is reached the patient feels a tingling sensation through his head and falls asleep within a few minutes. A small flag mounted on a little block of wood is placed upon the patient's chest; the flag moves with the movements of the chest that are watched all the time while the patient is sleeping. We generally let the current course through the body during one hour, then we turn it off. But the patient continues to sleep. On awaking the patient feels refreshed; if he is very sensitive he may remark that he feels "a bit chilly." This chilly feeling is probably caused by the vasoconstriction during the passage of the current.[1] We believe, on the basis of these experiments, that during natural sleep there is also vasoconstriction, and consequently decreased energy of osmosis through the vascular walls in the cerebral arteries.

Electric sleep or analgesia should not be combined

Myogram No. 6.—Reaction at make of direct-current feeding field coils, at make of arc and at break of direct-current feeding field coils and vacuum tube. M, make; A, arc; B, break.

with morphinization, chloroforming or any other soporific agents.[7]

Locally.—In clinical work we have applied electric anesthesia in numerous cases.[8]. The chosen part of the body or limb is included in the circuit, the cathode always being nearer the central nervous system, the anode the distal electrode. If the chest is in the circuit, the amperage should be governed judiciously, as may be judged from all our published papers dealing with electric sleep and resuscitation.[9]

Surgical Application in Man; Locally.—We ap-

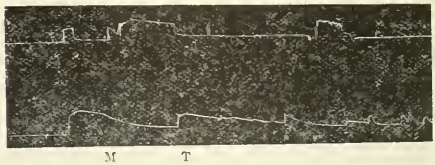
Myogram No. 7.—Upper trace: wireless; one end of wire connected with binding post of damp chamber. Other end of this wire held at a distance of fifteen centimeters from field coils and arc in vacuum tube; these coils and arc in vacuum tube in operation. No weight on muscle.

Lower trace: End of the wire three centimeters from tube anode. Reactions take place at make and break of arc in vacuum tube.

plied locally electric analgesia in man for surgical purposes January 24, 1910; the patient, a man twenty-three years old, was at the St. Francis Hospital, Hartford, Conn. Dr. M. M. Johnson operated and was assisted by Dr. Edward Herr. The leading physicians and surgeons of that city witnessed the operation.[10] The patient talked with those near him while his toes were being amputated. The great toe of one foot and the great, second and third toes of the other were amputated. The operation was bloodless. Four milliamperes of current and 54 volts were used in this case. Other surgical cases in which we applied electric analgesia locally are not yet published. One of these was a major operation of the lower limb and was also bloodless. The vasoconstriction accounts for this.

In some cases we used 9 milliamperes for amputation of the toes (one in a man, another in a woman) and 18 milliamperes for resection of the leg in a man. Neither of these patients withdrew their limbs during the operation, although the surgeons urged them to do so if the patients felt pain. But they complained of the tingling sensation caused by these strong currents. We believe, therefore, that 4 milliamperes of current, applied with electrodes of the dimensions reported by Dr. Johnson, are most favorable.

Local analgesia depends entirely on proper technique of application of the electrodes. In the lower extremities application of the electrodes is quite easy, because the anterior crural nerve and its accompanying vessels in Scarpa's triangle are readily



M T

Myogram No. 8.—Lower trace: Primary coil only. "Wired" circuit with "gap" of five centimeters. *M*, reaction as soon as ribbon vibrator is in operation and magnetic flux brought into play. *T*, reaction while operator was touching base of stand holding muscle-nerve preparation. Rest of trace, spontaneous irregularity, while free end of wire was held in magnetic flux.

Upper trace: With a circuit "gap" of five centimeters and end of wire held near magnetic flux. No reaction when wires withdrawn from field.

reached with an electrode; so are the anterior and posterior tibial nerves in the leg. In the upper extremities it is rather difficult to locate the large trunks of nerves and vessels. When the electrodes are properly applied to them the analgesia is good; but it is difficult to keep the electrodes in their

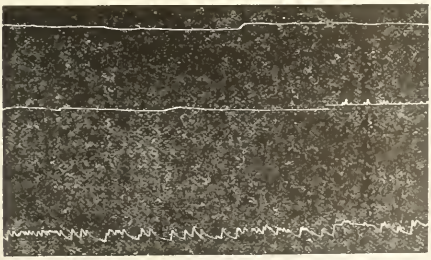
proper places. For this reason we recommend patience until we perfect a technique that will make this application simple and easy. The advantage presented by local over central analgesia is self-evident. Locally, the amperage may readily be increased above 4 milliamperes; we do not recommend higher amperage than 4 milliamperes of the interrupted current; but 5 or 6 milliamperes may sometimes be necessary. Centrally, 4 milliamperes is as strong a current as we should like to apply. Slightly stronger currents than this should be used by none but the expert in this work. The major advantage of this analgesia is that it is not dangerous when properly applied, with proper instruments and proper currents.

Myogram No. 9.—"Unipolar." Primary coil only (10 inches long, six layers of wire, of which diameter is 12/10 mm., condenser in circuit. Core one inch in diameter. No weight on muscle); reaction when one end of the single wire is connected with damp chamber, the other end touching any part of the metal frame near magnetic flux. M, reaction when end of wire touches any part of metal frame; T, operator touching with hand base of drum on which trace is registered; S, operator touching base of stand holding muscle-nerve preparation.

Contraindications.—Electric sleep, and particularly analgesia, when applied centrally, causes abortion in pregnant animals. The current is contraindicated in cases of high arterial pressure, in the apoplectic and in the epileptic, because this current increases arterial tension.

II.

November 4, 1909, we presented the results of a new variety of electric current obtained with a Vreeland oscillator.[11] Rabbits and dogs were subjected to the effects of this current and a certain degree of analgesia and sleep was produced. In one rabbit we even cut through the tissues of the back of the chest and scraped with a knife the bones of the spinal column without causing any reaction to pain. But in dogs we could not produce any analgesia for operative purposes. The more interesting feature of the effects of the pulsating current used by us was in regard to sleep. December, 1909, a dog was put into a closed wired circuit of this current. The animal remained stretched out on its side, in a condition of muscular relaxation, during a period of three hours, when one of the electrodes was disconnected and fell to the ground; but the animal remained in a condition of somnolence. The circuit was broken during a period of one-half hour, but the animal remained motionless on its side upon the table. A pin was thrust through its skin and the animal arose to its feet. We repeated similar experiments of unipolar connection with the working current of the oscillator and similar results were obtained. We then disconnected both electrodes and still the dog remained on its side in a drowsy condition upon the table, awaking only when shaken vigorously.

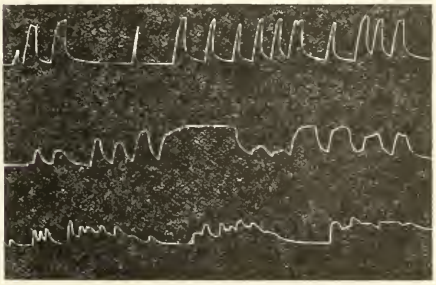


Myogram No. 10.—"Wireless." No weight on muscle. From below upward; lowest line; Tesla high frequency. Preparation grounded; no spark across Tesla terminals; apparatus one foot away from preparation.

The two upper traces; oscillations conducted to preparation by operator's body, as explained in the text. Spark across Tesla terminals.

While the animal remained in a drowsy condition the oscillator was in operation. The oscillator's important features in relation to this sleep were not the working current supplied by the apparatus, but the two field coils and rapid electric oscillations in the vacuum tube of the apparatus made for the purpose of supplying the working current. The magnetic flux and the arc in the vacuum tube caused displacement currents in the air, as will be shown in the myogram studies.

In our experiments the continuance of electric sleep in dogs by means of displacement currents was practised after the animals had been subjected to the effects of the pulsating current conducted through a closed wired circuit during periods of from two to three hours. We are not in a position to affirm that this sleep could be caused to take place in all dogs without the preliminary effect of the pulsating current in a wired circuit. But myograms obtained demonstrate the decided effect of displacement currents on living tissues; these studies seem to indicate that in cases of failure to produce sleep with displacement currents at our disposal it was because these currents were not sufficiently strong for the purpose.



Myogram No. 11.—"Wireless." Weight on muscle. From above downward: 1, reaction at a distance of 2 meters; each end of solenoid screwed into respective binding posts on disc of damp chamber. 2, reaction at a distance of 2 meters, one end of solenoid being free in the air. 3, reaction at a distance of 2½ meters, solenoid with one end free in the air reinforced.

In these experiments the muscle-nerve preparation is in a damp chamber, covered with a glass globe; the nerve lies across two nonpolarizable electrodes; these electrodes are filled with a saturated solution of zinc sulphate; wires connect these electrodes with binding posts on the disc of the damp chamber.

Myogram No. 5, taken by Dr. F. M. Law and ourselves. Unipolar method. One wire connected one binding post of damp chamber with the oscillator. Properly speaking, this wire made no connection with the oscillator, because the working current was not used. The single wire simply helped the displacement current to bridge over

space. Field coil excited by direct current, but arc of vacuum tube not in operation. Makes and breaks indicate closure and opening of switch controlling direct current that feeds the field coils and the vacuum tube (but in this case the vacuum tube was not in operation). The muscle-nerve preparation reacted to these makes and breaks. The reaction at closure was less marked than at opening of circuit. Weight on the muscle.

Myogram No. 6, unipolar method, as in myogram No. 5, shows a decided effect of the make of the arc in the vacuum tube following reaction already obtained with excitation of field coils.

Myogram No. 7 shows wireless reaction as follows: Damp chamber holding muscle-nerve preparation is at a distance of 85 cm. from field coils. One wire connected with binding post of damp chamber; end of this wire at various distances, 10, 15, and 20 centimeters from field coils and vacuum tube. Muscular reaction at make of direct current that excites field coils; additional reaction at make-and-break of arc in vacuum tube.

These muscular reactions are certainly caused by displacement currents in the air.

The effect of other electric sources were then tested. Reaction was obtained from the effects of the magnetic flux of an ordinary small-sized core of a primary coil as follows: Wires were screwed into each of the two binding posts on the disc of the damp chamber; the free end of one of these wires was screwed into one side of a switch; a piece of wire connected the other end of this switch with any binding post on the frame of the primary coil, as near the magnetic flux as possible; the free end of the other wire of the damp chamber was made to touch any metallic part in the magnetic flux, while the ribbon interrupter vibrated; the blade of the switch was in the air; in other words, the open switch made a gap, of from 3 to 5 centimeters. Properly speaking, there was no circuit here; the gap was only one of the gaps in this circuit. Muscle-nerve reaction was obtained every time the free end of the wire touched metallic parts in the magnetic flux; there was also reaction when this end of the wire touched either of the binding posts of the switch controlling the direct current feeding the primary circuit. While the ribbon vibrated and the free end of the wire was in the magnetic flux or touching one of the binding posts of the direct current, additional reaction was obtained when the operator touched or grounded the metallic registering drum or the metallic stand that held the muscle-nerve preparation. The registering drum and the stand were in touch by means of a metallic lever that served as a pen for recording the contractions. A layer of thick-coated paper separated the drum from the recording lever. (Myogram No. 8.)

When a larger sized magnetic flux was used (core 10 inches long, 1 inch in diameter, within a primary coil of six layers of wire, 12/10 mm. in diameter, and condenser on the primary, source 110 volts) reaction was obtained with only one wire screwed into one of the binding posts on the rim of the disc of the damp chamber, the other end of the wire being placed within the magnetic flux or else touching any part of the metal frame near the flux, while the ribbon interrupter was vibrating. Reaction was also obtained when touching with the free end of the wire either of the binding posts of the direct current feeding the primary circuit, while the ribbon was vibrating. It was also noticed that a direct current (the street current) placed near, but passing through another part of the apparatus and having no connection either with the coil or with the vibrator, increased the effect of the displacement current. (Myogram No. 9.)

It seems that the vibrator in the primary circuit acts in relation to the magnetic flux in a manner similar to that in whch the arc in the vacuum tube of the oscillator acts when added to the effect of the field coil considered in myograms Nos. 6 and 7.

With the Tesla high-frequency currents reaction was obtained by wireless means; the maximum working distance with the smallest portable Tesla apparatus at our disposal was 1 foot.

Myogram No. 10, taken by Dr. Law and ourselves. Wireless method. The smallest portable high-frequency Tesla apparatus gave the following results: Maximum working distance for oscillations causing visible muscular reaction was 1 foot. Other conditions showing reaction: Oscillations conducted to preparation by operator standing near point of discharge and holding wire leading to preparation, so that there was a gap in circuit between operator and discharge, about 8 inches.

Conclusions.—Living beings and muscle-nerve preparations react to displacement currents. A muscle-nerve preparation may react to currents that an ordinary telephone receiver does not detect. A muscle-nerve preparation seems to be a sensitive detector of displacement currents. If our interpretation of the tuning-fork reaction in myogram No. 3 is correct, the muscle-nerve preparation may be considered as a capacity.

An electromagnetic flux of an ordinary portable small-sized primary coil with a ribbon vibrator in operation causes muscle-nerve reaction in circuits with gaps of from 3 to 5 centimeters. A larger electromagnetic flux (core 10 inches long, 1 inch in diameter, primary coil six layers of wire, diameter 12/10 mm., with condenser on primary) causes marked reaction by unipolar methods.

The experiments here recorded show that it is possible to produce effects on animal and living tissue by means of unipolar and wireless methods. The question of producing sleep in man by these means in paths of displacement currents is one for further study.

In view of the above experiments, the laboratory method of using closed-wire electric circuits for demonstrating muscle-nerve reaction at makes and breaks of circuits of secondary currents seems to be cumbersome. In our experiments the operator is relieved of the annoyance caused by bad contact in the secondary circuit, because we obtain reaction without secondary circuits and without contact.

Since the presentation of this paper we have made further studies of wireless effects of displacement currents on living tissue; positive results were obtained without grounding the muscle-nerve preparations and even when everything connected with the experiment was insulated on a platform. This proved that reactions could be obtained by reason of free displacement currents in the air. These results were published in the MEDICAL RECORD, August 13, 1910, under the heading of "Electric Sleep in Paths of Displacement Currents: New Findings."

Studies made since last August, with a view to utilizing displacement currents for producing electric sleep and other effects, enabled us to obtain wireless effects on living tissue at distances of from 2 to 2½ meters. These effects are recorded in

myogram No. 11, weight on muscle. Reading the tracings from above downward, the conditions were as follows: Each end of a small solenoid was screwed into each of the two binding posts on the disc of the damp chamber. A brush discharge from a special high-frequency apparatus caused reaction at a distance of 2 meters. Instant reaction took place at the moment of electric discharge; then reactions were caused to take place every time the operator touched with his finger the metallic recording drum or the metallic stand holding the preparation. The floor was of concrete. Reaction was also obtained by changing the distance between the brush discharge and the preparation.

In the second or middle tracing one end of the solenoid is unscrewed from the binding post in the damp chamber and remains free in the air. Reaction is obtained as above, at a distance of 2 meters.

In the lower tracing reaction was obtained at a distance of 2½ meters; one end of the solenoid was free in the air, but the solenoid was reinforced by a mechanical device.

Reaction was also obtained as follows: The operator conducted the current through his body by placing one hand near brush discharge, while the other hand touched one of the binding parts of damp chamber.

The presence in the air of these displacement currents can also be detected by vacuum tubes or lamps placed within the active field; the tubes or lamps light up with a brilliancy corresponding to the intensity of the electric discharge.

These effects and newer findings on tissue reaction at longer distances will be the subject of a later contribution.

THE NORMAL AND PATHOLOGICAL LIVER PULSES.

BY THEODORE B. BARRINGER, JR., M.D.,

NEW YORK,

FROM THE MEDICAL SERVICE OF THE NEW YORK HOSPITAL.

THE presence of a venous liver pulse in normal individuals has not as yet been recognized, although the liver pulse accompanying various cardiac lesions has been described at length by Mackenzie. He recognizes two forms of pathological liver pulse, the auricular and the ventricular, and of these

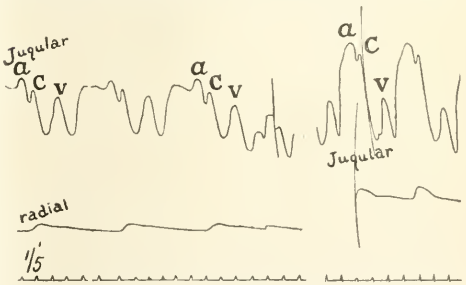

FIG. 1.—Jugular and radial tracing from normal individual taken before (a) and after (b) exercise, showing auricular venous pulse.

the auricular has been of doubtful significance, for while it has been present in a number of cases of tricuspid stenosis it has also been observed in other cardiac lesions. Whatever the form of liver pulse its prototype is found in the jugular pulse, for when both liver and jugular pulses are present in an individual they are always of the same kind. Mackenzie first pointed this out and my own experience has been similar. If then a normal liver pulse

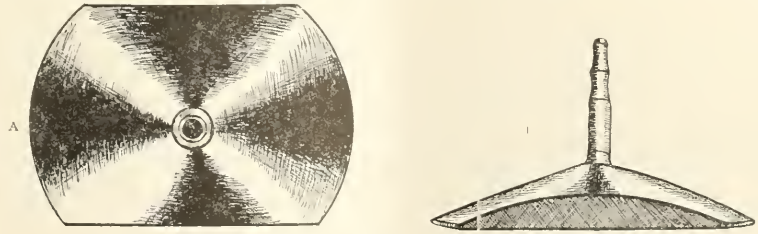

FIG. 2.—Liver cup, ⅔ natural size; A, top view; B, side view.

exists it must correspond to a normal jugular pulse.

In considering the question of a normal jugular pulse I find but little information as to its incidence in healthy persons and some doubt seems to exist as to its significance. Thus Mackenzie says,[1] "To a great extent we are even at this day quite at loss to explain all the conditions that give rise to a venous pulse. Some people in apparently good health show it, while in cases of marked heart failure it is entirely absent. Some people when in robust health show no signs of it, but if they become slightly debilitated the venous pulse may appear in the neck."

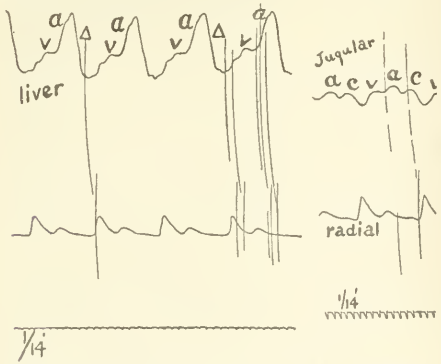

Fig. 3.—Jugular and liver tracing from a case of compensated double mitral lesion. The fall marked Δ represents the retraction of the liver caused by cardiac systole.

In a series of twenty-five young adults whose hearts were normal on physical examination, every one showed, however, a well-marked auricular venous pulse.* The waves were all prominent and after exercise (running up three flights of stairs) they became more so, but showed no other changes, except in one case, which developed a few auricular extra-systoles. Following is one of these normal jugular tracings, taken before and after exercise.

Before discussing the normal and pathological liver pulses the technique of obtaining a liver tracing and its interpretation will be considered. The cup used was one devised by Dr. Haven Emerson, which I have found more useful than the Mackenzie cup, and is shown in Fig. 2, p. 1041. At the end of expiration it was placed deep in the right hypochondrium with its face directed upward and backward, following which the patient held his breath.

The interpretation of a liver pulse tracing is sometimes difficult because its waves have to be distinguished from two normal epigastric move-

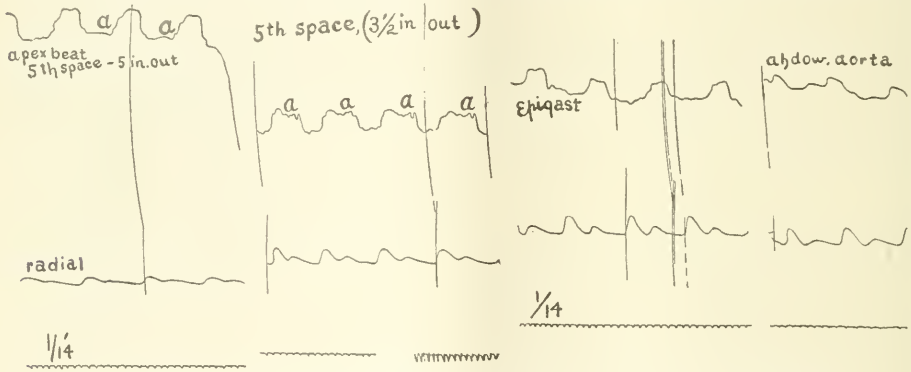

Fig. 4.—Tracings from the apex beat showing a normal cardiogram, and from the right ventricle showing a reversed cardiogram; from the epigastrium just below the ensiform, and from the abdominal aorta just above the umbilicus.

ments which may appear, viz.: (1) an up and down movement of the liver, due to the systole and diastole of the heart, causing a rise or fall in the tracing, and (2) the pulsation of the abdominal aorta, causing a systolic rise in the tracing. The epigastric pulsation, or better, retraction from a dilated right ventricle, is simply an exaggeration of the above-mentioned mechanical displacement of the liver. The movements of the right ventricle are transmitted to the epigastrium by the liver and this normal epigastric retraction may be considered therefore as due primarily to the systole of the right ventricle and secondarily to the liver movement. I have never seen a systolic outward pulsation in the epigastrium from an hypertrophied left ventricle and I am inclined to think that such a pulsation is always due to the abdominal aorta. The following tracings, from a case of compensated double mitral lesion, with marked right and left ventricle hypertrophy, have been selected to illustrate these various epigastric move-

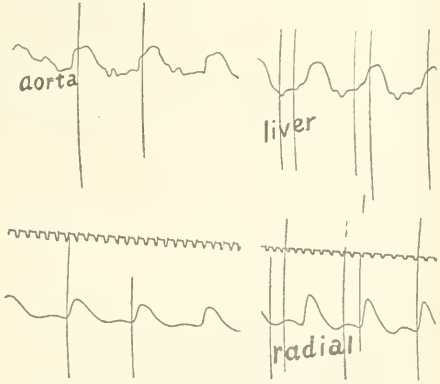

Fig. 5.—Tracings from liver and abdominal aorta in a case of aortic and mitral regurgitation.

*I attribute the ease with which it was demonstrated to the receiver used, which was fairly shallow and of a pattern different from the usual type.

ments, and their relation to the auricular liver pulse.

By comparing the times of the apex beat the radial and the liver fall (△) it will be seen that △ occurs just after the aortic valves open. The general resemblance between the liver tracing, the region resemble those of a ventricular venous pulse, but comparison with the abdominal aorta shows them to be transmitted aortic pulsations.

Liver tracings were also taken frow twenty normal individuals. It was most interesting to find

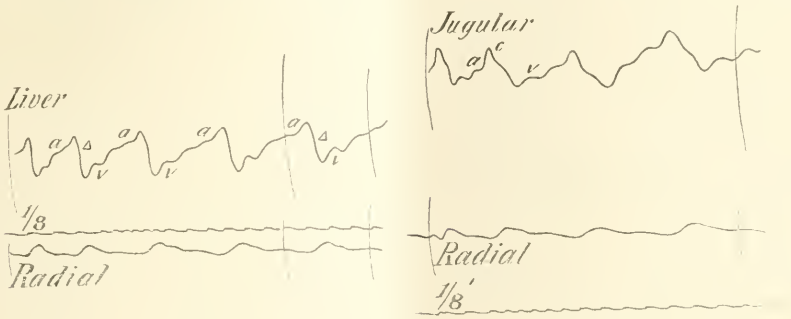

Fig. 6.—Tracings from jugular and liver of a normal individual.

epigastric tracing (which was taken just below the ensiform) and the tracing from the right ventricle shows that the fall in each case was due to the systole of the right ventricle (the systole of the left ventricle probably contributes somewhat to the epigastric fall.) The "a" and "v" waves in the jugular and liver tracings are often not quite synchronous, because of the longer distance that the jugular waves have to travel.

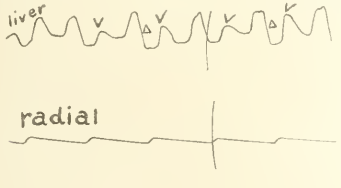

Fig. 7.—Jugular and liver tracings from normal individual.

There is only one certain way of distinguishing between the auricular wave of the liver pulse and the epigastric movement due to the ventricular systole, and that is by timing the fall in the liver tracing in relation to the apex tracing. In the auricular wave the fall begins *before* the aortic valves open, and in the other case *after* they open. In looking over liver tracings in the literature I have found these waves confused a number of times. Fig. 5 illustrates another condition which might lead to a misinterpretation. The pulsations in the liver

that in fourteen we were able to demonstrate a liver pulse of the auricular type. In each of those fourteen the "v" waves were more or less well

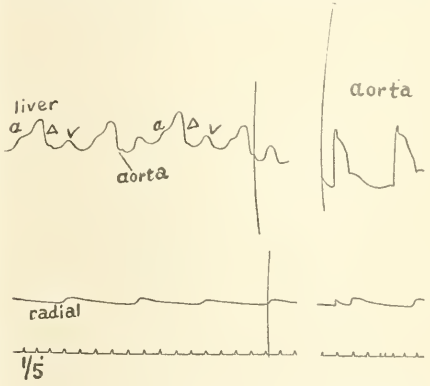

Fig. 9.—Liver tracing from a case of aortic and mitral regurgitation.

marked, while in many the "a" waves could be clearly distinguished. Fig. 6, 7, and 8 illustrate the character of this normal liver pulse.

In routine polygrams of the heart cases at the New York Hospital (House of Relief) I have frequently found an auricular liver pulse, illustrations of which are given below.

It will be noticed that the "a" waves in both the normal and abnormal cases are not very prominent.

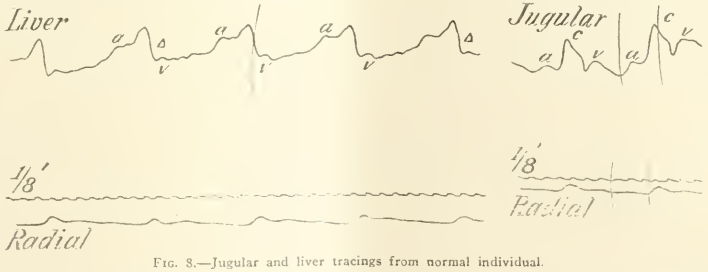

Fig. 8.—Jugular and liver tracings from normal individual.

Mackenzie has reported a number of cases showing liver pulse tracings with marked "a" wave in which the post-mortem examination revealed a tri-

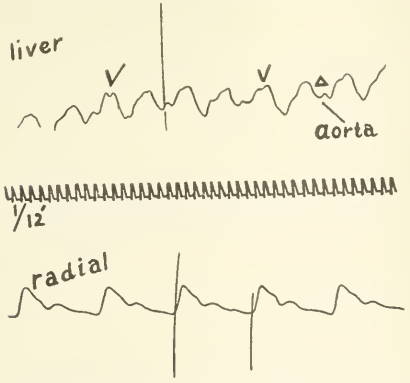

Fig. 10.—Liver tracing from a case of aortic and mitral regurgitation.

cuspid stenosis. I have seen only two such cases. In one the autopsy showed extreme cardiac hypertrophy and dilatation, with much widened tricuspid and mitral orifices, no valvulitis, and a narrow aorta.

The other patient, still living, had a complete heartblock with much hypertrophied heart and an aortic systolic murmur.

The following tracings are from the case of hypertrophy and dilatation.

They show a rather unusual type of ventricular venous pulse, the heart rhythm being regular. This

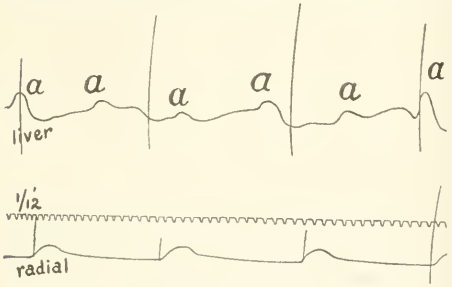

Fig. 12.—Liver tracing from a case of complete heartblock showing a marked auricular pulse.

form of venous pulse is accompanied as a rule by marked cardiac arrhythmia and an absence of "a" waves in the tracings, and then indicates the existence of the "nodal rhythm." The "s" wave (Bachmann), which Mackenzie[1] calls the "a" wave, and Hewlett the "p" wave, is absent or blended with the "v" wave because of the marked tricuspid regurgitation, and the "v" wave appears earlier than normal for the same reason. The "a" waves might be mistaken for "s" waves were it not noted that they always begin before the ventricular systole.

The following is a tracing from the case of complete heartblock.

The usual form of ventricular or positive systolic liver pulse is so familiar that no examples are given. It can often be detected in tracings with the liver cup when palpation fails to reveal it.

Conclusions.—The auricular venous pulse in the jugular veins is probably a normal event and has no pathological significance.

A large percentage of normal people show a more or less marked auricular liver pulse.

No deductions can be drawn from the presence of an auricular liver pulse in cases of cardiac diseases, unless the "a" waves are decidedly prominent.

I wish to thank Professors W. Gilman Thompson and Warren Coleman in whose services at Bellevue Hospital several of the heart cases were observed.

A FURTHER REPORT ON THE TREATMENT OF FACIAL NEURALGIA BY ALCOHOL INJECTIONS.*

By O. KILIANI, M.D.,
NEW YORK.
PROFESSOR OF CLINICAL SURGERY, COLUMBIA UNIVERSITY, SURGEON TO THE GERMAN HOSPITAL.

I APPRECIATE the honor of having been invited by your president to read before this society a short paper as a further report on the treatment of neuralgia by alcohol injections. I regret to be unable to give exact statistics, as the time of two weeks allowed me for preparation was far too short to do this properly, but I hope to give more elaborate details in a paper on this subject, to be read before the Surgical Society in January, 1911.

As is probably known to most of the members of

[1] Mackenzie, Jas.: "Diseases of the Heart," 1908, p. 115.

*Read by invitation before the N. Y. Neurological Society at its regular meeting at the Academy of Medicine, Nov. 1, 1910.

this society, I employ Schlosser's method exclusively. Since my last publication in May, 1909, I have had sixty-eight cases of facial neuralgia. In all of these cases the treatment was successful, that is, in every case the patient was rendered entirely free from pain for a certain time. This result I ascribe to three causes. First, I am more careful than ever in making the diagnosis of trigeminal neuralgia. The more patients I see, and especially such, who are not sent by their physician, but who come of their own accord or at the instance of former patients, the more I recognize the necessity and difficulty of differentiating true facial neuralgia from so-called functional neuralgia, or from hysterical conditions, or from psychosis. Even with the greatest care it is sometimes extremely difficult to decide whether we have to deal with a severe facial neuralgia combined with deep mental depression resulting therefrom, or with a real psychosis due to other causes, aggravated by neuralgia. Only very recently I came near having a failure in such a case; I finally got the patient free of paroxysms, but not of the anxiety and fear of further attacks; the mental depression also was only partly improved.

The second cause of my better results is that I think I have improved my technique. Let me state at once that I had occasion to use the ganglion Gasseri injection only in one case; in all the others I made peripheral injections. There are several reasons for this; the injection into the foramen ovale according to Schlösser's method is difficult, but safe and sure. I am not convinced of this, if the injection is made according to the Levy-Baudouin method. The injection into the foramen rotundum proper, and not only near it, is, in more than 50 per cent., impossible according to any method, owing to individual peculiarities of the skulls. I do not venture to discuss the question where the seat of pain is in facial neuralgia, for the simple reason that I do not know it. I, therefore, leave aside the theoretical question, if it is not desirable to attack the nerve or its branches, either by injection or other operative procedures at the ganglion gasseri, or as near to it as feasible. I simply state the practical experience, that in all the cases I have treated since May, 1909, with the exception of one case where I injected into the ganglion gasseri, I have succeeded with the peripheral method. I have to add at once that among this new series of cases there was none that had been gasserectomied. In those cases the deep foramen ovale injection is of course necessary. By the peripheral method I do not mean only injections into the foramen or incisura supraorbitalis for the first branch, the foramen infraorbitale for the second, and the foramen mandibulare for the third, but, wherever necessary, other branches or their ganglia are injected, as especially the ganglion sphenopalatinum and the nervus palatinus anterior and nervus palatinus posterior. An injection into the foramen mentale may become necessary too.

The third cause is the greater clinical experience which I have acquired. For instance, second and third branch seem to be affected. On two injections into the second branch the pain disappears, not only in the region of the second, but also entirely in that of the third. The patient is then so satisfied that it may be hard to convince him of the necessity of making at least one injection into the third branch. If this is not done, a recurrence after twelve to fourteen months may be the result, but a recurrence not in the second branch, but in the third. *Vice versa,* I have seen cases where the pain was referred by intelligent patients distinctly to the region of the second branch alone, but would not subside until the third branch, which was apparently not affected, was treated also.

I have stated that all my cases in this new series got free of pain, while in my last publication I mentioned five failures. I cannot give you any reliable statistics on the lasting results, since it is much more difficult to get regular reports from all those patients distributed over the different States. While I had formerly reports, favorable or unfavorable, from all patients, this is not the case any more. Besides, neuralgia patients sometimes remain free of pain for a number of months or even years without any treatment at all, especially in the beginning of the disease. Any attempts, therefore, at statistics in this line are more or less futile. I must state, however, that most of my cases are very severe and usually of long standing. As far as I am able to determine, the average time of freedom from pain is about one year, and then the recurrence mostly slight, which is to say, that the patients usually come back if there is the slightest indication of a return of pain. If a recurrence appears sooner, I am inclined to think either that the treatment has not been thorough enough, or that not all the branches affected have been treated.

The intervals between recurrences seem to grow longer, with the exception of a few very obstinate cases, where multiple surgical operations had been performed before injection, and Schlösser, with whom I have conferred personally this summer, expects that the majority of cases eventually get entirely free of pain. Since I have a number of cases where the patients have stayed free of pain, three years after the original treatment or one or two recurrences, I am rather inclined to join Schlösser in his expectation. If such is the case, one would have to assume that the repeated injections of alcohol into these sensory nerves finally produce a state where they are unable to conduct pain, a state produced by a sort of severing the continuity of the nerve, as in resections, without the possibility of regeneration.

I have seen in my own cases no hemorrhage as an undesirable secondary symptom. One case has come to my observation where after an injection according to the Levy-Baudouin method (with no result as to the alleviation of pain) a hematoma occurred that reached from the temporal region down to the mamilla. I have seen no facial paresis in my own cases, but one where two Levy-Baudouin injections had been performed. No oculomotorius paresis has occurred, no herpes. Twice an ulcer on the lower lip appeared which healed in three and four days; this is due to trauma, the patient biting the anesthetic lip. In ten cases a drooping of the upper lip resulted from an injection into the second branch of the same side, lasting from three to ten days, in one case six months. This is due to paresis of the rami zygomatici of the facial nerve, which supply the infraorbital head of the quadratus labii superioris and the caninus. These nerve fibers are pierced in an injection into the foramen infraorbitale, and slightly paralyzed if some of the alcohol regurgitates out of the foramen or if the injection into the foramen was not perfectly accomplished.

One important point is trismus of the masseter, so that the patients cannot open the mouth prop-

erly; this has happened to me in about 6 per cent. of injections into the third branch. This may last from one to three weeks, and did persist in an out-of-town case for eleven months, where the patient was satisfied as long as she had no pain.

Trismus in neuralgia of the third branch without treatment is rather frequent, and in severe cases pathognomonic. I had always considered this a defensive cramp of the masseters and pterygoids, produced by the desire of the patients to avoid pain by not moving the jaw, until I found that in one case, where no operations or injections had been made, I could not open the jaw in considerably deep narcosis. I dare not decide whether this is a true spastic condition of the chewing muscles due to an irritation of the motor root of the third branch. This cramp disappears very soon if the pain subsides after an injection into the third branch. But on the other hand, this trismus occurs after injection into the third branch, where it did not exist before. There are two explanations possible for this phenomenon. One is that the muscles which depress the jaw are paralyzed. The lower jaw is moved downward principally by the musculus digastricus, and if the hyoid bone is fixed by the genio- and mylohyoideus; as the digastricus is supplied by the facial nerve, this has to be excluded as a source of paresis of these muscles, except where there are other symptoms of rather pronounced facial paresis. But the mylohyoideus is supplied by the mylohyoid nerve of the third division of the trigeminus, and the geniohyoid muscle is supplied by fibers from the first and second cervical nerves, which accompany the hypoglossal nerve and are thus in direct communication with the third branch. These last-named two muscles might, therefore, very well become paralyzed by an injection into the third branch. But it is much simpler to assume that the injection along the inner surface of the lower jawbone results in a myositis, followed by shrinking of the muscle and production of scar tissue. This assumption is supported by the clinical experience that massage and mechanical prying open of the mouth with a wooden wedge and the "Heyster" overcome the resistance. Schlösser informed me that a large number of injections of fibrolysin (30-40) is exceedingly helpful in those cases. My personal experience in this line is still too limited.

I have given you, in short, some of my experiences and views on this subject. While for several reasons I am not prepared to say positively that I have cured one patient definitely, I have achieved that all my patients got free of pain for such a long time that, even if a certain percentage got a recurrence, and had to be treated again, they were very happy over the results and nothing could have induced them to submit to any other kind of a treatment, especially not surgical operations, and least of all gasserectomy.

44 West Seventy-seventh Street.

Cough.—The causes of cough are exceedingly numerous, but it is useful to remember that a cough which wakes the patient up after he has been asleep is probably due to lung disease. In the treatment of cough in children one should remember that nearly all cough mixtures tend to upset their digestion. A simple febrifuge mixture should always be preferred, and will often prove sufficient throughout the illness, unless there is a clear demand to aid or diminish expectoration.

A PRELIMINARY REPORT ON THE IMPORTANCE IN SCARLATINA OF AN EARLY BACTERIAL EXAMINATION OF THE SECRETION FROM THE POSTNASAL REGION.

By ERNEST C. SCHULTZE.

NEW YORK.

PHYSICIAN IN CHIEF, GOOD SAMARITAN DISPENSARY.

In view of the fact that English, French, and American investigators have produced scarlatina in healthy children by means of transferring secretions from the mucous membranes of the nose and throat by swab or hypodermically from children ill with scarlatina, the following report may prove of interest:

My investigations so far have extended over a period of three years and I am fully convinced that the danger of infection in scarlatina is harbored in the throat and nasal passages and not in the scales from the period of desquamation. While Acting Assistant Director of the Diagnosis Laboratory of the Department of Health, New York City, and making examinations of smears for Klebs-Loeffler bacilli my interest was aroused by the uniform appearance of smears made from certain cultures, especially those sent in by the Willard Parker Hospital, an institution for contagious diseases (scarlatina and diphtheria), where it is customary to take a culture from the throat of every patient admitted. These cultures are each accompanied by a report giving the name, age, duration of disease, and clinical diagnosis, *i. e.* scarlatina diphtheria, or both. The coccus which I describe I have found in 459 out of 555 cultures taken from the throats of patients clinically ill with scarlatina.

During six months I examined personally 2,000 cultures, 500 of which were taken from the throats of cases clinically ill with scarlatina. Immediate microscopical diagnosis corresponded with the clinical diagnosis in 301 instances and after an exhaustive search of the smears in other instances 108, making a total of 409. Sixty-one smears of the 2,000 cultures presented a microorganism closely resembling the one I consider characteristic of scarlatina, but clinically they had not been considered such. How many of these cases, if any, later developed scarlatina, I am unable to say. Three hundred and twenty-eight cultures from clinically true scarlatina, besides numerous other organisms, were complicated by a streptococcus in the majority of instances of a fine, short variety. It is worthy of note that 10 per cent. of these cultures—that is, from clinically true scarlatina—showed an organism morphologically identical with the Klebs-Loeffler bacillus. The balance of the 2,000 smears coming from the Willard Parker Hospital showed Klebs-Loeffler bacilli. This investigation having excited my interest in the possible presence of a distinct organism in scarlatina, the investigation was continued at the Good Samaritan Dispensary. Here a bacteriological examination of cultures from the throats of 100 children varying in age from 2 to 9 years, with no previous history of scarlatina, failed to show in the smears from a twenty-four-hour blood serum culture incubated at 37° C. the characteristic microscopical picture which had been observed in true scarlatina. (See the illustrations.)

Not satisfied with these observations, smears

from twenty-four-hour cultures were made from 100 throats of patients averaging in age from 3 months to 60 years and considered clinically as diphtheria, erysipelas, measles, rubella, autointoxications, erythemata, parotitis, varicella, pneumonia, and influenza without finding the microscopical picture found in smears from the throats of patients suffering from true scarlatina, although a coccus resembling the organism was occasionally found, especially in cases of parotitis. Fifty nasal cultures were secured from children varying in age from 3 to 6 years without a previous history of scarlatina, and but three showed an organism morphologically identical with the organism present in scarlatina. During the same period fifty-five children ill with scarlatina were studied and the organism found in fifty out of the fifty-five cases; in two as early as forty-eight hours before the appearance of the rash, and in one case six months, following discharge from the Willard Parker Hospital. A large number of cases simulating scarlatina—that is, presenting a rash, mild angina, temperature, rapid pulse, tonsillar exudate—but giving no history of vomiting, no marked angina, and from which twenty-four-hour cultures failed to show the organism, were investigated and found not to be scarlatina, although the rash, temperature, rapid pulse, and mild angina at the time of the first examination might have justified a positive diagnosis. The following cases will illustrate the value of an early bacteriological examination of all suspected cases of scarlatina.

Case I.—Child, aged 10 years. History: Illness of two days; conjunctivitis; general malaise; tongue heavily coated; left tonsil dark gray membrane; pharynx congested; no rash, but history of vomiting; temperature, 104°; pulse, 160; respiration, 40. Chest and abdomen negative. Twenty-four-hour growth on Loeffler's mixture showed a large coccus predominant. Thirty-six hours after the case had been seen at the dispensary a fine punctiform rash appeared about lumbar region. Pulse, 150; temperature, 104°; respiration, 36; marked angina; tongue strawberry appearance. At this time another child in the family, aged 6 years, complained of a sore throat and an examination revealed a coated tongue; severe angina; no other physical signs; temperature, 103°; pulse, 104; respiration, 30; no rash discernible. Direct smear showed the same microscopical picture found in the first case. Six hours later the cases were seen by a diagnostician from the Health Department and both cases sent to the Willard Parker Hospital with a diagnosis of scarlatina. The next morning I examined a twelve-hour culture from the throats of these children and found numerous typical organisms present.

Case II.—This culture was sent to the Department of Health from one of the city hospitals with a diagnosis of diphtheria. History: "Pus from the

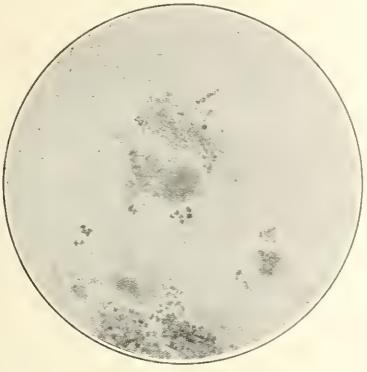

Fig. 1.

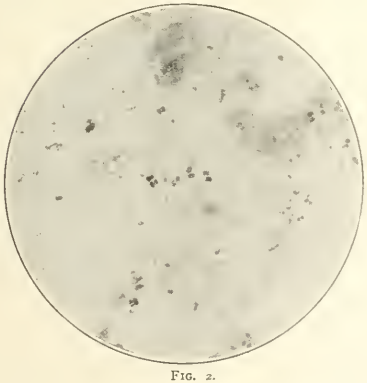

Fig. 2.

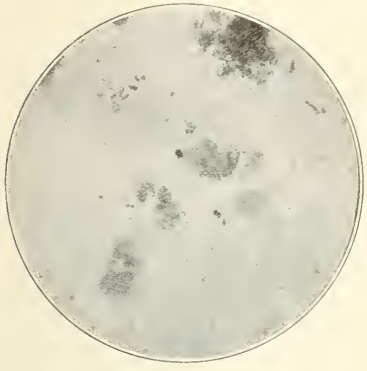

Fig. 3.

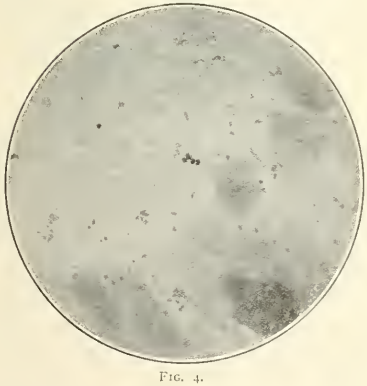

Fig. 4.

Figs. 1, 2, 3, 4.—Direct smears from the postpharyngeal space of a patient ill with scarlatina; stained with Loeffler's alkaline methylene-blue solution: x 1000. The coccus takes a much deeper stain than the rest of the field.

eye; examine for Klebs-Loeffler bacilli." Eighteen-hour growth on Loeffler mixture showed numerous typical organisms found in scarlatina with staphylococci. Upon investigation I found that the case had been one of scarlatina ten days prior to the taking of the culture. No Klebs-Loeffler bacilli were found.

Case III.—Culture was sent to the Department of Health by a private physician from the throat of a child aged 6; temperature, 106°; pulse and respiration not given; diagnosis, "meningitis." A twelve-hour growth showed a microrganism warranting a diagnosis of scarlatina. On communicating the facts to the physician the latter declared that during the night and twelve hours after the culture had been taken the child had developed a typical rash.

Case IV.—Child, aged 4 years; ill two days; temperature, 104°; pulse, 140; respiration, 30; no vomiting; tongue negative; slight angina; no rash; no other symptoms. A twelve-hour growth showed the organism found in scarlatina and bacteriologically the case was diagnosed as such.

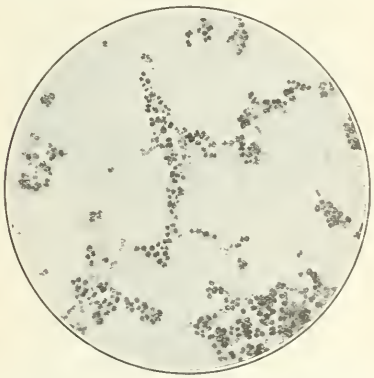

Fig. 5.—A twelve-hour culture in Loeffler's mixture, from a case of clinically pure diphtheria and scarlatina; stained with Loeffler's alkaline methylene blue solution: x 1000. The film is ten months old and shows how the coccus has retained the stain while the bacilli, streptococci, etc., are unrecognizable.

Twelve hours later signs of a rash appeared and the case ran a typical course, desquamating, etc.

Case V.—Child, aged 4 years; ill two days; tentative diagnosis "urticaria." Culture taken one week later showed in twelve-hour growth typical organisms found in scarlatina. Reporting the case to the institution as probably scarlatina, my diagnosis was not accepted. One week later the child profusely desquamated.

Case VI.—Boy, aged 14, a relative of one of the employees of the Good Samaritan Dispensary; ill one day; temperature, 106°. Physician in attendance declared he would be unable to make a diagnosis for at least forty-eight hours. Immediate culture taken by employee showed in a direct smear and a twenty-four-hour growth numerous organisms found in scarlatina. Twenty-four hours later the child developed a rash and ran a typical course of scarlatina.

Case VII.—Child, aged 11 years, brother of Case VI. Three days after the other child had developed scarlatina this boy complained of a sore throat. He was brought immediately to the dispensary, examined, but with the exception of a slight angina, physical examination negative; however, his temperature was 103°; pulse, 170; respiration, 30; culture taken; a twelve-hour growth showed typical organisms with numerous streptococci. The following day the child developed a rash and died on the fourth day of the disease.

Case VIII.—Child, aged 11 years. Had been treated for autointoxication at a dispensary. Five days later the dispensary physician who had treated the child primarily changed his diagnosis to scarlatina and reported the case to the Health Department. No subjective or objective symptoms being present in the child during the following week, the parents were inclined to doubt the correctness of the diagnosis. A twenty-four-hour culture was made from a smear, and its study showed numerous typical organisms. Ten days later the child began desquamating.

A culture from the throat in true scarlatina will not only help to confirm the diagnosis, but a bacteriological examination of the mucous secretion from nose and throat, especially the postpharyngeal space, will oftentimes clear a doubtful diagnosis, as the following cases will illustrate: Visiting a suspected case of scarlatina, but one which had not shown a typical organism, I was struck by the peculiarity of the rash, my visit being on the seventh day of the disease. Not satisfied that this was a true case of scarlatina, although it had been reported as such to the Department of Health, Dr. Lapowski, attending dermatologist to the Good Samaritan Dispensary, saw the case in consultation. On coming to the tenement, we mounted to the wrong floor, entering by a door that also had been labeled by the Department of Health as scarlatina, and here we found another case similar to the one I had examined on the floor above. Both cases were diagnosed by Dr. Lapowski as cases of erythema infectiosum.

The following case was of a girl aged 14, whose illness had been diagnosed in the dispensary as scarlatina and reported as such to the health authorities. This child presented a history of vomiting, rash; fever, 103; pulse, 120; respiration, 30, but no angina, no coated or strawberry tongue. A direct smear was found negative and a twenty-four-hour growth showed no typical organism, but chiefly streptococci. On investigating the case the next day I found the child up and around, no temperature, pulse normal, no rash, no fever. This case I followed very carefully for two months and no other sequelæ took place in that time.

Another case was a girl aged 13 years; temperature, 106°; pulse, 170; respiration, 40, with a pronounced punctiform rash covering the upper extremity and extending down the inner surface of thighs. This rash was so marked that a tentative diagnosis of scarlatina was made. The child did not give a history of vomiting, however, her throat was markedly hyperemic, the tongue heavily coated, but without so-called "strawberry" appearance. A direct smear showed a streptococcus infection and a twenty-four hour growth the same organism. When visited the following day the child had a normal temperature, no rash, and subsequent results proved the case not to have been scarlatina.

A number of other doubtful cases might be mentioned in which this coccus was not present and in which later developments showed the cases not to have been scarlatina, although they had been diagnosed as such by careful and capable dispensary physicians.

The following is the technique employed in obtaining the culture. With a sterilized cotton swab touch the posterior pharyngeal wall, not *the tonsils*, as this coccus is but rarely found on the tonsils or in the anterior part of the buccal cavity; then plant on Loeffler's blood serum and also make a direct smear on a clean glass slide. After the smear has been allowed to dry cover the film with a drop or two of Loeffler's alkaline methylene blue solution, heat gently for a minute, then rinse in sterilized water and dry with blotting paper, when the slide will be ready for examination. This same procedure is carried through with a twenty-four-hour culture, using a platinum needle to obtain the material and staining the same as a direct smear. "Direct smears" on account of numerous large cocci found in some normal throats are as a rule unsatisfactory.

Distribution of the Coccus.—A microorganism, morphologically identical with the coccus just described, I have recovered from the serum of a papule from the finger of a child that died of scarlet fever. Examinations of specimens of blood of five cases showed in one case a streptococcus and this microorganism. From the skin desquamation in seven cases I was unable to recover an organism identical with the coccus described. Pus from the eye and pus in five cases of otitis media following scarlatina showed a large, deeply stained coccus. Five cases of malignant scarlatina showed at the outset of the disease a preponderance of this organism and a fine, short streptococcus. As to the length of the infection period, I have found this coccus present in a number of cases from two to six weeks after the onset of the disease, and in one case I was able to demonstrate the organism at the end of six months, following the discharge from the Willard Parker Hospital. This might explain why in the fall of the year, when the schools reopen, scarlet fever shows a steady increase in the contagious Health Department Bulletin. Hypertrophied adenoids no doubt play an important rôle as harborers of these germs. It is a well-known fact that the Klebs-Loeffler bacillus lies dormant in the throats of healthy children, still infectious to others, for an almost indefinite period. Why, then, as both diseases begin with a sore throat, is it not possible for the organism that causes scarlatina likewise to remain virulent for months?

Conclusion.—Streptococci have been found in pure culture in pus, blood, and specimens taken from the organs of children who died from scarlatinal poisoning, but the investigators by further inoculations of these cocci never have succeeded in reproducing scarlatina in the animal or human body. Five pigs which have been inoculated with a pure culture of the coccus described have developed a rash, fever, general malaise, etc. A future report will tell subsequent results. Some recent investigations have shown a large coccus to be often present in the blood of children ill with scarlatina. Numerous observers of late, especially in England, have shown that by the cleansing treatment of nose and throat with a mild antiseptic healthy children could be kept in contact with children ill with scarlatina without contracting the disease. Personally, I have treated two families, six children in each family, where one member had contracted scarlatina, and by the simple process of cleaning the nose and throat three times a day for six weeks I have prevented any further spread of the disease.

240 West Seventieth Street.

FRACTURES OF THE SKULL.

By ALANSON M. POND, M.D.,

DUBUQUE, IOWA.

In considering the features of fracture of the skull the injury to the bones of the head are of the least consequence. It is the damage done to the brain and its coverings, from hemorrhage of the injured cerebral vessels, the serious infections probable, and the compression of the brain by blood clots that puts the cases of fractured skull in a class far more grave than fractures elsewhere. From time immemorial skull fractures have been recognized and treated, and quite periodically some enthusiastic worker attempts to conform the skull to some mathematical body in order to better compute lines of fractures from force applied upon a given point. Attempts to lay rules for the lines of fracture have so far been futile except in the most general way. The term contracoupe, meaning contrastroke, originated by the French surgeons in the eighteenth century, and technically is improperly used when intending to describe an injury of the skull or brain as a result of a blow in directly opposite lines. This is possible only in a spherical body and, of course, the usual skull conforms more perfectly to the oblong spheroid type, which renders direct transmission of the force impossible.

There are two distinct classes of bone in the formation of the skull. All that forms the dome of the brain cavity is to a degree elastic and that which forms the base is dense and inelastic. Force applied to either side of the head produces fracture of the base before the vault will fissure. By reason of this difference force applied to the vault, such as a blow on the head, falling from a distance and striking the vault, or by some falling body, expands the diameter of the vault at its base and exerts a decided pulling influence upon the inelastic base, much as a bow pulls upon its string when pressure is applied to its center. This pulling is the direct cause of basilar fracture in these cases and is the transmission of force as is understood by the term contracoupe, but in fact is the result of the elasticity of the vault.

Lateral pressure produces fracture of the base by causing a fissuring usually extending to the bones which form the vault, and as soon as the fissure is complete through the rigid base immediate compensation is obtained by the elasticity of the vault. The capacity of the skull is rigidly fixed. Anything which increases its contents or decreases it disturbs the circulatory balance. A tin vessel may hold exactly a quart; but if a dent be made into it the contents of that vessel is diminished exactly to the extent of the area of the dent, and conversely so if the skull has a fixed capacity, a depressed fracture or hemorrhage is bound to increase the tension of the skull contents and the symptoms of coma, shock, or pressure is in proportion to the disturbance of circulation as determined by capacity necessary for that circulation to be normal.

The bones of the vault differ anatomically from the bones of the base in the fact that they are made up of two layers of dense structure with an interval of very porous bone between. In vault fractures it is the inner table that produces the trauma to the dura and brain. This damage is produced by the tendency of the inner table to splinter extensively; and where the fracture of the outer table might be insignificant, extensive splintering of the inner table

is reasonably certain and these sharp spicules of bone produce the laceration of underlying structures. This destruction of the inner table is explained in the same way as splintering occurs in long bones suffering a "green stick" fracture. The force is applied to the outer table, producing a clean cut or linear fracture, while the inner table forms the outer arc of the depression caused by the trauma and splinters in exactly the same way as occurs in the "green stick" fracture above referred to. The clinical features of fracture of the vault are depression of outer fragments, splintering of inner table causing more or less damage to the dura or brain, which give rise to the condition of brain pressure, and in cases where the fracture is compound and where wound of the scalp complicates the injury to the skull and its contents there is almost invariably an infection. This infection proceeds from the scalp which, by reason of its exposure to dust and air, with its covering of hair and the anatomical structure of this layer rich in hair follicles and sweat glands, is a veritable hotbed for bacteria, and it would be quite impossible to have a compound fracture of the vault without an infection possibility. The features of basilar fracture are expressed by the fissuring of the base, either single or multiple, which usually involve the vessels of the brain and becomes infected when communication with the ear, nose, or mouth occurs. The importance of this infection hazard cannot be overestimated; and any treatment which does not presume to prevent it is surely not along surgical lines and is prone to disappointment.

The person suffering fracture of the skull is usually rendered unconscious. There is commonly a wound of the scalp when the vault has been fractured and hemorrhage from the nose, ears, and mouth incident to fracture of the base. The rule concerning treatment of these fractures is "No wound, no symptoms, no operation." By "no symptoms" we mean no focal symptoms or after-effects of intracranial pressure. The first attention to be given this person is thorough examination. The hair of the scalp should be thoroughly shaved wide from the edges of the wound and in a direction away from the incision. The wound itself should be packed with sterile gauze until this shaving process is completed. The hands should be rendered as surgically clean as possible, and then only after such thorough preparation as the conditions will permit should examination of the wound be made. Foreign substances, hair, and clots are removed by very gently wiping them away or by irrigation with hot normal salt solution. Hemorrhages of the scalp are controlled by pressure or by the application of the forceps. The exploration of the wound should be done by the finger. A probe here is untrustworthy. An incised pericranium may give to an examining finger the sensation of a fissure fracture. By inserting the finger nail under its edge this membrane can be lifted and thus identify the character of the injury. A fissure of the vault may resemble a cranial suture. The line of fracture is always filled with blood and reappears after cleansing. Identification is not difficult. Oftentimes hair or other foreign bodies are caught between the two edges of the scalp. The fissure may be explored by a trephine button of bone at either extremity and the condition of the inner plate ascertained. The scalp should be incised to expose the entire fracture. A crack of the outer table is almost invariably accompanied by a serious condition of the inner plate, and all these fissures should be opened up. About the greatest danger in this class of fractures is their apparent innocence, which fosters the hope of recovery without an operation. The fissure may be explored by chiseling away scales of bone of the outer plate. This should be done in the direction away from the line of fracture. The chisel is placed in the thin slit and by gently striking it the outer table is made to scale or chip away, thus opening the wound only in the diploe. Repeat this process on the other side and then open the furrow until the inner plate can be observed and palpated. As the inner plate is approached dark blood escapes, which now shows the reddish irregular fragments of the splintered inner table. The outer opening should be enlarged sufficiently to permit of the removal of these thin pieces, and this should be accomplished by sliding them into the open space instead of by tilting or by a forcible extraction. These thin scales of bone are very sharp and their removal can produce serious damage. If the dura is torn and the brain exposed clotted blood with fragments of bone may be removed in the case of an extensive injury. Great care should be exercised in the removal of all of these particles of the inner plate.

Puncture fractures are caused by the penetration of the skull by some sharp instrument, such as fencing foil, a knife blade, or the sharp portion of a falling body. The wound through the scalp is insignificant in extent and oftentimes impossible to find, and the wound in the skull may be obscured by hemorrhage and perhaps occluded by some foreign body. The importance of recognition in this injury can scarcely be overestimated. There is sure to be splintering of the inner table with some degree of injury to the underlying part and a usual infection. It is better to make an unnecessary simple incision of the scalp than to overlook a serious puncture fracture of the skull. If the site of the puncture can be found there should be removed a button of bone which has the site of this wound at its center. The inner table can then be explored, and if serious fissuring has taken place it is better to turn down an ample flap of bone about the trephine opening and cleanse the wound thoroughly, inserting a drain which may emerge through the opening made by the trephine in closing.

In the more extensive fractures, with or without depression the wound of the outer table is usually comminuted. Fine lines of fracture extend from the circumference of the depression to the center. The fragments are triangular in shape with an apex forming a shallow cone. Frequently there is no opening to insert an instrument with which to pry these fragments up so that it may be necessary to use a chisel at the outer margin just enough to free the wide edge of one of these fragments. When this is accomplished it is easily removed by grasping the fragment of bone at its base with tissue forceps. Others follow readily because they are freed. Any tilting or lifting of these fractures may produce an injury to the brain and should be avoided. The damage to the inner portion of the cranium is always more extensive than that of the outer table and it is frequently adherent to the dura by laceration. Never use force to remove these pieces of bone. Grasp them at their broadest edge with forceps and free their under surface with a director and slide them out of the wound. It will be necessary at times to use a rongeur before they can be freed, perhaps even requiring a trephine

opening at their margin to protect their sharp edges from inflicting injuries. All blood clots are removed and a gauze wick inserted to the site of the greatest injury and brought to the surface at the angle of the most dependent end of the wound to favor drainage. Extensive defects of the skull occasioned by these large crushing fractures can be overcome by replacing the removed fragments of bone after sterilization. Experience shows that these fragments may be replaced safely even after boiling. If there should be fractures with serious splintering of the inner table the dura may present itself through the wound as a dark tense mass. If pulsation is absent a subdural hemorrhage is reasonably certain and that membrane should be incised and the blood clot removed, after which it is drained.

Fractures of the base occur along fixed lines. They partake of the fissure type and usually involve two or more fossæ. When the anterior fossæ suffer fractures there is usually a communicating fissure involving the middle fossæ. Hemorrhage of the nose, escape of meningeal fluid through the nose or mouth characterize fractures of this region. Hemorrhage of the ear should always be considered a fracture of the middle fossæ and thus treated. Not that every hemorrhage of the ear means a fracture of the base, but it is so constant a feature that it is always safe to so consider it. Basilar fractures are treated by the time honored methods of rest, ice, and supportives unless some very positive focal symptoms point to a site of pressure. Coma is relieved by modern methods of spinal puncture and the withdrawal of a few cubic centimeters of spinal fluid, which in case of a fractured base is always blood tinged, and hence is of value in obscure cases as a means of diagnosis. When compression exists operation is always indicated. The skull should be opened and the cause of pressure sought and removed. This rule applies as well to fractures of the base as of the vault. The presence or absence of focal symptoms will point to the site of operation. The constant danger of infection must always be uppermost in mind in the treatment of these cases. In basilar fractures the nares and the ears should be thoroughly cleansed and packed with sterile gauze or cotton. In fracture of the vault or in case of extensive operation the greatest danger is from infection by the scalp wound. This is usually due to streptococci and is very serious. I make it a practice to give antistreptococcic serum at the earliest possible moment where the skull and scalp have suffered injuries. This is as important in these cases as the use of antitetanic serum in the treatment of Fourth of July injuries or gunshot wounds and it is followed by just as favorable results. The tendency in the treatment of skull fractures is to rely too much on hope and do too little. All splinters of bone must be removed, all blood clots evacuated if possible, and all sources of infection guarded. Any treatment that will incorporate these requirements will render the most satisfactory immediate results and will be free of the many unfortunate sequelæ so common after these injuries.

Delirium Tremens.—Make sure that the kidneys are sound, then give opium boldly. Begin with 60 m. of laudanum, rather than with 20, and then 40 and then 60, the latter method is not only ineffectual but often dangerous, and may induce a tolerance which will defeat the object. Every effort must be made to get nourishment into the patient; until his nutrition improves progress will be slow and opiates likely to fail.

CARBOLIC ACID INJECTIONS IN PILES AND GOITER.

By HOSIAS SCHIEMANN, M.D.,

NEW YORK.

At a time when private practice is looked at as an inferior art, and there prevails a general belief that success in treatment can be obtained only in magnificent hospitals with the aid of complex and expensive apparatus, at such a time a plea for simpler methods would naturally invite derision. Nevertheless, in the interest of the public, especially the poorer working classes, as well as of many general practitioners, I feel constrained to remind my colleagues of a simple method which, in some instances, is able to compete successfully with the knife.

For the sake of brevity I shall omit details and shall allude merely to some of the most important features of the method.

Let it be understood at the outset that by piles is meant the uncomplicated kind, without prolapsus recti and other complications, and by goiter is meant the hard, hypertrophic variety of inflammation of the thyroid gland, affecting either one-half of the organ or the whole gland. Likewise it is of no importance whether or not this state is accompanied by the tachycardia and exophthalmos characteristics of Graves' disease. Before resorting to injections it is in goiter sometimes necessary to administer hematinics and to increase the patient's strength. The size of the enlarged gland or part of it, treated by me, did not exceed a large egg or a pear of medium size, but, as observation showed, the process was always in full development.

If a patient visits me after an acute paroxysm, and the history and inspection show that there are numerous piles, I advise the patient to wait until the beginning of the next attack, for this reason: In the acute state all the piles are well contoured and one will not make mistakes as to which tissue is to be injected. Every pile should be treated separately. The pain of the patient will guide one to the most sensitive elevations, which frequently are little swellings of the mucous membrane surrounded and covered by larger piles, but of less sensitiveness. This is a matter of the greatest importance. If one fail to properly attend to these trifling piles one's work may become useless, for the same pain experienced before may not be relieved. To subdue the pain at once and to make the piles disappear gradually is the object of the proposed method. Pain, to a certain degree, will continue for a short time after the injection. It is a pain of an itching, burning character caused by the injected solution, and is quite different from the sense of pressure and fullness in the rectum caused by the disease, which disturbs the comfort of the patient, interferes with the act of defecation, and causes nervousness and sleeplessness.

Treatment of enlarged thyroid gland: The practice of injecting this gland may be resorted to after all other remedies have failed to improve the condition. Hypertrophy of the thyroid gland in women is frequently caused by pregnancy. Especially is this so in weakened women, and for this reason the administration of iron and other tonics has been recommended.

I am unable to confirm this belief. Indeed, with advancing years and with repeated pregnancies the circumference of the woman's neck increases. In proportion to the whole neck the gland, either wholly or in part, may likewise be enlarged. But

it is difficult to conceive of pregnancy alone causing overgrowth of the gland, or even of a section of it.

On the one hand, in a fairly normal woman of good family history, I never have seen development of goiter during pregnancy, and, on the other hand, in cases attributed to pregnancy, I have never seen any good results from iron, arsenic, air, plenty of food, etc. For these reasons I believe that the cause of partial or complete hypertrophy of the gland is latent in the organism long before the occurrence of pregnancy. This can be considered responsible merely for awakening the disease earlier than it would have developed otherwise.

Finally, the fact that the male gland is likewise, though not frequently, subject to hypertrophy, also argues against the etiological roll of pregnancy, which can be considered merely as a stimulus, producing increased vital action of certain cells or favoring bacterial action.

In short, pregnancy repeats here the part which it plays in heart disease, tuberculosis, and other ailments. At any rate it is desirable to try first the "building-up cure," inasmuch as patients with hypertrophy of the gland are mostly persons of anemic type. If after a month or six weeks this trial has no effect, it is desirable to resort to the carbolic acid injection.

Where possible, for the greater comfort of the patient, I perform the injection in the latter's room. After the injection the patient is put to bed and on the following day, as a rule, is permitted to attend to his usual work.

The patient with piles is placed on a table or bed in the lithotomy position, or on his abdomen with pelvis elevated, the lower extremities hanging down the side of the table or bed. In case of hypertrophy of the thyroid, the patient lies on his back. It is of the greatest importance that the diseased area be at an adequate height with respect to the physician, who may work in the standing or sitting position, with good illumination.

The carbolic acid solution used should be of 5 to 10 per cent. strength. Stronger solutions are painful. This holds true even if the area of injection has been made painless by cocainization or freezing. It must be borne in mind also that the effect of carbolic acid is more profound and continues after other effects have disappeared. Besides, strong solutions are able to produce gangrene. To the carbolic acid solution I add, as a rule, glycerin in 5 to 10 per cent. strength. I am convinced that in the presence of glycerin the absorption of the injected solution goes on more easily and the tissue is less damaged. The solution should be of such consistency as to go through the thinnest needle. A fine needle, of course, saves pain to the patient and trouble to the attendant.

Having cleaned the instruments (razor, rectal speculum, blunt forceps for cases in which the speculum cannot be used, syringe, curved and straight fine needles for the same) and the hands of the physician, as well as the diseased area and everything that comes in contact with them in the usual surgical way, the rectum of the patient with piles is irrigated by means of a soft catheter. I inject into every pile separately 1 to 3 mm. of a ½ per cent. cocaine-adrenalin solution for anesthesia, and afterward, in the same order, a few mm. of carbolic acid solution. The same is done in the case of the enlarged thyroid.

The amount to be injected must be calculated so as not too tightly to distend the piles or to cause too great a tension on one part of the gland and in order to avoid gangrene. Into an enlarged gland a whole syringeful containing 15 to 16 mm. and even more, may be emptied, but the injections should be made in different places; 3 to 5 mm. being injected at each puncture.

If before the injection the piles were of cherry-like color and size, fluctuating and sensitive, after the injection they become dark colored, enlarged, hardened, but painless. You may handle them roughly, the patient scarcely feeling the manipulation. At least this is so if you have not failed to treat every painful spot separately. The bleeding from the punctures, if any, is easily controlled by the application of hot 5 per cent. boric acid with alum or adrenalin. The patient is now given a suppository of iodoform (if the odor of iodoform is not tolerated, tannin, antipyrin, or adrenalin may be used as suppositories). The anus is covered with a thick gauze pad, kept in place by the aid of a bandage. On the next day, as a rule, the patient attends work.

If a strange observer, who does not know of the injection, should accidentally see our patient a few days following the treatment, because of the dark colored, swollen tumors of the anus as well as of the bloody discharge, he would easily make the diagnosis of gangrene or malignant neoplasms. But proof against such a possible condition is furnished by the perfect feeling of the patient who is at work, the absence of pain, and bad odor. Most of all that encourages the patient is the restored normal defecation. This usually takes place on the second or third day, sometimes three to four hours after the injection, which occurrence can be taken as evidence that pain was the most important factor of the disturbance.

If the case is accompanied by bleeding from the rectum this ceases in a few days by itself; very seldom I administer Carlsbad salts for a couple of days. The use of suppositories and dressings is continued for eight to ten days, during which period the discharge becomes so trifling that the patient can neglect bandaging and substitute for it ordinary cleanliness. Partially by the discharge of a serum-like material, partially by absorption, the piles are slowly but constantly decreasing in size, until after four to six weeks only small, solid, warty like, perfectly harmless fragments are left. Frequently the process of healing takes this course. The injected wall of the pile comes off in a few days, leaving a deep, but clean and painless wound which granulates and cicatrizes in the usual manner, without any accidents. In such a case a linear scar is the final result. I had no recurrences.

In goiter, the hitherto painless gland, or part of it, after injection becomes swollen and sensitive, the pain radiating in the direction of the larynx, ears, throat, and tongue. Though the pain may be considerable, it can be controlled by the application of heat, or by the administration internally of the opium preparation. At any rate in six to twelve hours the pain subsides and the patient is able to return to his work.

The size of the gland, which after injection becomes even more enlarged, will now be observed to be gradually decreasing, at the expiration of one and one-half to two months reaching the normal. This can especially be observed if only one-half of the gland is affected, the other half being used for comparison and control.

If the injection is made carefully into every pain-

ful pile or in the center of the thyroid tumor, a single injection will suffice to overcome present conditions as well as prevent their future reappearance. This conclusion I may draw from eighteen years' observation.

I once observed in piles a triangular-shaped gangrene of the skin with a base of about an inch and an altitude of one and one-half inches. This happened, I think, because the injection was made too tensely and in a part too near the boundary of the skin.

Carbolic acid injection for piles was recommended long ago, and there is considerable literature upon the subject. I find it recommended in my university notes of twenty-one years ago. In regard to goiter, I do not recall having seen this method recommended in any literature or institution. After the valueless injections of the Lugol solution, which was in vogue some decades ago, I experimented with ferri sesqui chloride and obtained good results even in a shorter period than with carbolic acid. The pain was of a more acute character and of longer duration. This led me to the choice of carbolic acid.

Against the results, the cleanliness, neatness, and other ideal conditions of this method, those only can object who have never tried it. Several objections, however, seem to be not without foundation. Such are the poisonous character of the drug and the possibility of injecting a blood vessel, causing emboli and thrombosis.

If I recall the large amount of carbolic acid that I have injected into diseased parts of the human body with good results in combating anthrax and in applying high lavage with carbolic acid solution in dysentery and other cases, it seems to me very doubtful whether a trifling amount of the drug as I have been using in goiter and piles (less than one and one-half drops of the pure drug in a whole syringe), can have any serious consequences in adult people.

As to the possibility of injecting the solution into a blood vessel, the disconnected needle should first be inserted, and when no blood appears through its free end, the syringe containing the carbolic solution is attached and the injection is made slowly. Considering the frequency with which injections are made in the acute state of piles, I have never heard of any fatal results from emboli and thrombosis. This can be explained by the fact that the congested mass of the piles shows a tendency to become localized.

The method can be performed by any physician, at any place, upon any patient, without any help, trained or untrained. It is harmless and gives a sure and steady relief. It is for the patient less expensive than the treatment of a small abscess. The workingman is not compelled to stop work for a day nor to lose his position, which to a laborer is a very important matter. The patient is able to enjoy his usual comfort. The injection leaves no bad consequences, as fistula and impairment of the sphincters, and in the case of the thyroid saves the gland for the organism and the recurrent nerve is out of danger. Nobody knows exactly the function of the thyroid gland in the organism, but many scientists are inclined to hold that the removal of the gland is responsible for many grave changes observed in the body. In view of all these advantages I recommend the method for a broader clinical trial.

PRELIMINARY REPORT OF A STATISTICAL ANALYSIS OF OVER THIRTY-TWO THOUSAND CASES OF SCARLET FEVER

By ABDULLAH K. SALLOM, M.D.,

PHILADELPHIA.

During the past twelve years there has occurred in Philadelphia, according to the official weekly report of the Bureau of Health, 32,317 cases of scarlet fever. Of this number 1,759 died, giving a mortal-

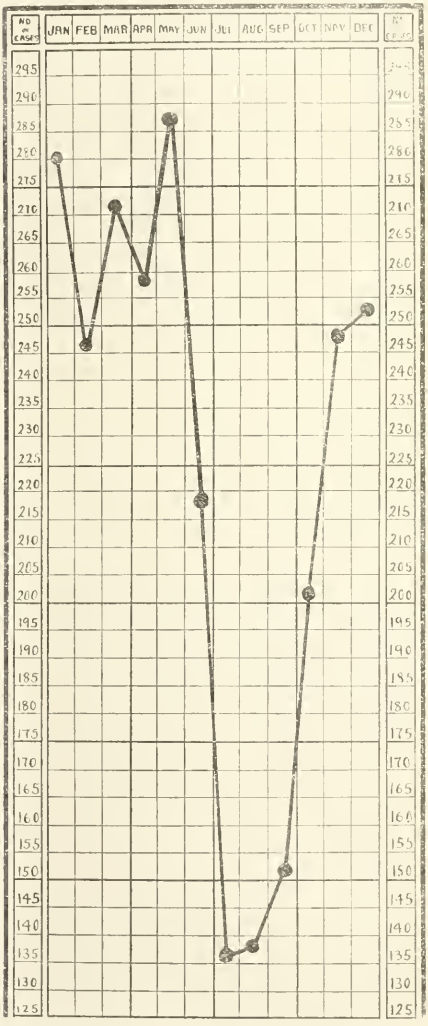

Chart 1.—Showing the average of cases of scarlet fever occuring during each month of the year; a statistical analysis of 32,317 cases.

ity of slightly over 5 per cent. The mortality, however, fluctuates considerably, as it will be noted in Table I that the mortality has varied from year to year from slightly less than 3 per cent. to a little over 7 per cent.

Table I gives the morbidity and mortality by

months and at the foot of each column the total number of cases and deaths as well as the percentage mortality for each year is given. To the right of the table the total and average number of cases and deaths for each month is given. On the extreme right the percentage mortality for each month of the year has also been added. A careful study

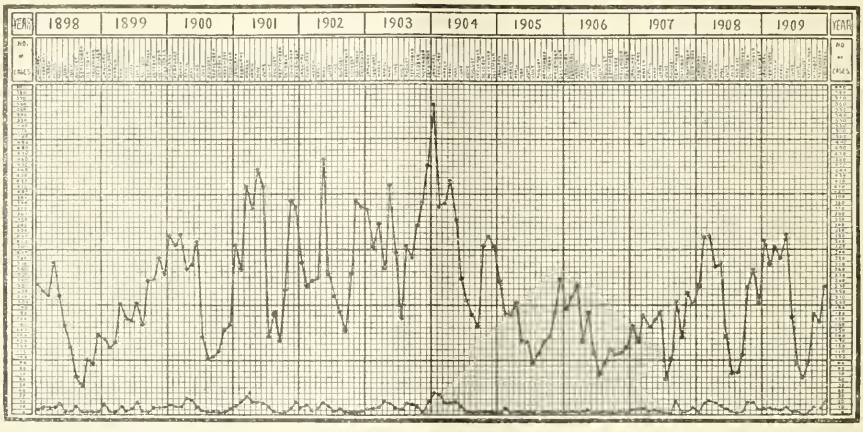

CHART 2.—Graphically showing the monthly number of cases and mortality of scarlet fever in Philadelphia from January 1898 to December 1909; a statistical analysis of 32,317 cases.

of this table in all its aspects reveals a few facts which are of the greatest interest and importance.

It is a somewhat curious fact in the history of medicine that the influence of season upon scarlet fever has been overlooked to a remarkable extent and yet the effect is so conspicuous that it is difficult to explain the oversight. As will be noted in

Chart II graphically shows the number of cases and mortality of the disease in Philadelphia from month to month and year to year. It reveals at a glance what long study of the numerical figures of Table I would probably fail to convey. It colaborates what has been stated in a few textbooks that epidemics are more frequent in winter than in sum-

CHART 1.—Showing the monthly number of cases and mortality ofscarlet fever occurring in Philadelphia from January, 1898, to December, 1909.

Chart I, which graphically portrays the influence of season upon the disease, the average number of cases for January is rather high—280. During February this falls to 246 cases, only to rise during March and again fall during April. May claims the maximum number of cases, an average of 287 being recorded. It then rapidly falls and reaches the

mer. The upper line represents the number of cases, the lower the mortality. Reading from left to right, each space represents an interval of one month and each twelve spaces are blocked representing one year. Marked fluctuations are noted, especially as the disease becomes more prevalent.

New York, December 10, 1910.

REPORT OF THE SURGEON GENERAL OF THE ARMY.

THE annual report of the Surgeon General of the Army for the fiscal year ended June 30, 1910, has just been issued, and provides instructive, interesting, and on the whole satisfactory reading. It would be impossible within the limits of an article to review adequately the entire report, so that merely the most salient points will be chosen for comment. The mean strength of officers was 3,822, as obtained from the returns of the Medical Department. There were 2,404 admissions, 18 deaths, and 115.7 constantly non-effective from all causes equal to ratios of 628.99, 4.20, and 30.27, as compared with ratios of 575.47, 4.85, and 29.41 for the year 1908. The admission and constantly non-effective rates were a little higher than for 1908. The principal causes of admission in the order of their importance were influenza, 51.02; bronchitis, 40.55; diarrhea and enteritis, 33.23; sprains and muscular strains, 31.40; malarial fever, 26.69, and dengue, 24.33. The mean enlisted strength of the army, white and colored, for the year 1909, as reported on the monthly sick reports of the Medical Department, was 74,319. During the year 1909 American troops were stationed in the United States proper, the Philippine Islands, Alaska, Hawaii, and Cuba, from which island the army of Cuban pacification was withdrawn during the months of February and March, 1909. Native troops served in Porto Rico and in the Philippines, statistics for which were separately compiled. The constantly non-effective rate, which is the true measure of the loss in efficiency of the army from sickness and injury, was 41.48 per 1,000, as compared with 42.68 for 1908, 46.17 for 1907, and 49.79 for 1906. The total number of admissions to sick report was 79,000, equal to an admission rate of 1,062.99, as compared with 1,188.03 for the previous year, and 1,218.26 for 1907. The deaths from all causes numbered 370, of which 228 were from disease. The death rate for all causes was 4.91 and 3.02 for disease, as compared with 6.13 and 3.48, respectively, for the preceding year. The discharges for disability numbered 1,270, the rate being 16.84, as compared with 18.48 for 1908 and 20.15 for 1907. The ratio of admissions for disease was 865.92 per 1,000 mean strength; for the previous year, 962.88, and for the decade, 1,379.25. The health of the army has constantly improved since the year 1899, when its admission rate for disease alone was 2,125.74.

Perhaps the most instructive part of the report is that which attempts a comparison between the health of American troops and those of foreign armies. An exact comparison is impossible, chiefly owing to the fact that in most foreign services many of the minor ailments which in the United States Army are treated in quarters and recorded with the same accuracy and care as in hospital cases are not made of record in the foreign armies' medical reports. However, these tables show that the United States Army holds the unenviable distinction of having admission rates for alcoholism and venereal diseases taken together much higher than in any foreign army included in the tables. This is also true of venereal diseases, with the exception of syphilis, for which the admission rate is 35.1 in the British Army, as compared with 26.85 in our army. For malaria the admission rate, as compared with the United States, is higher in the British, Russian, Japanese, and Spanish, and much lower in the French, Prussian, Bavarian, Austrian, and Belgian. Typhoid fever is higher in the British, French, Russian, and more than twice as high in the Japanese. Lobar pneumonia is higher in the Bavarian, Prussian, Austrian, Russian, Japanese, Dutch, French, and English. Pulmonary tuberculosis is higher in the Spanish, French, Japanese, and Dutch. Diseases of the heart are higher in the Spanish, Austrian, Belgian, Russian, British, French, and Prussian. For mental diseases our rate is the highest, being 2.04 for colored and 1.62 for white troops. It should be noticed that the above quoted figures are for the American troops for the year 1909, for the British 1908, for the Dutch 1905, and for all others 1907.

The outstanding and most sinister feature of the report is the deplorable increase and prevalence of alcoholism and venereal diseases among American troops. Venereal diseases caused the largest proportion of rejections, and the total number of admissions from the cause was 14,640, representing 12,605 cases, with an admission rate of 196.99, as compared with 194.13 for the preceding year, and a constant non-effective rate of 13.07, as compared with 11.65 for 1908. It is stated that although this is a disheartening state of affairs, the army record is exceeded by the prevalence of these diseases in civil life, and it is pointed out that it will be difficult to make any substantial improvement in the record of the army in this respect until the State and municipal authorities are aroused to the necessity of taking serious sanitary measures to restrict their ravages. The whole matter is discussed at considerable length in the report, a part of which is in the following outspoken language: "The venereal question has come to outweigh in importance any other sanitary question which now confronts the army, and neither our natural optimism nor the Anglo-Saxon disposition to ignore a subject which is offensive to public prudery can longer excuse a frank and honest confrontation of the problem. There is no reason to think that these diseases are beyond the reach of preventive

medicine any more than other contagious diseases, and their immunity from restriction must be attributed to the public disinclination to discuss them and legislate concerning them. It is now believed by most sociologists, as well as sanitarians, that the evil, being primarily a social one, can only be reached by a propaganda of public discussion and education, and that education in sexual matters and in the danger of venereal diseases should begin with the young and be carried on by means of all the agencies of popular enlightenment. A number of State and municipal health authorities, as well as private associations, are now publishing and distributing literature on this subject. It is believed that the War Department cannot do better than adopt this general attitude and many of these methods, including a philosophical indifference to criticism on the part of self-constituted censors of public morals whose susceptibilities are offended by a public discussion of these questions, measures, and regulations, have been set afoot with the view of decreasing the prevalence of venereal diseases in the army, but as yet the time is too young to make any definite statements as to their efficacy. The opinions of army medical men are unanimous with regard to the absolute necessity of devising and putting into force methods calculated to restrict the prevalence of venereal diseases among soldiers."

The admission rate for tuberculosis was somewhat greater than for the previous year, while the decrease in the prevalence of malarial infection has been steadily maintained. Typhoid fever, too, has been more prevalent and very considerable progress has been made during the year in the campaign for the protection of the army against the disease by means of vaccination with killed cultures of the *Bacillus typhosus*. It is believed that its protective value has been proved, while the innocuousness of the procedure has been entirely demonstrated. Uncinariasis has been fairly common among Southern-bred recruits, and several Northern-bred soldiers became infected in the Philippines.

The most encouraging part of the report is that which refers to the health of the American troops in the Philippines. Both the admission rate for disease and the death rate for disease and external cause were lower than in 1908. The most important diseases showing a reduction were malarial fevers, diarrhea and enteritis, alcoholism, tuberculosis, Asiatic cholera, and variola. On the other hand, there was an increased admission rate for typhoid fever, dysentery, dengue, and venereal disease. The recommendations in the sanitary reports for the Philippines relate mainly to the necessity for establishing sewer systems, systems of pure-water supply, antimalarial and antimosquito measures, and steps to be taken to lessen the occurrence of venereal diseases.

Attention is paid to the teeth of the American soldiers, in evidence of which is the fact that the number of dental operations during the year was 47,378. The ratio of operations per 1,000 of mean strength was 567.33. Nevertheless, the authors of the report think that the number of dentists should be so increased that each man in the army could receive at least one treatment yearly. As to surgical operations performed during the year, in 3,933 operations there were only 23 failures, with 30 deaths. The anesthetics used were: Ether, 1,326 cases; chloroform, 335; chloroform and ether, 100; local, 1,873, and none, 299.

The laboratory work done was of much interest and value. In the Manila laboratory the Noguchi modification of the Wassermann test has been used with very satisfactory results.

The report shows that the life of the soldier is healthy, due to the care taken to surround him with a sanitary environment, and it is also a valuable summary of medical and surgical work performed under varying conditions of climate and place.

AURAL TUBERCULOSIS IN CHILDREN.

An excellent review of our present knowledge on this subject is given by Dr. W. Milligan in the October issue of the *Journal of Laryngology*. The difficulties of diagnosis of the condition are considerable mainly for the reason that the stage of pure tuberculous infection is often a comparatively short one, while the almost constant mixed infection, pathogenic or saprophytic, masks the true nature of the original and underlying process. In the author's experience about 20 per cent. of hospital children under six years of age suffering from purulent otitis media owe the origin of the disease to an underlying tuberculous infection. These figures have been arrived at by means of the von Pirquet test, Calmette's test, or inoculation experiments. The disease is a frequent accompaniment of pulmonary tuberculosis. While pulmonary phthisis is rare in young children and cavitation infrequent, it cannot be deduced that this aural condition does not frequently occur. There are various channels through which bacilli may gain an entrance into the middle ear cleft. The author mentions six; aerial, air passing up the Eustachian tube and depositing its bacilli upon the tubal lining; respiratory tuberculosis; lymphatic, vascular, along the blood-vessels following the entrance of bacilli from the respiratory or digestive canals; through the lymphoid tissue which exists in such abundance in the pharynx and nasopharynx and around the lumen of the Eustachian tube, bacilli being carried inwards by means of the leucocytes and that often without any demonstrable lesion of the epithelium; from the entrance of bacilli through a perforated membrane tympani, and finally through erosion of the dermal lining of the external auditory meatus. The possible passage of bacilli without demonstrable lesion of the epithelium will naturally render the tracing of the course of infection at times difficult or even impossible. The author believes that the most common route of invasion in adults is by way of the respiratory system. In children it is probably by way of the lymphoid tissue.

The author digresses a moment to speak of the rôle of infected milk in this connection. His idea is that the bacillus is swallowed with the milk upon which the child is fed. Then the regurgitation of food so common in the child forces the semidigested fluid into the tonsillar crypts, the nasopharynx and especially the mouths of the Eustachian cushions. It

must be remembered that in infants and young children the tubes are shorter and wider than in adults, while their pharyngeal orifices lie nearer the oral and choanal cavities than is the case in the adult. Hence in the child the entrance into the tube of infecting material is favored. Dr. Milligan describes fully the pathological changes set up in the middle ear cleft by the entrance of the tuberculous material. The finding of bacilli in the aural discharge is by no means a constant fact. A more certain method of diagnosis is the examination of portions of tufts of exuberant granulations removed from the depths of the tympanum and subsequent inoculation experiments. Numerous other acid-fast bacilli than the tubercle bacillus are found. Chief among these are the bacilli of leprosy, Lustgarten's bacillus, the smegma bacillus, the grass bacillus, the butter bacillus, and others associated with fetid lung suppuration. In 100 specimens of aural discharge Wingrave found 24 with acid-fast bacilli, of which number 17 proved to be tubercle germs. Much attention is given by the author to the use of the modern von Pirquet and Calmette reactions in making the diagnosis. None of these should be omitted in doubtful cases. His experience has been that healthy children, at least up to ten years of age, do not respond to the von Pirquet test. The local changes in the ear when perforation has occurred show an absence of that distinct reaction so invariably seen in cases of ordinary inflammation.

The characteristic symptoms of the disease are the painless onset, absence of the inflammatory reaction, the frequent presence of two or more perforations, the early enlargement of the periauricular glands, and facial paralysis. The absence of initial pain is generally regarded as due to the very slow and insidious destruction of tissue and terminal filaments of the sensory nerves of the part. An uninfected tuberculous discharge from the ear is thin, watery, and for the most part odorless, containing gray or white granules or flakes and abundant lymphocytes, but this condition soon changes to one of mixed infection, and we have the products of pus bacilli to deal with, yet by means of the methods of diagnosis referred to we are generally able to make a positive diagnosis.

The desiderata of treatment are to remove infected bone and establish sufficient drainage. These results are to be secured early before the process has advanced. The provision and maintenance of drainage, supplemented by judicious use of tuberculin may effect a cure. The author is in the habit of exposing as much of the dura as possible, of removing the labyrinth, and of rather welcoming a view of the internal carotid artery than otherwise, believing that the greater the amount of the temporal bone removed, the greater the chances of recovery. He believes that the usual irrigation with antiseptic lotions is practically useless. Removal of adenoids and nasopharyngeal lymphoid deposits is a preliminary to any and all treatment. Enlarged glands are left for a time. The author believes that as long as they are not broken down they act as a first line of defence in preventing dissemination and hence fulfil a useful purpose.

Rat Plague in England.

In Suffolk, a county on the east coast of England, plague among rats was discovered a few weeks ago. At about the same time, too, four deaths from plague occurred in Freston, a lonely village in Suffolk. The first area found to be infested with infected rats was restricted, but the disease seems to be spreading considerably. Mr. A. E. Shipley, a well-known English zoologist, contributed to the London *Times* of November 9 an article on rats and their habits. As soon as a campaign is directed against rats the rats scatter, leaving their own districts and invading others. Instead, therefore, of commencing exterminating operations at the place most infected, the exterminators should draw a circle round the district outside in which no infected rat has been found, and then working from this circle to the center should, if possible, drive in and destroy the rats. Every care should be taken that the fleas on the rats are destroyed before they have had time to leave the dead body, and the rats and fleas should be burned, not buried. Mr. Shipley's advice is sound and the authorities of England might gather much useful information from reading of the manner in which rats were destroyed in San Francisco and the campaign which is still being undertaken by members of the Public Health and Marine Hospital Service in certain parts of California. Of course, the extermination of plague infection is a highly specialized undertaking requiring considerable experience, as is also the destruction of rats whether infected or not. As to how the infection reached the remote village of Freston in Suffolk there seems to be no idea. Since the four deaths among human beings at the commencement of the outbreak there have been no further fatalities. There is little fear that the disease is liable to spread on a large scale in Suffolk, where cleanliness is the rule and the inhabitants keep their feet covered, but on the other hand rats exist in veritable hordes in East Anglia and it will doubtless tax the resources of the authorities to the utmost to exterminate or even appreciably to diminish the number of the disease-bearing rodents.

The Automobile Smoke Nuisance.

The comment has frequently been made that there is in the United States less personal liberty than in most of the monarchial countries of Europe. The principle that "one man's liberty ceases where another's begins" has never been thoroughly mastered by the free American citizen, who disregards many of the primary rights of his fellow-man, often with an exasperating degree of immunity. In most of our large cities the general public shows a surprising amount of tolerance of abuses which are sometimes serious, yet often easy of redress. The National Highways Association is endeavoring to secure an amendment to the Callan Automobile Law, which is calculated to make it more practicable in its provisions against smoking cars. The language of the present law is, "dense" smoke, a term which has in practice been found to be unfortunately lax, with the result that arrests of chauffeurs for allowing their cars to smoke within the city limits have practically ceased within the last few weeks, as conviction and fine have been too difficult. The emission of visible vapors is entirely unnecessary, and is usually an evidence of unskillful driving. To the public, who have to inhale such vapors, it is a nuisance of the first rank, and should be abolished.

News of the Week.

City Death Rate.—For the week ending November 26, the death rate in New York was 13.95 per thousand of population, the total number of deaths being 1,284. For the corresponding period last year the rate was 13.36. Among children under five years of age there occurred 302 deaths during the week. Pulmonary tuberculosis caused 151 deaths, an increase of 17 over last year, and pneumonia caused 188, a decrease of 17. Diphtheria and croup caused 29 deaths, the same number as last year, and heart disease 180, an increase of 34.

Tuberculosis Show.—The Ontario Provincial Government has leased from the Canadian Pacific Railway a car which it purposes to fit up with a complete exhibit of matters pertaining to the anti-tuberculosis campaign. The car when equipped will be placed under the charge of lecturers and demonstrators and will be sent to every railway station in the province. Free lectures will be given and literature will be distributed. It will take the entire winter to make the complete tour mapped out for the car.

Bureau of Public Health.—In the annual report of the Department of Agriculture, Secretary Wilson declares that, while he is in hearty accord with the general proposition to provide better facilities for work in the interest of the public health, he is strongly opposed to any plan which will remove from the Department of Agriculture the inspection work involved in the enforcement of the Food and Drugs Act and the Meat-Inspection Law. Such action would, he believes, be a great detriment to the work of his department and to the agricultural and live-stock interests without any corresponding gain in efficiency or public advantage, and would result in increased expenditures rather than in economy. For example, the field work for the eradication of diseases of animals is carried on mostly during the summer, while the work of the slaughter houses is heaviest during the winter, and it is thus possible and economical to shift men from one branch of the service to the other as occasion requires.

Investigation of Infantile Paralysis.—The New York State Board of Health will ask the Legislature at its coming session to provide funds sufficient to permit of a thorough field investigation of infantile paralysis during the epidemic season next year. For the past two or three years the disease has occurred epidemically over an ever-widening territory, and it is estimated that the records of 1910 will show upwards of 3,000 cases, of which 10 per cent. terminated in more or less permanent paralysis. At present the New York State Health Department enforces the same sanitary precautions and quarantine regulations in regard to this disease as are observed in cases of diphtheria. It also requires that all cases be reported to it on special blanks, and a study will be made of these records; but a field investigation made house by house is also necessary in order to determine the factors which favor the spread of the disease.

Civil Service Examination.—The United States Civil Service Commission announces an examination to be held on January 18, 1911, to secure eligibles from which to make certification to fill a vacancy in the position of anatomist (male), at $1,600 per annum, in the Army Medical Museum, Office of the Surgeon General, and vacancies requiring similar qualifications as they may occur. The examination will cover the subjects of pathological histology, gross pathology, bacteriology, photomicrography, and training and experience. Application for blank forms should be made at once to the Civil Service Commission, Washington, D. C. According to a recent act of Congress an applicant for this examination will be required to be examined in the State or Territory in which he resides.

Hospital Saturday and Sunday Association.—Mr. George Macculloch Miller, president of the Hospital Saturday and Sunday Association of New York, since its inception thirty years ago, has recently resigned, and has been made honorary president. Mr. Robert Olyphant has been elected to fill the office thus made vacant.

The Harvey Society.—The third lecture of the Harvey Society will be delivered by Dr. Harvey Cushing of Johns Hopkins University on the evening of Saturday, December 10, at half-past 8, at the New York Academy of Medicine, 17 West 43d street. The subject of the lecture will be "Certain Clinical Aspects of Dyspituitarism." Professor Castle of Harvard University will deliver his postponed lecture on "Unit Characters in Heredity" on February 25, 1911.

The Cartwright Prize.—This prize, which is offered by the Association of the Alumni of the College of Physicians and Surgeons, Columbia University, New York, and is open for universal competition, will be awarded at Commencement, 1911. The amount of the prize is $500. The essays submitted in competition must contain original investigations made by the writer and must be the work of only one person; they must be typewritten, in English, marked with a device or motto, and accompanied by a sealed envelope, similarly marked, containing the name and address of the author. Essays should be sent to Dr. H. E. Hale, Secretary, 770 West End avenue, New York, on or before April 1, 1911.

Dentists for the Navy.—The House Committee on Naval Affairs has favorably reported the bill introduced a year ago by Representative Dawson of Iowa establishing a dental corps in the navy. The measure creates a corps of thirty, who, it is provided, shall enter the service as acting assistant surgeons. In eleven years the thirty will automatically resolve themselves into one Lieutent-Commander, four passed assistant surgeons, and twenty-five assistant surgeons. The age limit for entrance is from 24 to 32 years.

The Price of Radium.—The Radium Institute of London recently purchased a gram of radium from the Austrian government, the price paid being £15,000, or about $5,000 a grain.

Another Centenarian.—Josiah Zeitlein, said to be the oldest resident of Brooklyn, N. Y., died on December 2 at the age of 106 years. Mr. Zeitlein's rules for a long life included the abolishment of worry, hurry, quick lunches, meat, and doctors, and of drug stores except as places for buying stamps or consulting a directory. He added the comforting dictum that after the age of ninety was reached one might do about as he pleased.

Gift to Hospital.—The Paterson General Hospital of Paterson, N. J., has received a gift of $10,000 from Mr. E. E. Bell for the erection of a proposed new observation pavilion. The building is to be a memorial to Anna T. Bell, a charter member

of the Paterson General Hospital Association. The Board of Managers hopes to be able to raise sufficient funds to rebuild the entire institution.

Hospital Fire.—One of the cottages of the State Hospital for the Insane at Toledo, Ohio, was completely destroyed by fire on the night of November 30. No lives were lost, credit being due to the prompt and efficient work of the hospital officers and firemen in quelling the panic which followed the alarm among the 200 insane patients in the hospital.

Los Angeles and the A. M. A.—In an effort to make the meeting of the American Medical Association which will be held at Los Angeles beginning June 26, 1911, the largest in its history, circular letters setting forth the wonders and beauties of California and the advantages of Los Angeles, are being sent to all the members by Dr. Walter Lindley, editor of the *Southern California Practitioner* and ex-president of the California State Medical Society.

Addition to Hospital.—The Norwegian Deaconess Home and Hospital of Chicago dedicated its new addition on November 20. The building measures 120 by 50 feet, and is four stories high. The hospital now has accommodations for 100 patients.

Ehrlich Honored.—The Grand Cross of the Order of Alphonso XII of Spain has recently been conferred upon Prof. Paul Ehrlich.

Dr. Simon Flexner of the Rockefeller Institute was operated upon for appendicitis at the Presbyterian Hospital on Monday of this week. His friends and all the friends of scientific medicine will rejoice to know that the operation was successful and that his recovery seems to be assured.

Mrs. Mary Baker G. Eddy, discoverer and founder of the Christian Science Church, died on Saturday last at the age of eighty-nine years. Some of the dissenting Christian Scientists claim that she died many years ago and that the woman just passed over was an imposter, but that is probably an error, for the letters and poems recently given out are too like the previous writings of Mrs. Eddy to have been written by any one else.

Tri-State Medical Association.—At the twenty-seventh annual meeting of the association held in Memphis from November 15 to 17, the following officers were elected: *President,* Dr. J. W. Barksdale of Winona, Miss.; *Vice-Presidents,* Dr. John Darrington of Yazoo City, Miss.; Dr. R. P. Wall of Armarette, Ark.; Dr. A. G. Hudson of Raines, Tex.; *Secretary,* Dr. Eugene Rosamond; *Treasurer,* Dr. J. A. Vaughan.

Rolla District (Missouri) Medical Society.—At the seventy-first semi-annual meeting of the society held on November 19, the following officers were elected: *President,* Dr. C. F. Briglieb of St. Clair; *Vice-President,* Dr. S. B. Rowe of Rolla; *Secretary-Treasurer,* Dr. W. H. Brewer of St. James. The next meeting will be held at St. James in May, 1911.

Northern District Medical Society of California.—At the annual meeting of this society held at Sacramento on November 15, the following officers were elected: *President,* Dr. J. J. Hogan of Valejo; *Vice-Presidents,* Dr. R. A. Peers of Colfax, Dr. H. E. Wright of Sacramento, and Dr. R. M. Bramhall of Fair Oaks; *Secretary,* Dr. J. W. James of Sacramento; *Treasurer,* Dr. D. Hansbury of Chico.

Fifth District (Texas) Medical Society.—The following officers were elected at a meeting held in San Antonio on November 16: *President,* Dr. E. V. DePew of San Antonio; *Secretary,* Dr. F. C. Walsh of San Antonio; *Treasurer,* Dr. L. G. Wille of New Braunfels.

Eleventh District (Georgia) Medical Society.—The following officers were elected at the annual meeting in Valdosta on November 23: *President,* Dr. A. G. Little of Valdosta; *Vice-President,* Dr. H. C. Welchel of Douglas; *Secretary and Treasurer,* Dr. W. E. Miller of Eastman.

Mutual Aid Association of the Philadelphia County Medical Society.—At the annual meeting held November 14 Dr. Roland G. Curtin was elected *President* in place of the late Dr. James B. Walker. Dr. J. P. Shellenberger was reelected *Vice-President;* Dr. Lewis H. Adler, Jr., *Secretary,* and Dr. John B. Turner, *Treasurer.*

Hardin County (Ky.) Medical Society.—At the annual meeting held on November 10 at Elizabethtown the following officers were elected: *President,* Dr. D. E. McClure; *Vice-President,* Dr. S. N. Cowherd; *Secretary,* Dr. E. J. Strickler.

The Sixth District (Georgia) Medical Society at its semi-annual meeting on November 9 elected the following officers for the ensuing year: *President,* Dr. Marcus F. Carson, Griffin; *Vice-President,* Dr. E. M. Green, Milledgeville.

Southern Illinois Medical Association.—A two days' session of this society at Centralia was closed on November 4 with the election of the following officers: *President,* Dr. E. W. Fiegenbaum, Edwardsville; *Vice-Presidents,* Dr. Andy Hall, Mt. Vernon; Dr. H. E. Wilson, Centralia; *Secretary,* Dr. C. W. Lillie, East St. Louis; *Treasurer,* Dr. A. T. Telford, Olney. Mt. Vernon was selected as the place of meeting next year.

The Late Dr. Charles Jewett.—At a meeting of the Council of the Medical Society of the State of New York, held in Albany, December 3, 1910, the following minute was adopted: In the death of Dr. Charles Jewett not only has the Medical Society of the State of New York lost its honored President, but the medical profession of this country will miss from its ranks a tireless worker, a distinguished teacher, and an eminent surgeon. In the fullness of years and the ripeness of experience there was conferred upon him his last public honor —the presidency of the State Society. Unsought for and undesired, it was conferred by his colleagues as a fitting recognition of his distinguished achievements and his sterling worth. However distinguished the office there was something about the man that no office could compass and no honor could magnify. For whether in the councils of the mighty, or in the homes of the humble, his services were always distinguished, and his judgments clothed with authority.

Among obstetricians he was a leader by right of worth and superiority, by force of character and quality of achievement. He crystallized his knowledge into literature and enriched his profession by a fruitage that will live as a permanent asset. Because of his ability to sift, correlate, clarify, and vitalize the truth, he was a teacher of power and preeminence; and a host of students throughout the world are the living witnesses of his scholarly and forceful personality. Because of his advanced thought and judicial mind, his counsel and advice were sought by his brethren in the perplexities of human suffering, and the depth of his knowledge and the strength of his character were always an abiding inspiration.

The Medical Society of the State of New York, sorrowing in the loss of its distinguished President, humbly voices its appreciation of his work and his worth, and thus again renews its faith in the permanency of character, the supremacy of service, and the triumph of worth. *Signed:* William Francis Campbell, M.D., E. B. Cragin, M.D., J. A. Sampson, M.D.

Obituary Notes.—Dr. Landon B. Edwards of Richmond, Va., a graduate of the Medical Department of the University of New York in 1867; formerly professor of the practice of medicine and later professor of clinical medicine and chairman of the medical faculty, and now emeritus professor in the University College of Medicine, Richmond; ex-president of the Richmond Medical and Surgical Society and of the Richmond Academy of Medicine and Surgery; secretary and honorary fellow of the Medical Society of Virginia; a member of the American Medical Association, and the Ninth International Medical Congress; honorary member of the West Virginia Medical Society and of the Medical and Surgical Society of the District of Columbia; ex-president of the Association of American Medical Editors and of the American Medical Publishers' Association, and attending physician to the Virginia Hospital, died at his home on November 27, aged 65 years.

Dr. Leslie B. Shanklin of Sullivan, Ind., a graduate of the Central College of Physicians and Surgeons of Indianapolis, a member of the American Medical Association and the Indiana State and Sullivan County Medical societies, died in Pueblo, Col., of tuberculosis, on November 11, while on his way to El Paso, Tex., where he intended to settle on account of his health. Dr. Shanklin was 33 years of age.

Dr. Adolphus Berger of Lebanon, Ill., a graduate of the Humboldt Medical College, St. Louis, in 1862, died at his home of chronic bronchitis on November 8, aged 89 years.

Dr. Anselm D. Price of Harrodsburg, Ky., a graduate of the Medical Department of the University of Louisville in 1865, a member of the American Medical Association and of the Kentucky State and Mercer County Medical societies, died at his home on November 11, aged 70 years.

Dr. Samuel O'Callaghan of Philadelphia, a graduate of Trinity College, Dublin, in 1879, and of the Jefferson Medical College, Philadelphia, in 1882, died at his home on November 13, aged 71 years.

Dr. J. J. Smith of Enumclaw, Wash., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1891, a member of the Washington State and King County Medical societies, and president of the State Senate in 1903, died at his home of typhoid fever on November 12, aged 41 years.

Dr. Samuel D. Smoke of Fort Ogden, Fla., a graduate of the Medical College of the State of South Carolina in 1859, died at his home on November 13, aged 73 years.

Dr. Robert D. Dunlop of Louisville, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1884, a member of the Kentucky State and Louisville County Medical societies, and formerly a member of the Louisville School Board, died at his home of uremia on November 9, aged 56 years.

Dr. Thomas Gill Nock of Rome, N. Y., a graduate of the College of Medicine, Syracuse University, in 1883, a member of the American Medical Association and of the New York State and Oneida County Medical societies, formerly coroner of Oneida County, mayor of Rome, and a manager of the Utica State Hospital, died at his home on November 28, aged 51 years.

Dr. Jane Howell Harris of San Juan, Porto Rico, a graduate of the Woman's Medical College of New York, died of pneumonia on November 21.

Dr. E. Agustus Reed of Knoxville, Tenn., a graduate of the Medical Department of the University of Louisville in 1891, a member of the Tennessee State and Knox County Medical societies, died at his home on November 25, after a long illness.

Dr. George S. Stein of Columbus, Ohio, a graduate of the Department of Medicine of the University of Pennsylvania in 1864, a member of the American Medical Association and of the Ohio State and Franklin County Medical Societies, died at his home on November 19, aged 72 years.

Dr. J. W. Cringan of Arrington, Virginia, a graduate of the University College of Medicine, Richmond, Virginia, in 1901, a member of the Virginia State and Nelson County Medical Societies, died suddenly on November 21.

Dr. John H. O'Bar of St. Louis, Missouri, a graduate of the St. Louis College of Physicians and Surgeons in 1907, and a clinical professor in the same institution, died at his home on November 22 of pneumonia, aged 39 years.

Dr. Elam B. Mauger of Pottstown, Pennsylvania, a graduate of the Jefferson Medical College in the class of 1875, died at his home of angina pectoris on November 21, at the age of 54 years.

Dr. Charles L. Mitchell of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in the class of 1880, one of the founders of the Medico-Chirurgical College, and its first professor of chemistry, died at his home on November 24, aged 59 years.

Obituary.

CHRISTIAN ARCHIBALD HERTER, M.D.

NEW YORK.

Dr. Christian A. Herter, Professor of Pharmacology and Therapeutics in the College of Physicians and Surgeons, New York, and physician to the Hospital of the Rockefeller Institute, died at his home after a long illness, on December 5. Dr. Herter was born in Glenville, Conn., on September 3, 1865, and in 1886 was graduated from the College of Physicians and Surgeons, New York. In 1894 he was made visiting physician to the City Hospital, New York, a service which he continued until 1904. He also held the chair of Professor of Pathological Chemistry in the University and Bellevue Hospital Medical College from 1897 until 1903. He was a member of the Association of American Physicians, the American Medical Association, the American Physiological Society, the New York Academy of Medicine, the New York Pathological Society, the Society of Experimental Biology, and the American Neurological Society, and since its inception a member of the Board of Directors and treasurer of the Rockefeller Institute. In research his work had to do chiefly with chemical pathology, the pathology of nutrition, and bacterial infections of the digestive tract, all subjects on which he spoke with authority.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COLLEGE OF SURGEONS' MEETING—PLAGUE CIRCULAR—RADIUM IN CANCER—TABES—INFECTIVE CARDITIS—HEMATOMA OF THYROID—SPONDYLITIS DEFORMANS—ADIPOSE GROWTHS—HOME OF RECOVERY—MEMORIALS AND OBITUARY.

London, Nov. 18, 1910.

Yesterday was the twenty-sixth annual meeting of Fellows and Members of the Royal College of Surgeons. Thus twenty-six years have passed since the Council yielded so far to the demand for representation of those who constituted the body of the colleges as to agree to meet there once a year and hear what they had to say, though still declining to admit that their opinions or resolutions would have any influence. You will remember that the whole power of this peculiar oligarchy is exercised by the Council—twenty-four persons. They are selected by the Fellows who have no other voice in their college and who number about 1,200. The members are licensed to practice and have no further connection with the college, and as they are the main body, many thousands in number, it is not surprising that they demand some kind of representation. A resolution to this effect was submitted for the twenty-sixth time yesterday by Mr. Joseph Smith, J. P., who is president of the society of members.

The rat plague in Suffolk was met by so determined an effort to exterminate rats that few are now to be seen in the district of the first outbreak. But the disease has been detected in places some miles distant. The local government board has therefore issued a memorandum by Dr. Arthur Newsholme, giving directions for sending material for bacteriological examination from suspected cases. Dr. Newsholme describes the symptoms of bubonic, septicemic and pneumonic plague, and says that for administrative purposes it may be regarded as a rat disease which occasionally attacks man, fleas forming the intermediaries between the diseased rat and man. If the fleas of infected rats or of such other animals as suffer occasionally from plague are excluded from access to man the disease will seldom, if ever, says Dr. Newsholme, spread from animals to man. The first step in the control of the spread of infection in man is, as in other infective diseases, the prompt notification of suspicious cases to the M. O. H. The memorandum advises (*a*) persistent and systematic destruction of all rats, (*b*) removal and obliteration of their nests, burrows and haunts, (*c*) removing all known harborage for rats in or near dwellings and making every dwelling as far as possible rat-proof, (*d*) allow no waste food, whether for man or animals, to accumulate in or about the house. Dr. Newsholme adds an encouraging assurance that freedom from risk of plague can be secured with almost complete certainty by acting on these directions.

Radium for cancer was the subject of a paper by Dr. N. S. Finzi at the Æsculapian Society on November 5. The whole tumor, he said, should be thoroughly treated with filtered rays, using plenty of radium and giving a full dose every six weeks. In sixty-four cases he said the growth had completely disappeared in seven. They were in the lip, breast, uterus, prostate, rectum, esophagus. In most of them microscopic examination confirmed the diagnosis. He had twenty-three other cases still under treatment and was very hopeful of some. Relief of pain and discharge was marked when the growth was not decreased. Cases should be selected according to their structure, position and size, the constitution of the patient and his strength not being overlooked. The rays were given out in all directions, even from flat applications, so that to get their full effect it would seem desirable to surround the radium as completely as practicable by the diseased tissue. The B and Y rays have a selective action on cancer cells, the Y more than the B. It is therefore well to cut off most of the latter by means of metallic filters.

Some interesting cases were shown in the clinical section of the Royal on Friday. There was a man of 40 who had tabes for six years. Seven months ago severe pain began and there is now marked lordosis with dislocation of the lumbar spine forwards and sub-dislocation of the sacrum backwards. Grating was felt and heard near the fifth lumbar vertebræ and sacroiliac synchondrosis. A man of 42 had been under observation at St. George's Hospital since August, 1909. For the first six weeks the evening temperature varied from 97.6° to 101°. Heart feeble and irregular, systolic and diastolic murmurs. October 4, a streptococcus was obtained from the blood and on October 14 was begun autogenous vaccination. By October 21 the temperature became normal, but recurrent attacks of fever returned until the last two months. The microorganism had been isolated on five occasions. It was not pathogenic for mice. The patient has improved, the temperature is normal, the weight has increased, and the blood is sterile, with a normal leucocytic count.

A woman of 50, subject for years of enlarged thyroid, was seized on May 28 with sudden dyspnea. It was relieved by ice packs, but the thyroid was greatly increased in size and next day stridor returned. The tumor was hard, not fluctuating with the laryngeal mirror; the aretenoid region was seen to be very edematous. The thyroid was removed and during the operation a portion of it was found tightly packed under the sternum. When this was shelled out the breathing was immediately relieved and recovery was uninterrupted. The specimen showed a hematoma in the thyroid.

A man of 39 with spondylitis deformans, the spine being rigid throughout in a kyphotic position. The ribs were immobile from ossification of ligaments and fixation of costvertebral joints. From time to time nerve root pains were present. The condition had continued for seven years, but none of the accepted causes could be traced. The man was diabetic. It was pointed out that this disease differed from oseoarthritis in being due to ossification of the spinal ligaments without joint disease.

At the previous meeting of this section we had some cases of irregular development of adipose tissue. One was an anemic woman, who had noticed some swelling under her chin. In March a small, fatty, painless growth appeared at the back of the neck. In April and June further fatty deposits affected the shoulders, back, and abdomen, these diffused masses being tender and painful. There was neuralgic pain in the arms. The thyroid was atrophied. She had taken thyroid tablets, which seemed to control the increase, but worried her eyes. Pituitary extract had been given without noticeable effect.

A man of 45 had fatty masses over the neck, shoulders, arms, abdomen, thighs and sacrum—not painful nor tender. A very stout woman of 44, who had long felt her legs painful, found lately fatty swellings on them and the thighs, which are both tender and painful. It does not seem that these cases shed much light on adiposis dolorosa, or Dercum's or Lyon's cases. So, awaiting further research, I am content to group them as irregular fatty developments.

Dr. Jameson Macan, who died in October after two days' illness, was an active contributor to medical literary work in the department in which he was most interested—gynecology. He edited the *British Gynecological Journal* and generally wrote the valuable summaries. He also worked on the *British Journal of Obstetrics*. He translated, conjointly with his late brother, Sir Arthur Macan, Schultze's "Displacements of the Uterus." After the amalgamation of the various societies in the Royal he took charge of the publication department of the obstetrical and gynecological section. To his pen were also due various reports of international congresses and other proceedings concerning his specialty. In all this work and much besides he retained the admiration for his capacity and the regard for his personal qualities of his contemporaries within and without the profession.

The Schiff Home of Recovery, for patients who have undergone operations in the large London hospitals, was opened on Friday at Cobham. It has been chiefly established by Mr. Ernest Schiff, who gave £100,000 to the scheme in memory of his brother Alfred. It provides for between seventy and eighty inmates.

A memorial to the late P. J. Fagan, whose death was lately reported, is being raised in Dublin. It is proposed to devote it to the maintenance and education of his family, for whom he had been unable to provide adequately.

Dr. J. Frank Payne, fellow and Emeritus Harveian librarian of the Royal College of Physicians, died on Wednesday. He graduated in arts at Oxford; in science and medicine in London, 1862-80. He became a fellow of the college in 1873. He gave the Gulstonian lectures in 1874 and the Lambian in 1891. He had been Radcliffe traveling fellow of Oxford, examiner in medicine at University of Cambridge and London, was on the Royal Commission on Tuberculosis and consulting physician to St. Thomas's Hospital. You will remember his "Manual of Pathology" (1888), and that he edited the second edition of Jones & Sieveking's "Path. Anatomy." He contributed important papers to the societies and journals and wrote the articles on plague and the history of medicine in the "Encyclopedia Britannica." He retired to New Barnet, where his funeral takes place to-morrow. Lately he presented to the college library some rare early editions he had collected.

The death has occurred of Dr. G. de Gorreguer Griffith, founder and late senior physician of the Grosvenor Hospital for Women and Children, and physician and lecturer at Zenana Medical College, which he also founded. He qualified at the Dublin and London Royal Colleges (1860-63). He contributed to the medical journals and societies on gynecological subjects, in which he was most interested, and wrote a work on "Treatment of Fibroids of the Uterus." For a number of years he took charge of the "Hospital Mirror" of the *Medical Press and Circular*.

Lieut.-Col. Rivers Mantell, late I. M. S., died on November 9, aged 77. Col. Mantell graduated M. B., London, and M.R.C.S., 1855.

The death is announced of Mr. W. B. Woodhouse, who took the diplomas of the two Royal colleges and the dental license also. He served as a house surgeon at the Dental Hospital and afterward went to South Africa, where he was appointed civil dental surgeon with the field force. Subsequently he settled at Pretoria, became dental surgeon to the hospital and a member of the Medical Council. He was only 38.

Dr. T. S. F. Caverhill, F.R.C.P., Edinburgh, died on November 4. He took a great interest in sanatorium treatment, established one in Perthshire and wrote a work on "The Crusade Against Consumption."

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, THIRTY-NINTH CONGRESS AT TOULOUSE —SIXTH CONGRESS OF GYNECOLOGY, OBSTETRICS, AND PEDIATRICS, TOULOUSE—FIRST CONGRESS OF VACATION COLONIES — NECROLOGY, PROFESSOR RAYMOND.

PARIS, October 25, 1910.

THE Congress of the French Association for the Advancement of Science was held in August in Toulouse. The Section of Medical Electricity was presided over by Bergonié. The principal questions taken up were electrotherapy and radiotherapy in the treatment of fibromyoma of the uterus. The readers of papers, Guilleminot and Laquerrière, showed that radiotherapy often brings relief to the size of the growth or to hemorrhages, or to both. The latest matter of rapid progress of radiotherapy has come through Nogier. He has employed for this purpose reinforcing apparatus which reduces the treatment to one-thirtieth or one-fortieth of a second. Instantaneous radiography has been realized with treatments of one one-hundredth of a second, and very rapid radiography is now generally practised. In the Section on Hygiene and Public Medicine, presided over by Maurel, the attention of the audience was occupied by an investigation of the morbidity from tuberculosis among the rural population of France. It has been demonstrated that tuberculosis is decidedly on the increase. The cause of this increase is emigration toward the cities, agglomerations of people caused by military service, the primary schools, where contagion spreads, tuberculosis of cattle, alcoholism, the deplorable hygiene of the country districts and of cities with their narrow houses, without light and air, with the absence of prophylaxis, and of disinfection.

In the Section on Tuberculosis the treatment of hemorrhages among the tuberculous was the subject of an interesting paper by Israel Jong. He believes that the therapeutics of hemorrhage should be pathogenic, that is, one should consider its causes; some of them are physical, such as climate and temperature. Thus hemorrhages are observed at times in the hospitals of Paris in series. Altitude and marine climate may also cause hemorrhage. As to treatment, rest in bed and silence are to be ordered. He considers that revulsives and applications of ice are useless. He has studied coagulants such as calcium chloride and serum gelatin.

Another most interesting question was submitted to the Congress, that is, whether a previous attack of tuberculosis immunizes to a later attack. Ac-

cording to the opinions submitted it would seem that previously localized tuberculoses confer on subjects who have been attacked by them a true immunity. It has been observed that pulmonary tuberculosis rarely develops in persons who have previously had attacks of scrofula and lupus. Also coxalgics who have been cured and cured pleuritics seem to be immune to pulmonary tuberculosis. Fernand Bazançon believes that in tuberculosis one must distinguish cures from remissions of long periods observed in this disease. Before pronouncing the word cure the patient must have remained cured for four years without any new manifestation. However, experimental facts have not shown the reality of immunity conferred by a previous attack.

The Sixth Congress of Gynecology, Obstetrics, and Pediatrics was also held at Toulouse, in the month of September. In the Section on Pediatrics, Aviragnet discussed curable forms of acute tuberculosis in children. The invasion of the organism by tuberculosis comes principally by the lymphatic mucosa of the nasopharynx with a latent location in a group of glands, which is generally in the mediastinum. Tubercular tracheobronchial adenopathy arises by a series of accidents, which cause modifications of vesicular murmur at the right apex, attacks of asthma, localized bronchitis, pulmonary congestion, and associated glandular enlargements, cervical and inguinal. Tracheobronchial adenopathies are the most precious indications of the presence of latent tuberculosis. The most effectual medication is supplemental alimentation and continuous fresh air in a marine climate.

In the Section on Obstetrics, Fieux treated of the pathogeny and treatment of incoercible vomiting of pregnancy. To explain incoercible vomiting in pregnancy Fieux believes that the hypothesis of toxemia caused by the villosities of the ovum is most seductive, for there exist in the serum of the pregnant woman antibodies specific for the secretion of young chorionic villi. Further, the interruption of pregnancy is always followed by the cessation of vomiting. The ordinary treatment is confined to attempts to await the end of the vomiting, so as to permit the woman to continue her pregnancy. Premature labor is not indicated except when the pulse is more rapid that 100 pulsations per minute, and when polyneuritis or true icterus appears as a complication.

Pousson of Bordeaux has made a study of the results of nephrectomy from the point of view of the possibility of rendering successful future pregnancies, with the aid of six cases operated on. He saw only 7 abortions against 59 normal labors with normal infants and the possibility of lactation. The answer to question of the desirability of marriage will be based on the condition of the remaining kidney. It is well to remember that mothers have survived and been able to nurse their children with a single kidney and purulent urine.

Audebert and Gillies have studied the relations of biliary lithiasis to pregnancy. The influence of the puerperal state on biliary lithiasis has been much discussed. It provokes and aggravates lithiasis by favoring infections. If lithiasis of the gall bladder is without influence on pregnancy, hepatic colic and icterus produce abortions. The medical treatment consists of rest and an appropriate diet. Operation is only indicated in grave cases, and then only it may be indicated to undertake cholecystectomy.

The Congress of Vacation Colonies was held at Paris on September 30. Created for the benefit of small citizens who were anemic, these colonies are the most efficacious remedy for toning up suffering and delicate infancy. Their object is to send into the country some hundreds of poor city children. Such marvelous results have been obtained from the point of view of physical regeneration that it is astonishing that they were not undertaken earlier in France, and in a larger way, more in relation with their great social value. The beginning of vacation colonies dates from 1890. They soon became very popular, and in 1910, 72,800 little French children of both sexes were sent to the country. Some were placed in the open country, others in the mountains, some isolated on peasant farms, some in groups, to remain from three weeks to six weeks, or more. A child who has passed his vacation in a colony is more robust, and better armed physically to struggle against tuberculosis and other infections. All scholars who are delicate, anemic, emaciated, nervous, and lazy should be sent to the country, and a life in the fields is better worth while than sitting in school. It is well to salute the magnificent results of the vacation colonies that have been shown by the first National Congress of Colonies.

Professor Raymond, who occupied at Paris, after the illustrious Charcot, the clinical chair of nervous diseases of the Salpêtrière, died September 28, 1910. Born in 1844, he studied at the school of Alfort, to which he returned after his graduation in 1867 as Chief of Anatomy and Physiology. Externe of Hospitals in 1870, and gold medal interne in 1875, Chief of the German Ear Clinic in 1887, Hospital Physician admissible to the Aggregation in 1878, with his thesis on "The Dyspepsias," he became Agrégé in 1880. Physician to the St. Antoine Hospital, he was elected in 1894 professor of the clinic of nervoous diseases at the Salpêtrière. Aside from various articles or communications in the journals of societies, Professor Raymond published a series of works on mental and nervous diseases. It is also necessary to remember his lessons on pathological anatomy of the nervous system, and his work on Fixed Ideas and Psychasthenia, written in collaboration with Pierre Janet. The Faculty, the Academy of Medicine, of which he was a member, his pupils, by whom he was loved, find his loss great. Professor Raymond was a Doctor of the University of Oxford and Commander of the Legion of Honor.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

ETIOLOGY OF BERIBERI—CHOLERA—OPPOSITION TO THE LISTING OF TUBERCULOSIS AS A REPORTABLE DISEASE—IMPORTATION OF MILK—REPORTED FAILURE OF THE COMAR TREATMENT—PERSONALS.

MANILA, P. I., September 28, 1910.

THE question of the causation of beriberi is still being extensively discussed in the Philippines and nearby Oriental countries; a set of men are gradually coming forward who do not believe that beriberi is due to the consumption of polished rice. As evidence they advance the fact that they can point to undoubted cases of beriberi in persons who have never used rice in any form. The defenders of the rice theory state that instances of this kind do not in any way nullify the contention that rice in Oriental countries is responsible for beriberi, asserting that rice is only responsible because it furnishes the staple article of diet for the masses who use it almost continuously to the exclusion of other food, and

that any other similar ration, which is deficient in phosphorus and other ingredients required by the human organism might also be the cause of beriberi, that the term "rice causation" only refers to the local conditions which prevail and that the disease may be contracted in other ways. As an illustration of this they point to the experiments recently made by Dr. E. D. Kilbourne, of the Army Board for the Study of Tropical Diseases, in which he was able to produce typical beriberi in chickens by simple starvation. Further confirmation of the rice origin of the disease has recently come to hand in the experience had at the Hospico de San José, which is a charitable institution in which are quartered between six and seven hundred orphans, insane, and other recipients of charity. For many years beriberi has been more or less constantly present. The use of unpolished rice was begun last June, and some weeks after that time all cases of beriberi disappeared, and the medical director states that practically for the first time in ten years they are entirely free from this disease.

The cholera conditions in the Philippines have improved considerably during the past few weeks, the provinces in Northern Luzon being almost entirely free of the disease. The rapidity with which the outbreak in Pangasinan was brought to a close as soon as the Governor-General impressed upon the provincial and municipal officials that they would be held strictly accountable for any failure to cooperate, and by giving practical effect to his orders by the suspension of several town councils, is another excellent example of how much may be accomplished toward eradicating cholera if the aid of the people in general can be secured. At present there is an average of about forty cases per week being reported, and fully two-thirds of this number occurs in the province of Batangas. In this latter province the disease gained quite a headway before the local officials would consent to having the Insular Bureau of Health take charge of the anti-cholera measures. This has now been done, however, and there is every reason to believe that there will be a rapid drop in the number of cases. In the city of Manila during the past few weeks there has been an average of one or two cases per day, but there is seldom more than one case in any one section, and it is most difficult to trace any connection between the cases. For the week ended September 24 there were five cases reported.

For the purpose of obtaining better statistics the Bureau of Health has placed tuberculosis and typhoid fever upon the list of reportable diseases. This action has caused considerable opposition from the Filipino press and from the Filipino physicians, who assert that this is a still further curtailment of their rights and privileges. The more ignorant class among the Filipinos have a great antipathy for hospitals, and they fear that this is another plan forcibly to compel them to enter a hospital in the event that they are afflicted with tuberculosis. For instance, at the out-patient free clinic that is conducted by the Bureau of Health and the Philippine Medical School, and which has had an average daily attendance of nearly 100 patients, the day the notice was issued that tuberculosis is a reportable disease practically no one applied for treatment, and it took several weeks of persuasion before any considerable number of the former visitors to the dispensary could be induced to return.

Since American occupation the importation of milk into the Philippine Islands has shown a steady increase. The record of the Customs House shows that in 1903 milk to the value of $247,366 was imported; this has steadily increased from year to year until in 1909 milk to the value of $406,607 was imported. The increase in the quantity of fresh milk is particularly noticeable; in 1903 there were 8,804 gallons imported, while in 1909 there were 113,397 gallons imported. In view of the fact that tinned milk is of necessity sterile and is generally used before there is any likelihood of contamination, milk in this form is much more sanitary than the fresh milk supplied by the average dairy in the United States.

It has been reliably reported that several of the cases of carcinoma that were apparently cured in Manila by the vaccine method as used by Coca and Gilman have relapsed, and that others have serious abcesses as a result of the injection, which apparently will not heal.

Dr. R. P. Strong, chief of the Biological Laboratory of the Bureau of Science, has been appointed chief of the medical wards of the new Philippine General Hospital and has entered upon his duties during the past week.

TREATMENT OF BARBERS' ITCH.

To the Editor of the Medical Record:

Sir:—A brief account of a simple but efficacious treatment of sycosis contagiosa or barbers' itch may be of interest. Sycosis contagiosa is a true eczema of the hairy portions of the face. It frequently affects the hair follicles, more especially the root sheaths, and is accompanied by considerable infiltration of the tissue between the follicles.

When the inflammation has reached the hair follicles, pustules form, each pustule being pierced by a hair. It naturally follows then that these loosened hairs, while in the follicles, act as foreign bodies and must be removed before a cure can be effected. Hence, every hair must be removed and when epilation is performed, generally speaking, every hair will be accompanied by its root sheath, swollen and loosened from its follicle.

The following case is submitted as an example of what one usually meets along this line: During the early part of July a farmer presented himself at my office seeking relief and cure for this troublesome disease of the skin. Some four weeks prior to his first visit he had been shaved by a local barber. In about a week the disease made itself known. He consulted two other physicians before applying to me. One called it ringworm; the other, common scabies. He said to me, after I had diagnosed his trouble, "Doctor, if I don't get relief tonight, to-morrow I will go to Philadelphia for treatment." I assured him if he would follow my instructions faithfully I would cure him. He consented. First with an ordinary pair of tweezers I epilated as much of the hair on his face as he could stand at one sitting. Second, taking a piece of absorbent lint I made a mask, covering the entire face, cutting out places for eyes, nose, and mouth. To this I applied a saturated solution of distilled verdigris, or subacetate of copper, and gave him a pint of the same solution with directions to keep the lint or mask constantly saturated. I also ordered a saline cathartic and one-fourth grain calcium sulphide four times a day, and gave him instructions to call the following afternoon. When he came his face expressed his gratitude. He said he had slept the previous night for the first time in

two weeks. I repeated the epilation operation and continued to do so every day until my patient was cured, which was in less than a week.

In conclusion, I will say that as the disease progresses toward a cure large scabs form in spots, when it is necessary, in order to hasten the cure, to incorporate the subacetate of copper in the form of an ointment, using 30 grains to the ounce of simple cerate. Dermatologists recommend bichloride of mercury, white precipitate, etc., but in my experience the treatment here given is more prompt, almost painless, and will not fail, if given a fair trial and there has been no mistake in the diagnosis.

The Technique of Operations for Stone in the Ureter. H. Cabot.
A Method of Staining Capsulated Bacteria in Body Fluids. W. H. Smith.
Cancer of the Scrotum. R. M. Green.
The Technique of Arthrotomy. C. F. Painter and A. P. Cornwall.

Operations for Stone in the Ureter.—H. Cabot states that ureteral catheterization and radiography enable one in the majority of cases to know beforehand in what portion of the ureter a stone is situated. A great majority of stones lodge at one of three points—1. The physiological constriction just below the pelvis of the kidney, about on a level of the lower pole of the kidney. 2. At the brim of the true pelvis where the ureter crosses the iliac vessels. 3. In the lower two inches of the ureter, near its point of entrance into the bladder wall. The author believes that incision on the stone in the ulcerated tissue is almost certain to result in some sloughing of the tissue, and that the already existing tendency to stricture is increased by the fact that suture further narrows the ureter, and that the sutures are likely to cut through with further sloughing. It is safer to incise the ureter one or two inches above the stone, then with suitable forceps passed into this opening withdraw the stone and extract it through the incision. Freedom of the ureter from obstruction is essential to success. This permeability may be ascertained by passing a small bougie à boule downward to the bladder and upward to the kidney. If stricture of the ureter is found it must be relieved either by the internal ureterotomy of Albarran or by some other method. The author's experience with inlying catheters in the ureter does not encourage the belief that their presence is not objectionable, as they undoubtedly favor infection. It has been the custom to put some drainage in the abdominal wound down to the point of suture in the ureter. In three recent cases of the author's, two of which were aseptic and one markedly infected, no drainage of any kind has been used, and the wound has been closed in layers including the skin.

Method of Staining Capsulated Bacteria.—W. H. Smith describes a new method of staining capsulated bacteria in body fluids, which he has found to bring more uniform results than any other method with which he is familiar.

Cancer of the Scrotum.—R. M. Green continues his historical study of this subject and reports seven cases that had been operated upon during the past twenty-five years in the Massachusetts General Hospital. It is interesting to note that all the patients were born in the British Isles and that two of them were spinners, though it is doubtful if these facts are of any etiologic significance. More important is the fact that in three cases there was a definite history of precedent trauma. Only accumulation of more extensive data would, however, justify conclusions on the subject. At present it seems that cancer of the scrotum, in its early stage at least, is one of the forms of superficial epithelioma for which radium treatment would be particularly suitable.

The Technique of Arthrotomy.—C. M. Painter and A. P. Cornwall conclude their series of papers on this subject. They describe the technique in arthrotomy of the hip joint and intracapsular fractures, excisions, and erasions. In their entire series of 198 patients operated upon there were eight per cent. of infections and a mortality of a little over two per cent. There has been improvement in their results as time has gone on and the use of urotropine as a routine in arthrotomies is destined, they believe to materially lessen the risks of infection. It is difficult to summarize the results of a series of arthrotomies performed for so many different conditions and where the results to be anticipated are of such a variable character. In the main, however, the results which it was sought to secure seem to have been attained in the large majority of instances with measurable success and the authors feel that arthrotomies may be undertaken for the relief of any of the conditions discussed in their paper without undue risk and that sufficient benefit will accrue to justify the performance of the operation. The technique, however, is one that should be perfected to such a degree that the liabilities of infecting a joint are reduced to a minimum.

Arsenic in Syphilis.—S. C. Runnels reviews the history of 606 and of the cacodylates.

Chemistry of Cancer.—S. P. Beebe states that within the past five years many chemical researches have been published dealing with such questions as the metabolism of cancer patients, the nature and properties of a possible cancer toxin or specific cancer poison, the nature and cause of cancer cachexia, the properties of the ferments in cancer tissue, and various studies dealing with the chemical characteristics of cancer tissue as compared with normal tissue. From observations extended over a period of some years he is convinced that extracts from sterile tumors given either subcutaneously, intravenously, or intraperitoneally are measurably more toxic per unit of nitrogen than extracts from fresh unautolized organs, but such results do not argue for a specific cancer toxin having a nature similar to the bacterial toxins. The metabolism studies which have been made do not materially add to the clinical observations in regard to the cause of cancer cachexia. From digestion experiments upon gelatin in which the proteolytic effect of the enzyme was measured with the help of the viscosimeter, Weil, working in the author's laboratory, has found that all tissues have some degree of proteolytic activity, but that this is with a cellular tumor quantitatively greater than with normal tissue. He is not prepared to say that this excessive proteolytic activity of the tumor may not be due to leucocytic infiltration.

Hot Air Treatment of Chancroid and Chancre.—E. W. Ruggles reports a second series of four cases in addition to the three previously reported, confirming the beneficial action of the hot air treatment of phagedenic ulcers. He describes a special oven that he has invented for the application of this mode of treatment.

Introduction of Gases into the Blood.—C. B. Fitzpatrick and J. P. Atkinson state that, according to the gen-

eral experience of investigators upon this subject, a dose (from 60 to 100 c.c.) of air given at one time, constitutes the usual fatal dose, causing death almost instantly. After a number of experiments with the previous introduction of glycerin or olive oil into the femoral vein, to prevent foaming or churning after the introduction of large quantities of air, the authors have found that the use of these substances is not necessary and they have obtained as good results without the use of olive oil or glycerin. The ability to introduce large quantities of oxygen into the circulatory apparatus can be readily used in treatment of disease in which oxygen is a therapeutic factor. Gas poisoning, drowning, anemia, blood poisoning, and similar diseases, which readily suggest themselves, are especially appropriate for this treatment. It has been noticed, for instance, that the symptoms of ether intoxication or poisoning, in the animals used for these experiments, have often been markedly relieved. In studying the mechanism of the retention, conveyance, and elimination of air by the vessels, they conclude that they have found evidence that the adrenals play a very important rôle in enabling the lungs and the circulatory apparatus to eliminate the air introduced. It is, moreover, apparent that if the air is eliminated by this means it is possible that it is carried in by the same means.

Clinical Statistics.—I. S. Wile believes that the compilation of a set of clinical statistics by the cooperation of physicians throughout the country would be of great value and would be a pronounced factor in determining the extent of morbidity in a definite group as contrasted with its mortality.

Treatment of Symptoms in Hospitals.—B. Robinson says that one of the sad, disheartening facts connected with hospital service, particularly medical, in his observation is the relative lack of interest by attending and house staff in the relief of painful or annoying symptoms of chronic disease. The diagnosis made and the prognosis determined, if cure seems impracticable, the patient does not always secure repeated, unwearying efforts to relieve symptoms, which are obligatory if the golden rule is followed in practice, as it should be. This lack of doing is doubtless explained by the too prevalent conviction that symptoms depend, of necessity almost, upon organic lesions, and if one cannot modify the lesions notably by treatment one cannot relieve symptoms. No greater, more lamentable, error exists. It is to this belief in part, among practitioners of reputation, that skepticism flourishes so largely and also quackery.

Improved Urethral Endoscope.—J. F. McCarthy describes his modification of the Luys' endoscope for observation of and operating in the anterior urethra.

Acute Myelogenous Leucemia.—J. A. Wolfer states that the diagnosis of acute leucemia necessitates more frequent blood examination, not counts alone, but examination of the stained specimen, for he is certain that quite a few patients go unrecognized and their death certificates are signed as some acute infection when the patient really succumbs to an acute leucemia. After diagnosticating the condition, it is necessary to study the case and try to establish an etiological factor. He would like to see the vaccine treatment more thoroughly tried.

The Prevention of Postoperative Exudates.—W. E. Dicken states that the exudates thrown out after surgical intervention are in exact ratio to the amount of tissue abrasion. Exudates may be mistaken for any kind of hard tumor in the neighborhood of the uterus. Inspissated exudates with broad attachments to the uterus may closely resemble subserous myomata. Inflammatory exudates differ from ordinary transudates in their higher specific gravity and their definitely increased amount of proteid matter; it is, however, in connection with serous surfaces that fibrin tends to form, and its formation in this region is associated with the breaking down of leucocytes. It is to this fibrin that one owes the plastic adhesions in serous cavities, and these adhesions play a most important part in limiting the spread and generalization of many bacterial inflammations. In operations one must avoid undue exposure to dry and cold air, mechanical trauma and bacterial infection. The author urges the importance of a proper technique, the appreciation of the significance of adhesions, and such care in operating that adhesions will not form again or will not originate *de novo*.

Esophageal Stenosis from Caustic Alkalies.—C. Jackson advocates the enaction of laws that will compel manufacturers to label as poisons the various corrosives that are employed in the kitchen. Considering the cosmopolitan character of the population, and especially of domestic servants, the caution label should be in many languages.

Widening of the Palatal Arch.—L. W. Dean reports a case which shows the beneficial effect of widening of the palatal arch. This causes widening of the nose throughout, the middle meatus being affected as well as the inferior.

A Head Support.—H. B. Smith describes an apparatus that he has devised for supporting the head and shoulders in cerebellar and high spinal operations.

Enteroptosis, its Etiology and Development.—R. R. Smith presents this subject, which was reported in MEDICAL RECORD, Vol. 77, page 1076.

Surgical Aspects of Enteroptosis.—A. J. Ochsner discusses this subject, which was reported in MEDICAL RECORD, Vol. 77, page 1076.

Enteroptosis—The Physician's Viewpoint.—J. H. Musser presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1076.

X-Ray Diagnosis of Enteroptosis.—E. H. Skinner deals with this phase of the subject, which was reported in MEDICAL RECORD, Vol. 77, page 1076.

Arthritis of Gastrointestinal Origin.—H. W. Marshall presents clinical data showing that the contents of the large intestine act as joint irritants, but says that there has been no special pathologic bacterium found to account for the toxins concerned. Whether the excessive development of non-pathogenic bacteria can produce the trouble is a question which he has sought to answer by the examination of the stools of arthritic patients. Patients with arthritis who respond to intestinal treatment exhibit luxuriant growths of intestinal bacteria, both the predominant *Bacillus coli* and also spore-forming anerobic bacteria. No new specific pathogenic microorganisms were found and a large majority of the spore-forming ones correspond to *Bacillus aerogenes capsulatus*. There are wide variations in the numbers of fecal bacteria in different individuals, and also at different times, so the number in any selected stool is not significant unless excessive. They are sometimes scanty in

arthritics because of purgation treatment, etc Patients with arthritis of other origins and also non-arthritic individuals may present identical appearances, lacking, however, the persistent excessive number of bacteria. Clinical data not here considered suggest that there is another type of arthritis existing in old age, independent of bacteria and due to defective digestion. Salient features of this type are its occurrence in old age and the existence simply of chronic dyspepsia in characteristic cases. In this type pronounced hypertrophy of bones occurs, which is absent in the bacterial type. To explain why some patients have intestinal arthritis and others do not, under the same conditions, he assumes a greater resistance of the latter in their joints. When arthritis occurs without any severe intestinal disturbances, if one is to assume an intestinal cause one must account for it by a greater joint susceptibility. Obscurity of origin is one of the prominent features of these intestinal cases, and, when no prominent etiologic factors are discovered daily colonic irrigations with general tonic treatment are advised for two or three weeks to ascertain the importance of the intestinal element in the etiology. The prognosis can hardly be made in chronic intestinal cases without a preliminary treatment test in many cases. The treatment is largely dietetic, together with antiseptic treatment of the intestines. The possibilities of constant reinfection must also be considered. The effects of mental depression are often underestimated in these cases. The only method of improving joint resistance is to increase the individual general health.

Formula for Milk Modification.—G. R. Moffitt publishes an elaborate mathematically calculated formula for milk modification in infant feeding.

Radical Cure of Malaria.—S. Harris presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1029.

Dietary Studies of School Children.—E. M. Sill, as the result of investigations made of the dietaries of undernourished school children of New York City, finds that all the dietaries studied could be improved as regards nutrition and expense. The bulk of the nourishment in the diets was obtained from meat, milk, and bread and rolls purchased from the bakery. It would have been better economy if they had bought the flour and baked the bread with the fire used for cooking other things. He remarks especially on the lack of proper instruction as to diet and cooking, and thinks it should be given in the schools for the benefit of future generations. For the education of mothers at the present time something can be done by lectures, cooking classes, etc., but more can be reached through large organizations as well as the press. Articles should be written setting forth, in simple language, proper diets, methods of cooking, proper nutrition, and the laws of growth. A great deal can be done by individual and group talks to mothers and children in the dispensaries. The nutrition of young children is especially important, for improper and unscientific feeding from the time of birth to maturity is one of the most fruitful causes, both directly and indirectly, of disease, disability, incapacity for work, susceptibility to infection and lack of resistance to disease already contracted. Many children who are put down as dullards are such through malnutrition and require nourishing food before they study books to feed the mind. Many families spend more than they can afford for food and yet are insufficiently nourished on account of their ignorance. When the income of the family is small, meat can be replaced to a large extent by corn meal, wheat flour and cereals in bulk, rice, oatmeal, dried beans, potatoes, whole milk and skim milk, which has a large nutritive value. A large variety of fresh vegetables is not necessary; one or two cheaper vegetables are sufficient. The cheaper cuts of beef contain more protein and fat with less waste than the more expensive ones. The cheapest source of protein is the cereals, next comes meat, and most expensive are fresh vegetables.

Miners' Consumption.—O. V. Huffman defines this term as one used by miners to designate emaciation associated with anemia, general weakness, shortness of breath, and, occasionally, palpitation. It is a layman's term for a general condition that may be due to a variety of causes. Impaired health is too prevalent among miners and the use of this term, miners' consumption, is so general among them that it merits the serious attention of the profession. It is not necessary to look far for causes of ill health among miners. Most mines and mining towns have no sanitation whatever. In the mine urine and feces are disposed of promiscuously. The house is situated almost anywhere, usually with the privy on the hillside above it and the well below. Since the families seem to thrive, however, one must look in the mines for causes Among the causes of ill health in the mines the author mentions the poisonous gases, ethane, methane, and carbon dioxide. When dynamite is used there is another source of poison. The inert matter with which the nitroglycerin is mixed is, with minute quantities of nitroglycerin itself, blown into the dust produced, and later is inhaled during the processes of shoveling, loading, etc. The poisons may also be absorbed through the skin. Hence the miner's headaches, palpitations, etc. It is important to have clean, well-ventilated mines. Filth hidden in darkness is no safer than anywhere else. Physicians in mining towns have no authority and it might come within the province of the new Government Bureau of Mines to make sanitary rules for both inside and outside of the mines. Some physicians jump to the conclusion that the miner has general pulmonary fibrosis (anthracosis). As a matter of fact, there is very little evidence of the implication of the respiratory tract in this way, much less, in fact, than in the coal handlers outside. Other physicians account for the miners' pallor by the lack of sunshine, but this is also fallacious.

Fatal Gunshot Wound.—A. F. Johnson reports a case of gunshot wound severing the popliteal artery, with death from hemorrhage.

Axis Traction Handle for Obstetric Forceps.—W. P. Megrail has devised a handle that can be attached to any obstetric forceps, making the latter a complete axis traction forceps.

India-Ink Method of Staining Spirocheta.—J. S. Barach states that this method, which was introduced by Burri, is open to objection. He has examined all the obtainable India inks, and has found in some of them the presence of spirochete-like objects which seem capable of assuming various shapes and sizes, and which may delude even the expert.

The Prospect Before the Medical Student of To-day. J. A. Lindsay.
Hereditary Cranio-Cleido-Dysostosis, with a Review of all the Published Cases of this Disease: Theories of the Development of the Clavicle Suggested by this Condition. D. C. L. Fitzwilliams.
Twenty Cases of Pulmonary Tuberculosis Treated by Continuous Antiseptic Inhalation. D. B. Lees.
On Fractures in the Neighborhood of Joints. R. Jones.
On the Use of Potassium Bichromate in the Treatment of Phthisis. J. B. Tombleson.
Two Cases of Compound Fracture with Tetanic Symptoms; Recovery after Injection of Antitetanic Serum. E. K. Williams.
Osteomyelitis of the Left Clavicle. A. MacDonald.
A Case of Uterus Bicornis Unicallis. J. L. M. Wood.

The Prospect Before the Medical Student of To-day.—J. A. Lindsay believes that medical education is at present in a state of flux, that the preliminary subjects of its curriculum must be shorn of much of their detail, must be taught with a due regard to the ultimate destiny of the student, which in nineteen cases out of twenty, at a moderate estimate, is to become a practitioner of medicine. The young graduate, if financial and other circum-

stances permit, should select an opening, whether a hospital or laboratory, that will enable him to continue his education. He should not submit to the early allurements of specialism. There are no great financial prizes in medicine, but the rewards are often substantial and fairly secure. Besides, medicine offers a work that is in touch with nature at first hand; law is man made; theology is trammeled by tradition; while medicine looks at the facts of nature as they are, is ever extending its borders, and is ever touching life at more points. Medicine is probably destined to take an ever increasing part in the work of social evolution.

Hereditary Cranio-Cleido-Dysostosis.—D. C. L. Fitzwilliams states that congenital defects of the clavicle occur and are usually associated with imperfect ossification of the cranial bones. Sixty cases have thus far been reported, including two by the author. The pathognomonic features are partial or complete failure of development of one or both clavicles, deficient and defective ossification of the bones forming the cranial vault, and sometimes a profound alteration in the skeleton of the face, the bones of which are said to be atrophied or undeveloped. This disease affects bones that develop in membrane. A great many opinions as to the cause of the condition have been advanced. Alcoholism, tuberculosis, syphilis, and rickets have all been advocated; but the accuracy of these opinions appears less and less probable with the growth of knowledge of the subject. The position that hereditary cranio-cleido-dysostosis bears to achondroplasia is helpful in enabling one to obtain an idea of the true nature of both these affections, the former being a condition of maldevelopment of the membrane bones, while the latter is a condition affecting the development of those bones which originate in cartilage.

Continuous Antiseptic Inhalation in Tuberculosis.—D. B. Lees reports good results from this mode of treatment, which he has described in a former paper.

Fractures in the Neighborhood of Joints.—R. Jones presents a brief outline of the methods and principles of treatment he has employed as the result of long practice in a manufacturing and mining district, where he had exceptional opportunities of seeing a very large number of injuries both immediately after the accident and at a later stage. Briefly, he pays more attention to function than to appearance, considers correct alignment of more importance than meticulous care in reposition of fragment, believes that pain is always an indication for physiological rest, and therefore deprecates early forced passive movements. If he prefers methods of manipulation and fixation in some cases where others of his colleagues would prefer an open operation, it is perhaps because for many years an increasing proportion of his work has been the treatment of deformities and disabilities, whether of traumatic origin or not, and he has thereby gained confidence in using powerful but carefully graduated force in cases where another would hesitate to do so.

Potassium Bichromate in Treatment of Phthisis.—J. B. Tombleson reports favorable results following the internal administration of potassium bichromate in phthisis. He employs this drug in doses of ¼ grain (2½ minims of a 10 per cent. solution in water) either alone or in a tonic mixture (phosphate, hypophosphite, or simple iron), such dose to be taken in a wineglass of water after food, at first twice and later three times a day. The first dose and possibly the second may cause vomiting, but this does not matter, as, in his experience, toleration is easily established without missing a dose. The color of some of the mixtures changes from yellow to green, but this seems in no way to impair their efficacy.

Compound Fracture with Tetanic Symptoms.—E. K. Williams reports two cases in which the early injection of antitetanic serum had a prophylactic action.

Osteomyelitis of the Left Clavicle.—A. MacDonald reports a fatal case of this condition in which the following points are of interest: 1. The misleading history. The fact that the mischief was left-sided suggested to one of the surgeons who saw the case that it might be a mediastinitis consequent to injury to the esophagus. 2. The absence of any reaction by the hemic system to combat the situation, inasmuch as the infection was widely disseminated, and there was no leucocytosis or glycogenic reaction, and (post mortem) there was no pus formation. 3. The fulminating character and, above all, the rarity of the lesion.

Uterus Bicornis Unicallis.—J. L. M. Wood details the history of a case of this condition in which pregnancy occurred in both horns of a bicornuate uterus. The left smaller horn had aborted, whilst the right horn retained a missed abortion.

Some Points Concerning Tubercle, Syphilis, and Malignant Disease. R. Morison.
The Röntgen Ray Appearances of Thoracic Aneurysm. A. C. Jordan.
Miner's Nystagmus. H. S. Elworthy.
On the Cause of Neuropathic States. G. R. Jeffrey.

Tubercle, Syphilis and Malignant Disease.—R. Morison states that the chronic inflammatory swellings produced by tubercle and syphilis have not infrequently been mistaken for malignant disease and *vice versa*. Hodgkin's disease, as yet ill understood, sometimes resembles tubercle, sometimes sarcoma, in its clinical course. Natural cure is the rule in syphilis, the exception in tubercle, and very rare in cancer. In all of them the cure of the local lesions is the result of fibrosis. These diseases may exist in combination with one another. That of syphilis and tubercle is a deadly combination. The author has seen cases in which tubercle attacked the lungs of a victim of secondary syphilis. In each instance the tubercle rapidly advanced to a fatal issue. The most disastrous form of "scrofula" is a combination of congenital syphilis and tubercle. Cancer and syphilis are very firm allies, and syphilis often provides a suitable site for the lodgement of cancer. If a person over 60 years of age contracts syphilis his death from cancer may be anticipated. Tubercle and cancer favor the same sort of soil. Persons who have recovered from tubercle in their youth are exceptionally liable to cancer in their later years. It is more than a coincidence that both occur in families with a history of some members having attained to an extraordinarily long life.

Röntgen Ray Appearances of Thoracic Aneurysm.—A. C. Jordan states that there are few cases of this condition in which *x*-ray examination does not clear up the diagnosis beyond possibility of doubt.

Miner's Nystagmus.—H. S. Elworthy states that this is a disease peculiar to coal miners, and that it is the absence of color that makes all the difference. The cause is fatigue of the eye resulting from working by artificial light with a black background and nearly black surroundings. Nystagmus seldom manifests itself until the miner has been working for some years. The first stage is latent. The first symptoms may be various. In some the lamps seem to move or become blurred; in others there is headache or pains in the eyes, or else everything becomes misty. The most constant symptoms are headache, giddiness, and movements. The two eyes may be unequally affected, or have different movements; one lateral, the other vertical or rotary. The importance of daylight seems to have been overlooked both by the miner and the employer. The author takes the view that, as far as nystagmus is concerned, working underground in daytime is a mistake, as the miner in doing so loses his opportunity of refreshing the eye by looking at colors in

daylight, and so, in a measure, compensating himself for working by artificial light without color relief.

The Cause of Neuropathic States.—G. R. Jeffrey states that at the meeting of the Societies of Neurology and Psychiatry, held in Paris one year ago, a remarkable difference of opinion upon the part played by the emotions in the genesis of neuropathic states was found to prevail among the eminent members who took part in the discussion. The whole discussion merely emphasized what the author had already maintained, that there is an inherited or acquired structural predisposition—an emotional diathesis. A more important point clinically is the determination of the actual extent of the lesion, whether it is reparable or not. About this one's knowledge is very scanty, and its further investigation is urgently needed. Taking the mechanism which he had suggested as the mode of origin of neuropathic states, definite indications for treatment necessarily follow. To ensure as complete rest as possible—that is, to ensure the absence of any fresh external stimuli—isolation is necessary. It is not only a means of husbanding the patient's resources, but it has also a certain psychotherapeutic value. To treat accompanying dyspepsias, constipation, sleeplessness, or other symptoms, complete rest in bed in the open air—combined with suitable diet—massage, with baths and electricity, are necessary to eliminate from the disease any accompanying autointoxication and malnutrition. The most favorable conditions for the nutrition of the nervous system of the neurasthenic are bodily health and mental rest. If after these conditions have been maintained for three months no considerable improvement has been made, the lesion is probably irreparable, and the only hope of amelioration would appear to lie in education, either by suggestion or other psychotherapeutic measures.

Berliner klinische Wochenschrift.

November 14, 1910.

Internal Secretion of the Generative Glands.—Munzer continues his monographic study of this subject. He devotes considerable space to the results of castration on the breast. In certain cases only do male castrates develop a female breast. On the other hand gynecomasty may be found in entire men. In regard to women, the older writers seem to have looked upon a certain amount of atrophy as constant after castration. More recent writers declare that in the majority of cases the breasts show no change. Sellheim has shown that mutation of sex in certain animals after castration is a fiction. Castrated hens do not act like cocks, nor do capons appear like hens. Similar observations might be multiplied for other animals. A change is usually in evidence in castrated domestic animals, but there is no real mutation in regard to sex. In other words, a castrate does not change its secondary sexual character. Naturally, castration in the very young tends to cause more extensive alterations in the latter. The periodical enlargement of the muscles of the male frog's upper extremity, which occurs at the breeding season, and enables the male to grasp the female more strongly, disappears after castration, but can be restored by grafts. Abolition of such periodical phenomena is, of course, very different from radical change in permanent secondary sexual qualities. Very early castration before development can but inhibit the appearance of certain of the latter. But this inhibition is associated more or less with universal subdevelopment. In other words, there is a genital infantilism. Möbius claims that in such cases sex cannot be recognized if the subjects cover the genital area. Such creatures are absolutely sexless. We are forced to conclude that the genital glands in reality preside over general growth and development. They cannot determine sex, which is purely a matter of inheritance. The vanishing of a periodical function like menstruation after castration is intelligible. Yet often a prolonged climacteric period succeeds, characterized by metrorrhagia, leucorrhea, etc. Fellner seems to have shown that the uterus possesses an autotoxic internal secretion, to which the lutein of the ovary is a natural antidote. By setting up menstruation it enables the uterus to be rid of its toxic material. The development of the ovary is responsible for puberty (menstruation), pregnancy, and the climacteric, as well as for the general development of the mature organism. Yet, as already stated, it does not determine sex itself.

Relation of Cancer of the Stomach to the Female Genital Organs.—Ernst Runge states that only recently has it become generally known that a relationship exists between the ovary and cancer of the stomach. When both organs are found to be cancerous at the same time it is sometimes difficult to decide as to which is the primary lesion and which the metastasis. But ovarian cancer occurs in large numbers without any lesion of the stomach; while the stomach is seldom the seat of a metastasis from other organs. Hence, the provisional conclusion that the stomach is the seat of the primary attack. The author fails to note that the rectum is often the seat of a metastasis from the cancerous stomach. The various theories as to how these simple metastases originate could surely be better discussed if the two sets of phenomena could be studied in common. Clinically the ovarian symptoms obscure the gastric symptoms, and the gastric cancer may be overlooked until revealed by the autopsy. The lesson to be learned in this connection is as follows: In women during the child-bearing cycle and especially in the later portion of the latter, symptoms which suggest a possible cancer of the ovary should lead the practitioner to examine the stomach, with special reference to chemical tests (absence of HCl). If cancer is diagnosticated there should be either a radical operation for removal or a temporary gastroenterostomy, according to the prognosis. The ovary should then be extirpated as soon as possible. No successful cases are cited. Incidentally the author remarks that cancer of the stomach is very rare in pregnancy.

Foreign Bodies in the Superior Mesenteric Vein.—The perforation of sharp substances through the digestive canal into contiguous structures is well known, as is also the occasional migration of such bodies when they do not set up local disease or become encysted. It has but seldom happened that these objects have penetrated into the large veins, and it is very difficult, if not impossible, to explain such a migration. Bends found at an autopsy that a piece of fish bone had penetrated into the superior mesenteric vein, causing thrombosis which extended into the portal vein, death resulting from thrombophlebitis. He can explain the event only by the supposition that the vein chanced to lie against that part of the intestine where the perforation occurred. Two similar cases are known to be on record. It must be borne in mind that the migrating power of a fishbone must be greatly inferior to that of a needle.

Münchener medizinische Wochenschrift.

November 15, 1910.

Arthropoda as Transmitters of Germ Diseases.—Under the term arthropoda are included by Müller crustaceans, protracheates, myriapoda, insects and their larvæ, and the arachnoids (the latter including ticks, etc.). As the part played by insects—flies, fleas, mosquitos, etc.—and the ticks in transmitting diseases is fairly well known, it should suffice to determine the rôle of members of other classes of arthropods. This is evidently a very insignificant one. The cyclopes, a lowly organized type of crab, are said to spread the guinea worm disease. Aside from this the most that can be said of crustaceans is that

the edible kind are sometimes poisonous, and that some myriapods have a poisonous bite, as do also many kinds of arachnoids. The protracheates are not mentioned in any way as causing disease. It seems somewhat disingenuous to drag in these orders of arthropods in this connection.

Trypsin in Surgical Tuberculosis.—Sohler gives a brief historical account of this subject with a good bibliography. As far as his own experience goes he has used the drug in conditions where it has been pronouncedly contraindicated, such as bone and joint abscesses and large burrowing abscesses. He has also taken pains to collect, in addition to his own experience, much of the unfavorable comment on trypsin, beginning with the time when it was first recommended for cancer. He formulates this combined experience into generalizations which tend to show that trypsin injections are painful, corrode sound tissue, and set up a toxemia. While he may have had such results from using the enzyme when it was contraindicated, it is hardly just to insinuate that these untoward results have been in any way constant. They have occurred only in a minority of cases, and these have certainly been offset by many beneficial results. A majority of injections has doubtless led to negative and harmless results.

The Ehrlich-Hata Remedy in Tabes and Paralysis.—Perhaps more interest is being taken in this subject than in any other aspect of this new kind of therapy. Both these affections may undergo spontaneous remissions, so that it is difficult to determine the influence of medication. It is also practically admitted that to be cured such cases must be treated in the formative period. Treupel has now treated twenty-one cases of tabes. He is able to assert that the pains are at first made much worse (as if from liberation of toxins), but in a few days they abate, while the patient gains weight. All the symptoms improve save those of the eye. The Wassermann reaction becomes negative in some cases. Unfortunately, this benefit lasts but a matter of weeks. The author does not mention second injections in this connection. In progressive paralysis the results are much inferior to those in tabes. Willige, in a second paper, states that he treats all recent cases of paralysis with an injection, which is almost invariably well borne, but which often causes a notable general reaction inside of twenty-four hours. The optic nerve never suffers. The Wassermann reaction was influenced favorably on the whole after the injection, but gradually returned to its original degree. Six cases showed marked improvement and three others improved so markedly that they seemed fit for discharge as cured. Willige made successive injections in these, and describes the improvement in detail. But, as the author admits, such cases of improvement or remission occur spontaneously, and as yet it is too early for differentiation. Among Willige's final conclusions are the following: We are as yet unable to determine with certainty the power of the new remedy over the metasyphilitic nervous affections. It may be that a certain natural tendency to remission is facilitated by the treatment. Points as yet unsettled are the dosage (size, repetition, etc.) and utility of combinations with other remedies. The influence of treatment on the Wassermann reaction cannot be determined. The new remedy does no harm in metasyphilitic nervous affections. Coincidence of diabetes is a contraindication. The author does not refer much to tabes because he thinks the remedy, on account of the tendency to optic nerve atrophy in this affection, constitutes a contraindication. He would therefore continue to treat tabes with the old antisyphilitics.

Deutsche medizinische Wochenschrift.

November 17, 1910.

Convulsions after Orthopedic Operations.—Codivilla concludes that the epileptiform convulsions which follow the various orthopedic operations on the lower extremity are not due to fat embolism, as has recently been alleged. In his opinion they are due to overtension of the reflex nervous arc, which in turn may disorder the higher nervous centers. It has been demonstrated that after certain repositions in the leg or foot the sciatic nerve is placed in a state of permanent tension. Convulsions are due in a measure to a neuropathic substratum. The author feels justified in submitting these patients to a bromide course before operating. He would do this in a merely nervous child as readily as in one who had always had convulsions.

Case of Traumatic Alexia.—Heiligtag sums up the symptoms of this case as follows: (1) Slight right homonymous contraction of the visual field. (2) Supersensitiveness of the labyrinth; disturbances of the equilibrium center. (3) Subcortical alexia (meaning inability to read letters and words and figures of over two places). (4) Traces of the injury to the head. The latter was represented by a scar over the right occiput, while on the left side there was a Y-shaped depression in the skull, evident also in an *x*-ray photo. The skin adhered to the bone. With exception of symptoms given above, the patient was found to be normal, including the nervous system. Investigation of the injury revealed that the patient nearly a year ago had suffered a complicated fracture of the left occiput, having a star shape, with penetration into the brain of spiculæ of bone. Patient unconscious for eight days, and sensorium not normal for fourteen days. He complained thereafter of headache and vertigo, and had convulsions several times. The fracture had been treated in the usual manner. Alexia appeared within a month, and had persisted until seen by the present author. Alexia occurring alone means a small circumscribed lesion. The reading center of the brain corresponds with the site of the lesion, and the latter evidently was seated in the gyrus angulatus.

Alimentotherapy of Diabetes Mellitus.—Graul writes this paper largely in the interest of von Noorden's oatmeal diet, which appears to have secured brilliant results at times, especially at the first appearance of acetonuria. The glycosuria should improve in the same degree as the acetonuria. In a certain percentage of cases prolonged oatmeal diet causes an increase in the glycosuria. The author then substitutes a strict diet of vegetables and vegetable albumin, which is efficacious against both glycosuria and acetonuria. Occasional fasting periods also improve the last-named condition. It is understood that the author is writing only of moderately severe diabetes, especially when associated with acetonuria. These cases should not be fed with large quantities of meats, fish, eggs, butter, etc., because such a diet produces a great strain on the already diseased organs and leads to such complications as nephritis and arteriosclerosis, and also tends further to the production of carbohydrate intolerance, the object of all plans of treatment being to preserve and restore tolerance to this class of foods.

Action of "606" on the Spirochetes Normally Present in the Mouth.—Gerber calls attention to the resemblances between the mouth-spirochete and the *Spirocheta pallida*, with especial reference to the identical behavior of the two when "606" has been injected. The mouth-spirochete is particularly in evidence in dirty and diseased mouths, but even in healthy and clean mouths they may be found about the necks of the teeth, on the back of the tongue, and in the tonsillar lacunæ. Thus far it appears that the remedy has been tested only on subjects in which both kinds of spirochete were known to be present. The mouth-spirochete seems to be somewhat more resistant to the remedy than the pallida. The author's few cases do not place his contention beyond the theoretical stage, but he hopes that systematic studies will be made of the mouth-spirochete.

Book Reviews.

The Medical Record Visiting List, or Physicians' Diary for 1911. New revised edition. New York: William Wood & Company, 1911.

This well-known visiting list contains about thirty pages of miscellaneous information, and the usual blank leaves for visiting list, consultations, engagements, addresses, cash account, and records of births, vaccinations, deaths, etc. The pages are well ruled and the paper is good. Those who have used this list in the past are sure to want the edition for 1911, and those who use this edition for the first time will be content with their choice. The book is useful, handy in size, and unusually attractive.

A Christmas Mystery. The Story of Three Wise Men. By William J. Locke. Illustrated by Blendon Campbell. New York: John Lane Company, 1910.

Christmastide is the season when all men should conspire, as far as is in them, to make new again the old, old story on which the feast is founded, to the end that our hearts shall not harden in indifference or greed. One way to make it new is the way Mr. Locke has taken in this arresting little story by going to the New Testament for his basic facts, and then clothing them in almost startling twentieth century dress. Christmas Eve three men, tired and wise with the wisdom of this world, a hovel, a mother, and a little newborn child, are once again the material from which a Christmas tale is woven, but the time is to-day and the wise men are our fellows. After a night of dreadful service to a dying mother, when "their watch was ended, they wrapped up the babe with precious care and carried him with them, an inalienable joy and possession, into the great world." We like to believe that they did. We like to believe, especially at Christmas time, that, as a dead poet has told us, "the angels *are* climbing Jacob's ladder, right between Heaven and Charing Cross," and we thank Mr. Locke for helping us to believe it.

Die durch Gonokokken verursachten Krankheiten des Mannes. Ihre medikamentose und chirurgische Behandlung. Von Dr. S. Baumgarten, Spezialarzt für Urologie und Chirurgie in Budapest. Wien und Leipzig: Alfred Hölder, 1910.

This book consists of 400 pages divided into forty-nine chapters in which gonorrhea and its different complications and sequelæ are considered from each viewpoint. The author has signally emphasized some important facts. For example: "Although through the gigantic progress in urology, our knowledge of the pathology and treatment of urethritis has materially broadened, we see even yet the majority of physicians accepting a visible discharge as sufficient diagnosis of gonorrhea, whereupon the patient receives a prescription for a syringe and a few dozen ancient formulæ, the result of which is left to pure chance." He writes in sufficient detail to satisfy the careful reader and the sections on treatment deserve praise in this respect. Much has been taken from contemporary works, but full credit is given and all is tempered with personal experience. Uranalysis and tests of cure are omitted; insufficient attention is accorded to stricture and the section on urinary fever is not modern, all of which detract from the value of the work. The eighty-eight cuts and illustrations are insufficient for a text of this size and these eighty-eight are below mediocrity. The arrangement of subject matter and the author's literary style are good. Throughout the work, more attention is devoted to medical than surgical treatment.

Diseases of the Colon and their Surgical Treatment. Founded on the Jacksonian Essay for 1909. By P. Lockhart Mummery, F. R. C. S., Eng., B. H., M. B., B. C., Cantab., Jacksonian Prizeman and late Hunterian Professor, Royal College of Surgeons; Senior Assistant Surgeon, St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum; and Senior Surgeon to Out-Patients, The Queen's Hospital for Children, London. Illustrated by colored and other plates, and numerous figures in the text, many of which are reproduced from the author's sketches. New York: William Wood and Company, 1910.

Within recent years improved methods of diagnosis have been the means of adding considerably to the knowledge of diseases of the colon, which subject has assumed such importance as not only to warrant but also to necessitate the preparation of a special book dealing with it. In this instance the want has been amply supplied. This book includes all that modern research and experience have contributed to our knowledge of the colon and its diseases. These have been becoming more frequent, owing to the modern diet of prepared foods containing little or no waste residue, and this, together with a sedentary occupation, fails to furnish the normal stimuli to peristalsis and digestion. The earlier chapters are devoted to the anatomy and physiology of the colon both in health and disease. The results of the latest investigations by Cannon and Hertz upon peristalsis and antiperistalsis are given in detail. The difficult subject of diagnosis is thoroughly discussed. The technique of sigmoidoscopy is lucidly presented; as is also the subject of the use of the *x*-ray. Special attention is paid to the effect of adhesions and to chronic constipation and obstruction in their various forms. Colitis, pericolitis, and cancer are fully covered. An entire chapter is devoted to Weir's operation of appendicostomy and valvular cecostomy. The numerous illustrations are of a high order of artistic merit. In this as in other respects the work represents the best of the bookmaker's art.

Nahrungsmitteltabelle zur Ausarbeitung und Berechnung von Diätverordnungen. Für Krankenhaus und Praxis. Von Dr. Herman Schall und Dr. August Heisler. Zweite, bedeutend vermehrte Auflage. Würzburg (Curt Kabitzsch): A. Stuber's Verlag, 1910.

The nature and scope of this set of tables are sufficiently indicated by its title. In addition to the data relative to the various foodstuffs useful information is given concerning the metabolic activities of the body, its caloric requirements under different conditions, etc. A marginal index adds to the convenience of the work for rapid reference.

Dyspepsia, its Varieties and Treatment. By W. Soltau Fenwick, M. D., Lond., Doctor of Medicine of the University of Strassburg; late Physician to the Evelina Hospital for Sick Children. Philadelphia and London: W. B. Saunders Company, 1910.

There are few diseases that present such confusing problems to the general practitioner, and none that he is called upon more frequently to treat than those included under the indefinite group, dyspepsia. For this reason a work such as this, bearing the genuine seal of scholarship, cannot fail to be helpful. Written in a fascinating style, this book covers the subject with a lucidity that is equalled only by its thoroughness. At the outset the fact is emphasized that "a disturbance of digestion in the stomach itself is rarely due to a primary disorder of that viscus, but is usually a consequence of serious disease of another and perhaps remotely situated organ of the body. The truth of this apparent paradox will be appreciated when it is remembered that the majority of the secretory, motorial, and inflammatory affections of the stomach result from the failure of some other organ to execute its proper functions." In the first chapter there is presented a short scheme for the clinical differentiation of the various forms of dyspepsia. One of the most interesting chapters is that which deals with the relationship of latent disease of the appendix, gallstones, and duodenal ulcer to gastric hypersecretion. The long continuation of the latter is apt to induce severe gastritis accompanied by numerous erosions of the mucous membrane, which sometimes occasion severe hemorrhages. The recurrent attacks of hematemesis and melena, as well as the symptoms of indigestion, disappear with the removal of the diseased appendix. The author devotes to the subject of displacements a space commensurate with its importance. The varieties of dyspepsia that appear during infancy and old age are given special prominence. The entire work is based upon the examination and treatment of 18,000 cases, while statistical investigations were confined to 1,000 examples of the complaint.

A Textbook on the Therapeutic Action of Light, including the Rho rays, solar and violet rays, electric arc light, the light cabinet. By Corydon Eugene Rogers, M.D., formerly Demonstrator of Anatomy in the University of New York City. New York: Published by the Author, 1910.

The excuse for this book appears to lie in the author's desire to exploit the uses of a new form of incandescent electric light, emitting what he claims to have discovered as the "Rho" rays. Whatever virtues these may possess are more than negatived by the extravagant assertions that they may cure nearly every morbid condition to which the body is subject, including diphtheria, tuberculosis, and pneumonia. The scientific uselessness of this book is closely paralleled by its literary and typographical inaccuracies, including the misspelling of the author's name upon the title-page.

The Practical Medicine Series. Under the general editorial charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School; Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Gynecology. Edited by Emilius C. Dudley, A.M., M.D., Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago; and C von Bachellé, M.S., M.D., Assistant Professor of Obstetrics, Chicago Polyclinic and College of Physicians and Surgeons; Gynecologist to the German Hospital, Chicago. Series, 1910. Chicago: The Year Book Publishers.

This book is divided into six parts, dealing respectively with General Principles, Infectious and Allied Disorders, Malformations and Tumors, Traumatism, Displacements, and Disorders of Menstruation, Sterility. The book is valuable and makes interesting and instructive reading.

Introduction to the Analysis of Drugs and Medicines. An Elementary Handbook for the Beginner. By Burt E. Nelson, Laboratory of the Binghamton State Hospital, and of Nelson and Lauder, Binghamton, N. Y.; Chemist to the New York State Hospitals, the Department of Health, Board of Water Commissioners, Etc. First edition. New York: John Wiley & Sons; London: Chapman & Hall, Limited; 1910.

While the practitioner is, as a rule, not especially interested in the analytical methods used for determining unknown drugs, except such as give color reactions when excreted directly in the urine, the results of such analysis are of the greatest importance to him, not only in the diagnosis of obscure cases of poisoning, but also in connection with the standardization of alkaloidal tinctures and fluid extracts. The first portion of the book is given up to general analytical methods, descriptions of apparatus, and a discussion of some of the more important qualitative and quantitative tests for inorganic substances. A chapter on ultimate organic analysis is followed by a long section on the analysis of medicines, both microscopical and chemical. There is also an extremely valuable table for systematic analysis of drugs, giving many useful points for the isolation and the identification of the pure substances. There are tables of melting points, of boiling points, and of physical and chemical constants of fats and oils, and, finally, a collection of the physiological actions of some of the commoner drugs. The volume should prove useful in the laboratory of every chemist and hospital worker who is interested in or required to do drug analysis. If any criticism were warranted it would be that the writer has attempted a little too much in a short space, and that some of the descriptions are not sufficiently detailed to allow any one but an expert to carry out the procedures. It is also unwise to tell a beginner in the laboratory to hold a non-luminous flame to an escaping jet of air and gasoline vapor. Something unexpected might occur.

A Manual of Operative Surgery. By Sir Frederick Treves, Bart., G.C.V.O., C.B., LL.D., F.R.C.S., Sergeant-Surgeon to H. M. the King, Surgeon-in-Ordinary to H. R. H. the Prince of Wales, Consulting Surgeon to the London Hospital; and Jonathan Hutchinson, F.R.C.S., Surgeon to the London Hospital. New (3rd) edition, revised and rewritten. In two octavo volumes. Volume II, 820 pages, with 302 engravings, and 8 full-page plates. Philadelphia and New York: Lea & Febiger, 1910.

The recent appearance of the second volume of this important work affords to American readers a complete and satisfactory record of the teaching of two of the most eminent British surgeons. Mr. A. J. Walton has also taken a part in the production of the present edition and his contribution is concerned with the revision of the chapters on operations on the skull and brain and also that on the middle ear, mastoid, etc. The subject of tendon suture and grafting has likewise been contributed by the same writer. In addition the present volume also includes a description of the surgery of the thorax, breast, arteries, veins, nerves, amputations, bones, and joints. Notwithstanding the great advances which have been made in the surgery of the brain, the authors are not favorably impressed with its applications to the removal of brain tumors, and consider that operative treatment is only justifiable where the locality can be accurately determined and the symptoms are such as to point to the tumor being small in size; if it can be readily reached and more especially if it has been in the motor area, and finally if its symptoms are such as would lead one to believe that it is a fibroma or localized sarcoma. The other tumors in the majority of cases are but poorly differentiated from the brain tissue and thus are not readily removable. The text of the book is in general fairly complete, but one of the omissions noted is an absence of any reference in the chapter on thoracic operations to the procedures rendered possible by the agency of the pneumatic cabinet, which has been developed by Sauerbruch and others. A number of excellent color plates have been introduced, but many of the remaining illustrations in the text are distinguished neither for execution nor novelty. The printed text and the general make-up of the volume are, however, excellent.

Atlas der bösartigen Geschwülste. Von Prof. Dr. D. V. Hansemann, Geh. Medizinairat. Mit 27 lithographierten Tafeln. Berlin: Verlag von August Hirschwald, 1910.

It is always a matter of regret that the American publisher is prevented by the high cost of labor from issuing at a reasonable price such beautifully illustrated volumes as this Atlas of von Hansemann's, which would be of great value to students and practitioners, but is now limited to those who can read German. The plates are very satisfactory, illustrating well all of the ordinary types of tumors, even though they do not perhaps reach the perfection of the lithographs in Borst's famous tumor book. From some of the diagnoses appended to the pictures one may be inclined to disagree, but they represent van Hansemann's well-known views on the classification of certain tumors. In addition to the twenty-seven full-page colored plates there is a short discussion of the methods of preparing thin sections for immediate diagnosis and a running commentary on the different types of tumors pictured. The importance of using paraffin embedding for diagnostic sections is properly insisted upon, and the dangers of employing frozen sections for hasty diagnosis, especially by inexperienced persons, are quite rightly emphasized. All in all it is a very satisfactory work.

Nursing in Diseases of the Eye, Ear, Nose, and Throat. By the Committee on Nurses of the Manhattan Eye, Ear, and Throat Hospital. J. Edward Giles, M.D., Surgeon in the Eye Department; Arthur B. Duel, M. D., Surgeon in the Ear Department; Harmon Smith, M. D., Surgeon in the Throat Department; Assisted by John R. Shannon, M. D., Assistant Surgeon in the Eye Department; John R. Page, M. D., Assistant Surgeon in the Ear Department; With chapters by Herbert E. Wilcox, M. D., Assistant Physician to the Hospital; Eugenia D. Ayers, Superintendent of Nurses. Philadelphia and London: W. B. Saunders Company, 1910.

This book is intended as a textbook for the nurses in the Training School of the Manhattan Eye, Ear, and Throat Hospital; it will, doubtless, serve a useful purpose in other similar institutions. The authors have kept in mind that the book is intended for nurses and not for physicians, and have endeavored not to go beyond the capacity of the best educated nurses. The illustrations are well chosen, and the book can be recommended to the nursing profession.

Operative Surgery for Students and Practitioners. By John J. McGrath, M. D., Professor of Operative Surgery at the New York Post-Graduate Medical School; Consulting Surgeon to the New York Foundling Hospital; Visiting Surgeon to the Harlem and Columbus Hospitals; Fellow of the New York Academy of Medicine; Member of the American Medical Association, etc. Third Revised Edition, with 276 Illustrations, including many full-page plates in color and half-tone. Philadelphia: F. A. Davis Company, Publishers, 1909.

The entire section on abdominal surgery in this edition has been re-written and much new matter has been added. A book such as this, covering ground that is covered by many similar books, derives its value largely from the manner in which the author arranges his material, from the clearness with which he sets forth what he has to say, and from the judgment which he uses in selecting the best from among a multiplicity of operations. All three of these conditions Dr. McGrath has met with the average amount of success. One may question the wisdom of devoting only 19 pages to the chapter on "General Considerations," and will question also the correctness of the author's advice to provide free drainage after resecting a tuberculous joint. There seems to be in the book an atmosphere of hurry—a lack of completeness. No mention is made, for instance, of the injection of nerve trunks in amputations. On the other hand, the value of a book like this to the man who practices surgery occasionally and because he is compelled to is manifest.

Society Reports.

PHILADELPHIA PEDIATRIC SOCIETY.

Stated Meeting, Held November 8, 1910.

DR. CHARLES A. FIFE OF PHILADELPHIA AND DR. ELI LONG OF NEW YORK IN THE CHAIR.

THE Philadelphia Pediatric Society held a joint meeting with the Section on Pediatrics, New York Academy of Medicine. The discussion of the papers was limited to members of the Section on Pediatrics of the New York Academy of Medicine. Following this meeting an informal smoker was given at the Hotel Rittenhouse.

The Symptoms, Management, and Treatment of Nasal Diphtheria.—Dr. EDWIN E. GRAHAM of Philadelphia read this paper. He said that it was important to remember that the Klebs-Loeffler bacillus might produce only the slightest irritation and discharge, with no membrane present, or it might produce the most intense inflammation with swelling and edema so extensive as to more or less completely block the nares. The amount of contagion was usually in direct proportion to the amount of discharge from the nose and nasopharynx. Diphtheria might be spread from a case in which there was little or no discharge present and yet the bacilli might be demonstrated to be present in the nose. Such cases were often the focus from which epidemics had their origin; they were a great menace to the community. If the bacilli were found for more than a reasonable time it was quite possible that they were not virulent and a guinea-pig should be inoculated to test their virulence. It was often extremely difficult to distinguish between the true and pseudodiphtheritic bacillus; therefore, inoculations in guinea-pigs should be made more often. After considering the symptoms of the mild, moderate and severe cases of nasal diphtheria, Dr. Graham stated that the membrane which appeared in the nose in most cases of scarlet fever and measles was not commonly diphtheritic, especially if it occurred early in the disease; if it occurred later in the course of these diseases then it was often diphtheritic. The occurrence of albumin in the urine was suggestive of diphtheria. In a doubtful case, in a child with a nasal discharge which persisted, a single negative culture was not positive proof that the case was not diphtheritic. With regard to the report of return cases, he believed that future investigation would conclusively prove that they occurred more often than was generally believed. He asked if one was warranted in sending such cases out without inoculating guinea-pig to test the virulence of the bacilli. There was no doubt in his mind but that all such cases with diphtheria bacilli in the nose, all clinical evidences of the disease having disappeared, were possible sources of danger. Cultures should be taken from all children exposed to the disease; those showing the bacilli should be appropriately treated. It was unwise to admit into a hospital ward or institution any child who had a membrane in the nose or had a nasal discharge, unless a bacteriological examination showed the absence of the diphtheria bacilli. All visitors entering a children's ward should wear a sterilized cap and gown. All children who had been exposed to diphtheria should receive an immunizing dose of antitoxin. Physicians and nurses should always wear cap and gown when in the sick rooms; all nasal discharges should be destroyed, and antiseptic gargles and sprays should be used frequently by all coming in contact with the patients. Where the discharge was abundant and the nasopharynx was more or less blocked with secretions, these parts should be kept clean with warm, mild antiseptic solutions. The fluid entering a nostril should escape from the opposite nostril and the mouth and, for this purpose, a fountain syringe was better than a piston syringe. This irrigation should be employed once in four hours. In case of nasal hemorrhage, irrigation should be discontinued. The earlier antitoxin was given in a case of nasal diphtheria the better. In the case of an infant one should not wait until the diagnosis was confirmed by a bacteriological examination. To postpone the early use of antitoxin in a case of profuse nasal discharge, when there was a membrane present, he considered inexcusable. Should anaphylaxis influence in any degree the giving of antitoxin? Much literature had been accumulated on the theories, phenomena, lesions, and mode of death in anaphylaxis in the lower animals, but one had difficulty in finding much in the literature regarding the serious results of anaphylaxis in man. Ker of Edinburgh advised caution in the administration of antitoxin in the treatment of relapses. Data given by Funk from the Municipal Hospital in Philadelphia showed that the children in the scarlet fever and diphtheria hospitals were given one or more doses of antitoxin, and the curative doses were large ones. Rashes, joint pains, and slight febrile disturbances were occasionally seen; yet no symptoms of a serious nature were ever observed. The concentrated serum was safer inasmuch as a smaller measure by quantity was required. A conservative and safe method consisted in giving a small initial dose of antitoxin, about the usual immunizing dose, in all cases where a previous injection of antitoxin had been administered. If no immediate reaction was observed, it was safe in a few hours to administer the remedy in appropriate doses. If the case showed an immediate reaction, it was immune to the administration of the larger doses, which might be given with safety.

DR. ROWLAND G. FREEMAN of New York said that although anaphylaxis was a real danger he thought this fact should modify the use of antitoxin only by inducing one to use a very large initial dose, and so, if possible, avoid the danger which would exist in the administration of subsequent doses. Should there, however, be any indication for a subsequent dose the danger of anaphylaxis was so small in comparison to the danger of diphtheria that it should not in any way modify one's conduct. The occurrence of this phenomenon was certainly extraordinarily rare. The speaker could not recall a single case in his experience when such a reaction had occurred, although he mentioned two cases of infants who had received between 40,000 and 45,000 units in repeated doses with no bad reactions.

DR. MATTHIAS NICOLL, JR., said that the subject of Dr Graham's paper was one of great importance. He had not the slightest doubt that one of the chief reasons why, notwithstanding a very general use of antitoxin as an immunizing agent, little progress was being made in decreasing the number of cases of diphtheria, which statistics showed remained approximately the same year after year, was due, first, to non-recognition of many cases of more or less chronic nasal diphtheria, and, second, to inefficient quarantine of convalescents from the disease. It was not generally recognized how severe a case of nasal diphtheria might be, and very often was. The average practitioner was very apt to regard it as a mild infection generally running a sub-acute or chronic course. In infants and very young children, and especially when occurring as a complication of scarlet fever and measles, it was a very severe and frequently fatal disease, only a little less to be dreaded than the laryngeal form of diphtheria. He recalled four young children in adjoining beds convalescing from scarlet fever, all of whom succumbed to nasal diphtheria, which went on to sepsis or bronchopneumonia. Dr. Nicoll was thoroughly in accord with Dr. Graham's statement that antitoxin should be given in full doses as soon as nasal diphtheria was suspected without awaiting the result of cultures. With regard to local treatment, the piston sy-

ringe should be dispensed with, for it was liable to force infectious material into the Eustachian tubes and set up ear complications. He preferred the ordinary fountain syringe used under low pressure. For this operation the patient should be thoroughly wrapped up from shoulders to feet in a sheet, firmly pinned in place. A few drams of the solution should be introduced at first to remove the accumulated inflammatory products, and the patient then given a moment's breaching spell, after which the irrigation was to be continued until the nasal passages were free. By this method, practised every three hours if necessary, the detached diphtheritic plugs were very satisfactorily removed, as well as the accumulated mucopurulent material, which if left undisturbed served as a nidus for the growth of complicating organisms. Normal salt solution answered every purpose, and was to be preferred to the use of strong antiseptics. Dr. Nicoll showed photographs of how patients were wrapped at the Willard Parker Hospital, and the method of irrigation as there practised, together with specimens of typical nasal plugs removed in this way.

Dr. B. van D. Hedges of Plainfield, N. J., said that they were beginning to recognize in diphtheria much the same conditions as existed in typhoid fever; they had the diphtheria carriers as they had the typhoid carriers. The cases of nasal diphtheria were in a large measure responsible for epidemics of diphtheria, because they were so often unrecognized. In Plainfield they recently had a mild outbreak of diphtheria in one of the public schools. At the suggestion of the Board of Health, the school physician took cultures from all the supposedly well children and found one case of postnasal diphtheria which in all probability had been responsible for the spread of the disease. No doubt many outbreaks might be traced to such a cause.

Dr. Thomas S. Southworth of New York spoke of enlarged cervical glands as a symptom of nasal diphtheria. He thought this was a sign of considerable value, especially when the discharge from the nose was not very noticeable. He recalled such a case which came to him, undiagnosed, for autopsy a few years ago; in this particular case the membrane was in the nasopharynx largely, and not visible in the pharynx. It extended back in the nose and down to the level of the soft palate. This impressed him with the importance of enlargement of the cervical glands; wherever one found enlarged glands in the neck without apparent cause he believed it was worth while to examine the nasal secretion for the presence of the Klebs-Loeffler bacilli. Among the common types of nasal diphtheria was that seen in small children, the marantic children, in which there appeared a slight bloody discharge from the nares. This was a common type in the institutions with which he was connected in New York, and it was a type that frequently was overlooked by the house staff. Dr. Southworth said he could pick these cases out in children who were often not supposed to be sick. When he saw a chocolate colored discharge from the nose, if it was not due to some foreign body, it was almost invariably due to the Klebs-Loeffler bacilli. In many of these cases irrigation of the nose was not as applicable or productive of as good results as in the larger children. A mixture of much value in these cases consisted of stearate of zinc suspended in albolene; this made a cream that was very healing. It was often surprising how rapidly the discharge disappeared and with it, for some reason, the Klebs-Loeffler bacilli as well.

Dr. L. E. La Fétra of New York asked Dr. Graham what they did with those chronic cases of nasal diphtheria occurring in institutions in whose cultures there were found non-virulent diphtheria bacilli. Did they consider that such bacilli could become virulent in other children? Were these children allowed to run around the hospital with the diphtheria bacilli in their nose?

Dr. Edwin E. Graham of Philadelphia, replying, said that in those cases where repeated examination of the nasal discharge had shown the presence of the Klebs-Loeffler bacilli, but where the inoculation in guinea-pigs had shown these bacilli to be non-virulent, he always considered it legitimate to allow such children to go home and mix with other children. That was the policy he had followed.

Some Anatomical Features of the Child's Heart and Their Practical Application in Physical Diagnosis.—Dr. George Fetterolf and Dr. J. Claxton Gittings of Philadelphia presented this paper. Their work had consisted in making sections and dissections of the bodies of infants which had been injected with ten per cent. formalin solution and then frozen. It was found that the thymus gland was of greater size and extent than was usually recognized; in places it touched the trachea. Sudden death would result if the gland became even moderately enlarged. Delay in involution would extend the danger period. The upper median portion was deeply indented posteriorly by the left innominate vein, which lay immediately on the anterior surface of the trachea. Any increase in venous pressure might cause compression of the trachea by this vein, the latter being braced anteriorly by the thymus. This was a possible explanation of death of the young during anesthesia. If there was any truth in this theory, venesection would be indicated in such an emergency. The horizontal position of the heart in infancy was well exemplified; the heart occupied a large amount of space, reaching, at its greatest depth, from the sternum to the vertebræ. Bronchial breathing posteriorly in cases of enlargement of the heart or pericardium was easily explained by the pressure on the left lung. The right auricle lay directly in front of the right half of the left auricle but did not touch the chest wall. The appendix was the only portion which did. The blood from the inferior vena cava was directed upwards by the Eustachian valve and not to the left, as was commonly supposed. The foramen ovale lay in an almost horizontal plane, and was not vertical. The tricuspid orifice was practically vertical, and opened to the left and slightly forward. The bottom of the right ventricle was nearly on a level with that of the right auricle, and gravity played little if any part in the passing of the blood through the tricuspid orifice. The right ventricle constituted practically all of the heart which touched the anterior chest wall, and was slightly overlapped on each side by the right and left lungs. Posteriorly it was bounded by two structures, the left ventricle below and the root of the aorta above. The aortic sounds, therefore, at the level of the second costal cartilage must be heard through the medium of the conus arteriosus. The left auricle was a horizontal cylinder, lying at the extreme back of the heart and extending throughout the entire width of the base of the heart. The right end of the left auricle lay directly behind the right auricle; the left end behind the left ventricle. The mitral orifice lay in a plane approximately parallel to the anterior facies of the vertebral column at this level. The mitral and tricuspid orifices, therefore, lay in planes which were almost at right angles to each other. The arch of the aorta passed almost directly backward, and not from right to left. Pressure upon the greater azygos vein by a dilated heart was impossible; whereas pressure upon the pulmonary veins, especially the right, could occur with even moderate degrees of enlargement. This explained in large part the hydrothorax and pulmonary congestion which were seen in many cases of enlarged heart without signs of stasis in the systemic circuit. The relatively loud sound of the closure of the pulmonic valves in children as compared with the aortic might be due to the persistence of the thymus, as well as to the fact that the upper lobe of the

left lung did not cover the pulmonary artery. More important, however, was the difference in tension. From a correct conception of the position of the heart *in vivo* they drew conclusions as to the pathological anatomy in case of enlargement. Increase in size to the left would be due mainly to enlargement of the left ventricle; to the left and upward mainly to the left auricular appendix, and to a slight extent the left auricle; to the left and downward to the left and right ventricles. Enlargement to the right would involve mainly the right auricle and appendix, and to a lesser extent the right ventricle and the right end of the left auricle. The mitral, tricuspid, and aortic orifices and valves were practically contiguous structures, readily explaining the difficulty in distinguishing the murmurs produced in cases of double or triple lesions or leakage. The difference in physical signs over the right and left apices of the lungs was due to the fact that the trachea and right apex were contiguous structures. On the left side they were separated by the aorta, left carotid and subclavian arteries, esophagus, areolar and lymphoid tissue. The bronchial lymph nodes at the bifurcation of the trachea were situated above the heart, so that there was no good conducting medium through which bruits could be transmitted to the chest wall. The persistence of the thymus, which could exert pressure on the vessels as they arose from the arch of the aorta, might explain the bruit heard over the upper sternum with the head extended. Surrounded as were the bronchial glands by structures which would give a dull note, it seemed highly problematical that enlargement of the glands could be diagnosed by percussion. The sections afforded a clear demonstration of the position of the lobes of the lungs and emphasized the fact that physical signs in the lungs posteriorly, as high as the spine of the scapula, were produced in the lower lobes. Anteriorly, on the right, the fourth rib divided the upper from the middle lobe, while on the left any signs heard above the heart and in front of the anterior axillary line would denote that the upper lobe was affected.

Dr. David Bovaird, Jr., of New York said that the demonstration made by Dr. Fetterolf showed clearly that the curriculum in the medical colleges needed a new course of instruction. They were familiar with applied surgery, but what they now needed was a course in medical anatomy. He was delighted at having the privilege of seeing such splendid preparations. It was impossible to cover all the points brought out in this demonstration, but Dr. Bovaird said he would venture upon two. First, the relationship of the thymus gland to the innominate vein had been made very clear; it showed that the most direct effect of any enlargement of this gland must necessarily be pressure upon the left innominate vein. This was a vexed question that had been much discussed; if one accepted the mechanical theory of the effects of enlarged thymus gland, implying pressure upon the left innominate vein, one naturally would look for cyanosis, but cyanosis was absent. Cyanosis was almost always absent in the clinical conditions associated with enlargement of the thymus gland, and especially in the cases of sudden death. Secondly, he was interested in the demonstration of the relationship between the chambers of the heart, the left lower lobe of the lung and the pulmonary veins, pressure upon which might cause hydrothorax. The demonstration had been very helpful in clearing up points that had been very obscure, and especially helpful in explaining the effects of pericardial effusion in children. He was particularly interested in the physical signs at the base of the left lung when pericardial effusion in children was present. He had been much puzzled in following the physical signs which were interpreted to be the result of pressure upon the left lower lobe of the lung to find that they were often gradually replaced by the signs of fluid in the left pleura. The use of the aspirating needle under such conditions often showed that one had to deal with a case of hydrothorax upon the left side, the pressure upon the pulmonary veins having gradually led to serious effusion into the plural sac. These facts were clearly explained by the demonstration made. There were a great many other interesting points in the demonstration which he said he would like to touch upon, but time did not permit. They all were certainly indebted to Dr. Feterolf and to Dr. Gittings for their presentation of the subject.

Dr. Godfrey R. Piser of New York said that those who were engaged in teaching physical diagnosis to students should be specially indebted to the readers of the paper; it was worth while to come to Philadelphia to see such a demonstration. There were many anatomical variations brought out that were worthy of notice; for example, the relation of the lobes of the lung to the thoracic structures and to the chest wall. Some time ago he had occasion to need absolute and reliable information on this point and he had a great deal of difficulty in finding it; in fact, he had to study the body itself to get the data he needed. A little patient of his was to undergo a negative pressure thoracic operation and the data he obtained proved to be of great assistance to the operator. Therefore, he felt that he would go away tonight with a great deal of information and with many facts to study. He asked Dr. Fetterolf whether he found that these relations which he had described held true for older children, those of two and five years of age?

Dr. L. E. La Fétra of New York said that a beautiful demonstration had been given them of the relation of the heart to the chest wall and the occupancy of most of the chest by the heart anteroposteriorly. This explained what they saw in young children when evidences of dullness were obtained by deep percussion over the left side of the back. With regard to the early signs of pericarditis, was it the enlarged right auricle which gave the dullness in the fourth and fifth interspace? The demonstration showed that the dullness in the fourth right interspace was accounted for by the presence of the right auricle. This was a point that was very valuable, especially to those who were teaching students, as it confirmed the statement of Lee that the normal right auricle could be made out by percussion in this situation, and that when engorged it produced dullness in the third or even in the second right interspace.

The Frequency and Significance of Albumin in the Urine of Normal Children.—Drs. S. McC. Hamill and K. D. Blackfan presented this paper. The object in carrying out this study was to secure some definite knowledge as to the frequency of occurrence of albumin in apparently normal children and to see if there was any associated condition which might account for its occurrence. Their results showed that 28 of 124 children had occasional casts associated with cylindroids and 6 had cylindroids without casts. An albuminous body precipitated by acetic acid in the cold was associated with the casts in the majority of instances, and serumalbumin in quantities varying from a very slight trace to a trace was associated in five instances. In the 124 children albumin was found 110 times or in 88.7 per cent. Thirty-four children or 27.4 per cent. showed serumalbumin almost always associated with the so-called nucleoalbumin; 106 or 85.4 per cent. showed nucleoalbumin, in 30 instances in association with serumalbumin. The authors were inclined to believe from their experience with certain groups of cases, in which their examinations had included twenty-four-hour specimens and had been conducted over prolonged periods, that the percentage of these albumins present in the urines of normal children was much greater than these figures indicate. They did not find any associated conditions to account for the presence of the albumin, and they concluded

that the so-called nucleoalbumin was probably frequently present in the urine of every child and that it was of no clinical significance in the amounts in which they found it and that the serumalbumin present in the amounts indicated, even when associated with occasional casts and cylindroids, the product of a temporarily overtaxed kidney, resulting from variations in the habits of life of the individual which were often too slight to be recognized.

Dr. Henry Dwight Chapin of New York said that the paper read by Dr. Hamill was of very great value as confirming perhaps the opinion of some of those present, although they had not had such exact proof as he had given. Some years ago he made a study of infants with bodily disturbances which were followed by the presence of albumin and casts in the urine. Eighty-six pulmonary cases were next studied; they varied from a very mild to a very severe form of bronchitis and pneumonia; forty-nine of these showed a trace of albumin in the urine; thirty-two showed both albumin and casts. He then took a series of forty-five cases of general illness, none of them being selected; of these thirty-one showed the presence of albumin in the urine. It seemed to him that so far as infants were concerned any bodily disturbance might throw down albumin and casts; this had no significance in the prognosis or treatment; it was simply due, in his opinion, to some irritation to the renal tubules and was without any significance. The series of cases reported by Dr. Hamill were cases in health; whereas the ones he had studied were ill. Dr. Hamill's paper he considered a very valuable one and one that should be read at one's leisure.

Dr. John Howland of New York said that the studies presented by the readers of the paper were both of practical and theoretical interest; they showed plainly that albumin could be present in the urine of perfectly healthy children. They all realized that albumin, with or without casts, could be present in the urine from time to time, and that this did not necessarily mean nephritis. However, very valuable information could be obtained from a careful observation of these cases. Under ordinary circumstances one could not attach very much importance to the occasional presence of albumin in the urine. After diphtheria or scarlet fever, however, the presence of albumin in the urine might give them considerable concern. The theoretical interest attached to the question whether there might not be instances of alimentary albuminuria. It was possible to produce, as they well knew, an alimentary albuminuria in man or the lower animals by feeding with excessive quantities of albumin. Merlin was able to show the presence of a gelatinuria when gelatine was fed to dogs in large quantities; also that when white of egg was fed in large quantities this appeared in the urine. Others had been unable to determine the character of the albumin that appeared because chemical methods failed. Gideon Wells attempted to show it with experiments, but could get no evidence of the presence of any albumin but serumalbumin. It was presumable that the permeability of the intestines and kidneys in children was far greater than in adults. This was shown in experiments carried out with bacteria. The observations of Wile were interesting in that they showed that starch granules could be absorbed from the healthy mucous membrane of the intestine, traverse three sets of capillaries and then be excreted in the urine. Hecker had attempted to prove the presence of foreign proteins excreted in the urine of children with albuminuria; he used the precipitin test. He obtained a precipitate with the serum of an animal immune to the beef protein in about 25 per cent. of his cases. What he did, however, could not be accepted as conclusive evidence. It showed that albumin might be absorbed from the intestine and excreted by the kidneys. In this connection Dr. Howland thought it would be interesting to learn if such cases as Dr. Hamill had investigated could be prevented by a temporary diet containing no milk, eggs or meat.

Dr. Floyd M. Crandall of New York said that the paper read was one of great importance and was in line with what he had felt, that traces of albumin in the urine of children, as a rule, meant very little. He was surprised, however, at the frequency of such findings in investigations so accurate and so closely observed. They must prove of great value to the practitioner in interpreting conditions seen in everyday work.

Dr. Ward Bryant Hoag of New York wished to voice the sentiments already advanced, that there was an immense amount of work manifested in the papers presented. The work of Dr. Hamill was most interesting, but it brought up certain vital questions. How did one know that a patient having albumin in the urine had it left over as the sequel of a previous unrecognized acute nephritis? Having albumin as a sequel of an acute unrecognized nephritis, what were the possibilities of another acute attack? Admitting the possibilities of the above first question, could they pronounce these patients "normal?" He reported a case in point. A boy born in the tropics suffered almost constantly because of malaria. He came to New York City when about six years of age, when Dr. Hoag first saw him. At that time he apparently was a healthy child. He was given a pair of roller skates and became over-heated and sat down on the sidewalk. After a week or so Dr. Hoag was called in to see him and found him edematous from head to foot with a large amount of albumin in the urine. Whether this was an acute attack the result of the inordinate use of the roller skates, and exposure, or an exacerbation of an old nephritis contracted at the time of his malarial infection, he could not say. However, the nephritis all cleared up except for a trace of albumin. Now the boy was ten years of age, but there was remaining a distinct trace of albumin in his urine. There were no casts or epithelium, other than squamous, present; the question was, what were the possibilities in regard to this boy's future? Was this trace of albumin, together with his history, a menace to his future? What would happen if at the end of ten or fifteen years he applied for life insurance? Would he be accepted as a good risk? To-day he apparently was perfectly healthy, robust and active. But was he normal?

Dr. Elias H. Bartley of Brooklyn said that these examinations of the urine of children were certainly very helpful to them; they frequently had occasion to examine the urine of children and frequently they found albumin present. The finding of a trace of albumin in the urine he regarded as having no pathological significance; it often appeared after active play of children, after exposure to cold, etc. With regard to the nucleoalbumin Dr. Bartley said he had always regarded that as a normal constituent of the urine of both children and adults; this was a normal secretion from the epithelial cells of most of the mucous membranes. What was called mucus in the urine was present in almost all urines and contained practically no mucin. Therefore the term mucus was rather misleading and confusing. The term now generally employed was "mucoid substance" and this was made up of nucleoalbumin. Nucleoalbumin was almost always present in the urine in traces, and very often in quantities large enough to be precipitated by 50 per cent. acetic acid. The slightest irritation of the mucous membrane or of the epithelial cells lining the kidney tubules, such as by a strongly acid urine, or crystals or uric acid or oxalate of lime, would produce this. There was no constant relation between the presence of casts and albumin in these cases. The casts as a rule were hyaline and not granular. They should regard the latter as positive evidence of a disintegration of the kidney structures with a granular deposit

in the hyaline material. Hyaline casts alone were of little significance, being of little more significance than cylindroids. It was very difficult to distinguish between cylindroids and hyaline casts. Therefore, he believed that the presence of cylindroids, a few hyaline casts and traces of albumin in the urine of children should be regarded as the result of a slight irritation of the tubular epithelium, and they were of no other significance.

A Case of Rabies.—Drs. Alfred Hand, Jr., C. Y. White, and John Reichel of Philadelphia reported this case. A girl, five years of age, was bitten on the face by a mad dog; the wounds were cauterized and healed promptly. Seventeen days later she developed fever, became restless and excited and three days later was admitted to the Children's Hospital. Meningitis was excluded by lumbar puncture and there were no signs of pneumonia, typhoid fever, or endocarditis. The temperature was 105° until a few hours before death, when it rose to 109.4°. The pulse ranged from 180 to 200. The case illustrated the susceptibility of childhood to rabies, the shortness of the period of incubation when the face or hands were bitten, because of the nerve supply, the extension of the virus being along the nerve trunks and the symptoms appearing when the central nervous system was reached. Three stages of the disease were described, which were more or less sharply defined: the premonitory, with restlessness, moderate fever, and sensory disturbances in the scar; the excited stage, with high fever, attacks of mania intermitting with periods when the patient was rational, painful spasms of the laryngeal and pharyngeal muscles and the emission of strange sounds; the paralytic, with stupor deepening into coma. The autopsy in the case reported showed only secondary changes such as cloudy swelling in the liver and kidneys and moderate congestion of the lungs. The meninges showed no exudate and cultures were sterile. Smear preparations from the cerebellum showed Negri bodies in the cells of Purkinje. An emulsion of the cerebellum injected into two rabbits was followed by the death of one twenty-five days later, the Negri bodies being easily demonstrated in the hippocampus major.

Pathological Society of Philadelphia.

At a stated meeting held September 22 Dr. F. D. Weidman presented a specimen of "Aberrant Pancreas in Capsule of the Spleen." The condition was discovered incidentally in the course of a complete histological study of the tissues from the body of a woman dead of septic endometritis. At autopsy a nodule was found that was thought to be a supernumerary spleen, and this as well as tissue within the substance of the spleen was found to contain acini and islands of Langerhans. Such deposits have been found in parts of the wall of the intestine, but this is the first recorded instance of deposition in the spleen. The condition is attributed to the inclusion of remains of germ cells. Dr. D. B. Pfeiffer exhibited a specimen of "Mixed Tumor of the Breast." The tissue was obtained from a woman 73 years old who presented a freely movable tumor of the breast, without involvement of the nipple or invasion of adjacent glands, and thought to be nonmalignant. After ablation of the breast the growth was found to present typical appearances of sarcoma. Recurrence in the regional lymphatic glands taking place, these were removed at a later date, but they were found to present typical appearances of carcinoma. Reexamination of the original growth now disclosed appearances of sarcoma in some situations and of carcinoma in others. Dr. D. J. McCorthy presented a specimen of "Pachymeningitis Hæmorrhagica Interna Complicating Fracture of the Skull." The patient had been a man with a history of alcoholic excess and of a fall some time previously. Toward the last there developed symptoms of Korsakoff's disease. Death took place suddenly from acute dilatation of the heart, and autopsy disclosed an unsuspected extensive fracture of the base of the skull, principally on the left side, with the remains of a pachymeningitis and a leptomeningitis on the right side, and a recent hemorrhagic pachymeningitis on the left side. Dr. D. B. Pfeiffer presented a communication entitled "Mixed Tumors of the Kidney." He reported two cases in infants, one with a growth involving the kidney and obtained after death, and the other with a growth in the region of the kidney and removed surgically. The first contained striped muscle tissue in addition to other structures, while the second contained a miscellaneous collection of tissue. These growths are perhaps to be explained as representing the inclusion of two or more varieties of undifferentiated germ cells.

College of Physicians of Philadelphia.

At a stated meeting held November 2 Dr. S. Weir Mitchell presented a communication entitled "Concerning Nervous Disturbances Following Surgical Operations and Anesthesias." He pointed out that there were to be considered disorders of the mind as well as neurasthenic states either developed or made manifest in the sequence of surgical intervention. Several factors are operative in this connection. Among these are the operation itself, with the resulting traumatism and loss of blood, and shock and the effect of the anesthetic. Some patients experience relief from preexisting nervous symptoms for a time following the operation, in a proportion of instances, however, with subsequent return. Dr. James G. Mumford read a paper entitled "Postoperative Psychoses." From a study of a number of cases operated on seven or eight years previously he found that in a certain proportion nervous disorders were presented that could be attributed to several influences, including functional loss, the sense of deprivation of a part, the withdrawal of an internal secretion. Experimental observation has shown that anesthesia and surgical operation are attended with definite cellular changes in the nervous system. Dr. J. Chalmers Da Costa read a paper entitled "The Diagnosis of the Postoperative Psychoses." He considered the several forms of mental disorder observed following operations, as well as the factors concerned in their development, and he dilated at considerable length on their differential diagnosis. Septic infection is an important etiologic factor, as also are fear and fright. Postoperative insanity is comparable to puerperal insanity. Dr. E. N. Brush of Towson, Md., discussed "Postoperative Insanities." He pointed out that there is no type of mental disorder distinctively a sequel of surgical operation. Heredity is the most significant etiologic factor. Infection and intoxication also are to be considered in this connection. Sometimes of course the mental phenomena are only exaggerations of a previously existing conditions. The discussion was continued by Drs. Howard A. Kelly, Edward Martin, Francis X. Dercum, John K. Mitchell and Chas. K. Mills.

Digestive Troubles and Epileptic Crises.—A. Rodiet gives observations on one hundred women at the Saint-Yvon Asylum. Often diarrhea or constipation is noted at the time of the convulsion. Of ten epileptics seven had digestive troubles preceding the attacks. The menstrual period is also favorable to the occurrence of the attack. In some cases the patients fail in appetite for from one to three days before the crisis. The symptoms noted most frequently in the author's cases were painful digestion, retarded salivation, constipation, and diarrhea, acute dilatations of the stomach, gastrointestinal atony, and urine rich in skatol and indican show the presence of gastrointestinal autointoxication in connection with the attacks. These poisons acting on a predisposed organism cause the crises. If these symptoms are lessened the attacks will also be decreased in number.—*Le Progrès Medical.*

THE EHRLICH-HATA PREPARATION, No. 606.*

BY M. S. KAKELS, M.D.,

NEW YORK,

ADJUNCT SURGEON, LEBANON HOSPITAL.

WHILE for hundreds of years many believed the doctrine that infectious diseases might be caused by microorganisms, only during the latter part of the last century did Pasteur and Koch, by their scientific investigations, prove the etiology of many of these diseases and thus through their researches opened up new fields in therapy. The aim of therapeutists was to introduce into the system some chemical or organic substance which would be fatal to microorganisms without at the same time harming the tissues and organs of the body.

For some considerable time Prof. Paul Ehrlich of Frankfort directed his efforts toward arresting the growth of bacteria in the body, destroying them or neutralizing their toxins, by some chemical substance simpler than the antibodies generated in the system. In other words, he endeavored to produce an artificially constructed chemical antitoxin. After repeated systematic and carefully planned experiments he succeeded in producing several chemical substances which have a special affinity for microorganisms, destroying them without at the same time affecting the tissues and organs of the host. These antitoxic substances, because affecting the parasites and not the organs and tissues of the host, are called parasitotropic.

If with the introduction of a single dose of a certain amount of a substance into the system of an animal suffering from an infectious disease it is possible to annihilate completely the microorganisms causing the disease, without seriously injuring the tissues or organs of the animal, an epoch-making discovery has been made and an ideal remedy obtained—a "therapia sterilisaus magna," as Ehrlich designates it.

Ehrlich has already succeeded in producing a number of chemical substances which have a specific action on certain microorganisms in the body. Of these chemical substances atoxyl, arsacetin, and arsenophenylglycin are best known. It was especially the specific effect of the last mentioned (arsenophenylglycin "418") on the trypanosome the cause of sleeping sickness and its wonderful effect on the spirochetes in syphilitic apes, that tempted the trial of this substance on luetic paralytics and led to the test of its influence on the intensity of Wassermann's reaction. Accordingly, Prof. Konrad Alt (*Münch. med. Woch.*, 1910, lvii, p. 561) of Uchtspringe made some practical investigations with this remedy (418) on paralytic idiots and epileptics who gave a previous history of syphilitic infection, and obtained excellent results, although certain unpleasant complications resulted from the injections; congestion of the face, a rise of temperature, restlessness, motor irritation, and slight paralysis of the lower extremities, a scarlatinaform eruption, without desquamation or renal effects were some of the unpleasant symptoms that followed. A permanent lesion never resulted. Of 140 cases treated with arsenophenylglycin none exhibited optic nerve or renal disturbance, complications which usually followed the use of atoxyl and arsacetin.

Because of these nerve and renal disturbances following their use, atoxyl and arsacetin have now been discarded. In witness of the specific effect of a single concentrated dose of arsenophenylglycin, a number (16.6 per cent.) of the patients with a previous history of syphilitic infection and who exhibited a positive Wassermann reaction before the injection, showed a permanent negative reaction thereafter. In 27.3 per cent. of the patients the reaction gradually became weaker. In some paralytics and epileptics the clinical symptoms improved rapidly. The drug influenced the lecethin metabolism and produced a leucocytosis.

Alt says that "in a large number of cases a rapid, astonishing, and lasting improvement followed." "It will require years of observation and many more tests for a positive assurance of a permanent effect."

By far superior, being more certain and more potent in its action and with less after effects than any of the above-mentioned preparations, is the Ehrlich-Hata "606" preparation. A new arsenic preparation, a derivative of arsenobenzol prepared by Dr. Bertheim, a coworker, in Ehrlich's laboratory. This preparation, $C_{12}H_{12}O_2N_2As_2$ 2 (HCl), a synthetic product, is a dioxydiamido arsenobenzol dihydrochloride and produced according to the following chemical formula:

It is made from the benzol ring, C_6H_6, by synthesis replacing an atom of hydrogen by a variety of chemical molecules thus

C_6H_6 Benzol,

$C_6H_5 - As = As - C_6H_5$ Arsenobenzol.

$OH - C_6H_4 - As = As - C_6H_4 - OH$
Dioxyarsenobenzol,

$OH \quad\quad OH$
$>C_6H_2 - As = As - C_6H_3<$
$NH_2 \quad\quad NH_2$
Dioxydiamidoarsenobenzol,

or

$C_{12}H_{12}O_2N_2As_2$ = Pure dioxydiamidoarsenobenzol.

By adding 2 molecules of HCl we have

$C_{12}H_{12}O_2N_2As_2$ 2 HCl, a salt dioxydiamidoarsenobenzol dihydrochloride.

As Dr. Hata, an assistant in Ehrlich's laboratory, conducted the animal experiments with this new

*Read before the Medical Society of the Borough of Bronx, November 9, 1910.

remedy under Ehrlich's supervision, and in order to simplify the long chemical name it was called Ehrlich-Hata preparation 606. The 606 denoting the 606th preparation produced.

With this new preparation relapsing fever in rats and mice was cured with a single injection; syphilis in rabbits and apes was also cured. Julius Iversen of St. Petersburg, in the fall of 1909 (*Münch. med. Woch.*, April 12, 1910, No. xv), injected this substance into fifty-two patients suffering from relapsing fever in whom the spirilla of Obermeier were found in the blood. In every one of these patients, after a single injection of 606, the spirilla disappeared from the blood and a critical drop in the temperature took place. The disappearance of the spirilla took place within 4 to 10 hours, never to return again. In other words, in 92 per cent. of the cases there was no return of the fever and the patients were permanently cured of their infection by a single dose. Aside from the pain at the site of the injection, no bad effects were observed in the optic nerve, kidney, or other organs of the body. He says that "in 606 we have a remedy which with mathematical precision is capable of annihilating the microorganisms in the living blood of patients suffering from relapsing fever without affecting the host, and which by its wonderful results proves it to be in fact a 'therapia sterilisans magna.'"

Ehrlich and Hata found that while arsenophenylglycin (418) had more affinity for the trypanosome of sleeping sickness, 606 or dioxydiamidoarsenobenzol exhibited essentially more affinity for the spirilla and spirochetes. After Ehrlich and Hata had studied the results on syphilitic infected rabbits and apes and had made its wonderful effects known, Prof. Alt and Dr. Hoppe in the fall of 1909 conducted investigations for the purpose of studying the therapeutic effects of this new preparation on human beings suffering from syphilis. Before trying it on patients two physicians voluntarily subjected themselves to the injection of 606 for experimental purposes. Excepting severe pain and a swelling over the injected area no untoward toxic symptoms followed its use. The pain following the injection was so severe in some of the earlier cases that morphine was required to relieve the suffering.

Some little skill and time were required in the preparation of the powder for hypodermic or intramuscular injections and an analgesic was added in order to mitigate the severe pain at the site of introduction. The pain was found to be due to the alkalinity of the solution, which in the first experiments was prepared as follows: 0.3 gm. of the yellow powder was mixed with 10 c.c. of sterile water, then enough sterile normal hydroxide of soda solution was added until only the least quantity of the powder remained undissolved (this requires from 2 to 3 c.c. of NaOH). Then more sterile water is added to make 20 c.c. Of this mixture 10 c.c. is slowly injected in each gluteus muscle. The pain following this injection lasts sometimes twenty-four hours, and is very excruciating at times. Although abscess never developed, a slight rise of temperature was noticed. No albumin or sugar ever appeared in the urine. Hoppe and Fischer of Uchtspringe found that the elimination of arsenic from the system after the injection of 606 was slower than when atoxyl, arsacetin, or arsenophenylglycin were used. This is an important point, for it meant a longer time in the system and, therefore, more continuous action on the spirochetes.

The pain of the injection was a great objection. 606 is an acid salt, not free from poisonous effects and is not suitable for subcutaneous use, even in small doses, in the acid solution, as it is poisonous and not safe, for it influences the action of the heart unfavorably. In a superalkaline state 606 is soluble and in this strongly alkaline state it was injected by Alt, Schreiber, and Iversen, but the injection was always attended with severe pain. It was then found that the more neutral the solution the less likely would local irritation arise.

L. Michaelis (*Berl. klin. Woch.*, July 25, 1910), in order to mitigate the pain of the injection, tried to introduce the preparation into the system in a neutral state, but as the substance in a neutral state is not soluble, the injection could only be made with the greater part of 606 in suspension. He found that if an aqueous solution of the dihydrochloride of 606 is simply neutralized by the addition of normal NaOH the substance is precipitated in lumps and irregular masses; if next the substance is dissolved with an overabundance of normal NaOH and then neutralized with an acid, the precipitate falls in a very fine powder, instead of masses and lumps, which is easily held in suspension and easily adapted for injection. Prepared in this way he is convinced that this mixture produces less disagreeable subjective symptoms than the strongly alkaline injection.

It was shown that the clinical results follow more quickly with intravenous injections of the preparation, and as no pain is experienced when used in this manner it was thought to be more advantageous. Schreiber of Magdeburg, and Hoppe of Uchtspringe (*Berl. klin. Woch.*, Aug. 1, 1910), prepared the solution for intravenous injection in the following manner:

In a graduated cylinder of 200 c.c. capacity, with a narrow neck and ground glass stopper, are placed 10 to 20 c.c. of sterile water, then 0.3 to 0.5 gram of 606 is put in and a few drops (0.3 c.c.) of methyl alcohol* added and well shaken until a clear solution is obtained. To this solution for each 0.1 gram of 606 used about 1.0 c.c. normal NaOH is now added and then enough 0.8 per cent. NaCl solution is poured in till the fluid reaches the line 180 on the graduated cylinder. This is again vigorously shaken for some time until a clear solution results. Should it not become clear after some time, one can then cautiously add a few more drops of normal NaOH solution and then finally fill the graduated cylinder to the 200 c.c. marked line with NaCl solution. This solution if carefully prepared is clear; it is then poured into a beaker glass from which it can easily be drawn into a syringe. The intravenous injection, though painless, is followed by chill, vomiting, and fever, and as the arsenic is more quickly eliminated from the system by this method its effects are not so lasting. On account of these objections W. Wechselman (*Deutch. med. Woch.*, Aug. 11, 1910) prefers to give 606 subcutaneously and prepared in a modified form from that made by Michaelis. 606 with 1-2 c.c. of commercial soda solution is dissolved in a mortar; if then drop by drop glacial acetic acid is added a fine yellowish paste is precipitated. This precipitate is dissolved in from 1-2 c.c. of distilled water and neutralized by the addition of 0.1 normal soda solution or 1 per cent. acetic acid, according to a carefully ascertained reaction with litmus paper. This gives about

*As the substance in its present form is more readily soluble in water, the addition of methyl alcohol is not necessary.

Results of Treatment with the Ehrlich-Hata Preparation.

8 to 10 c.c., which is injected midway between the scapula and spine, after previous disinfection of the skin.

Schreiber of Magdeburg (*Münch. med. Woch.*, July 5, 1910), Henerich Loeb of Mannheim (*Münch. med. Woch.*, July 26, 1910) have also prepared the substance with methods akin to that of Wechselman, but their injections were always painful.

An improved method of preparing the substance and one which is not followed by any lasting pain, the method I used in my first two cases, is the one which Michaelis has now modified and prefers to the one he first used. It is as follows: 25 c.c. of water, which has just been boiled and is still hot, is poured into a wide-mouthed glass receptacle of 50 c.c. capacity. Then 0.6 gm. of 606 is dropped into the water and dissolved by rubbing and constantly stirring with a glass rod. When all of the substance has been dissolved 6 c.c. of normal hydroxide of soda solution is added until the resulting precipitate is fully dissolved. Now 3 drops of ½ per cent. alcoholic solution of phenolphthalein is added, which turns the liquid red. We then add normal acetic acid until, with constant stirring, the reaction is neutral, as is evidenced by the discoloration of the phenolphthalein. The resulting neutral liquid holds the preparation in suspension and is of a light yellow color. Then in order to prevent a possible acid reaction, normal hydroxide of soda is again added drop by drop until a very faint red color of the phenolphthalein reappears. This fluid is now poured into a sterile flat receptacle, from which it can easily be aspirated into a syringe and then is injected subcutaneously between the scapulæ.

Michaelis claims that as long as such brilliant results have followed the intragluteal injection of the neutral suspension of 606, where the injected fluid remains as in a storehouse, he prefers this storehouse method to that of the intravenous injection. The substance was heretofore injected into the glutei muscles. After several trials of the injection into the subcutaneous tissues without any severe local irritation, he uses this method now regularly. Sometimes for several hours some little pain is felt but soon disappears under hydropathic treatment. Michaelis observed that occasionally on the third day patients again experienced a severe but evanescent pain, though accompanied without any sign of inflammation. In the first two cases injected by me with this method the pain was insignificant and elicited little complaint. If injected into the gluteus the large and lasting infiltrate (probably a fibrosis caused by the caustic action of the sodium hydrate) impedes walking and sitting. This is obviated by injecting it into the interscapular region. By massaging the skin over the site of injection, the fluid is distributed over a large area and the large surface which the mass offers plays an important rolê in the rapidity with which absorption can take place. I, too, have found this a most convenient place for the introduction of the substance, and the massaging of the surface seems to me a good procedure.

My attention was called by Dr. Meltzer to a modification in the technique of injecting 606 which he suggested, and which I used in several cases with gratifying results. Drs. Meltzer and Auer found that if adrenalin is injected into the lumbar muscles of animals, absorption takes place much quicker than when injected into the gluteus muscle, as was evidenced by the sudden rise in the blood pressure. Furthermore in observations made by Dr. Meltzer with 606 on man he found that the injection into the lumbar muscles gave very little pain and caused no other trouble.

For the injection into the lumbar muscles, one grasps the skin and inserts the needle of the syringe (the best syringe for this purpose is the "Record" syringe of 20 c.c. capacity) about one inch above the crest of the ileum until we reach the resistance offered by the tense fascia over the ileocostal muscles, and then slant the same and push it further into the muscle headward parallel to its fibers and then slowly inject the solution. The patient lies on the stomach with a sand bag under him in order to bring the lumbar muscles more prominently forward. This is a great improvement in injecting the substance, as patients experience hardly any pain whatsoever.

A quicker and simpler method of preparing the preparation is that described by Alt (*Münch. med. Woch.*, Aug. 23, 1910), although the resulting fluid is slightly alkaline. He places about 30 to 35 small glass beads into a slender, graduated glass cylinder with a narrow neck and ground glass stopper of about 100 c.c. capacity, and pours in 10 c.c. of distilled water and then the preparation. By energetic shaking for a short time all of the substance will be completely dissolved. To this solution, in order to make it alkaline, we add for each 0.1 gm. of 606, 0.5 c.c. of normal hydroxide of soda solution and shake again energetically for about one-half minute. There results a clear, yellow-colored, slightly alkaline solution which can be diluted by the further addition of distilled water. As the preparation is not always equally soluble it may be necessary, in order to obtain the clear effect, to add a little more or less of the hydroxide of soda. One sees that this preparation requires less normal hydroxide of soda solution and for this reason is more advantageous as it gives less pain when injected in this slightly alkaline state.

Alt believes an alkaline solution of the preparation prepared by the cautious addition of normal NaOH to be the best and most effectual, and at the same time least poisonous. Before coming to this conclusion he and his coworkers made many experiments on animals and human beings, in order to determine what form of solution and what method of incorporation of the substance into the system was least dangerous and at the same time most effectual. The addition of alcohol, the use of phenolphthalein as an indicator, a superalkaline solution of the substance and retitrating with acid, acid solutions, suspensions, etc., were all tried and discarded. He particularly states that the introduction of an acid solution was given up because it produced poisonous symptoms. Even in small doses it had an unfavorable influence on the heart's action.

In a neutral or not sufficiently alkaline solution the action is not as effectual because in this state too little of the substance reaches the circulation. Therefore, from his experiments and experience he came to the conclusion that only an alkaline solution obtained by the cautious addition of normal NaOH solution was the best and most highly to be recommended. From the great number of cases he as well as others have used it in, this alkaline solution, if properly prepared, seems to produce less pain than when other forms of solution are used. Prepared in this way a smaller quantity of fluid is used and a smaller induration follows. This is of special advantage in injecting into children.

I must say this method of preparing the substance appeals to me. It is much more rapidly prepared, and what is of great advantage, less difficult than the other methods, while at the same time is exact and requires less paraphernalia.

In two children, one of nine years and the other of twelve years, both suffering from syphilitic interstitial keratitis, this method was used; both experienced very little pain for the first twenty-four hours, which soon disappeared, however; the swelling was of little consequence and gave no inconvenience.

Kromeyer (*Berl. klin. Woch.*, Sept. 12, 1910) used a 10 per cent. emulsion of the preparation in liquid paraffin. He takes 3 gm. of 606 and rubs it up in a sterile mortar with a small quantity of liquid paraffin and gradually adds more paraffin until it is evenly and finely mixed. It is then poured into a glass stoppered bottle of 50 c.c. capacity, and more liquid paraffin added until it reaches the 30 c.c. mark. Each cubic centimeter (1 c.c.) of the emulsion contains 0.1 of 606. This emulsion must be well shaken before using. It must be kept from the light. A very large cannula must be used and it must be injected very slowly. For an institution where large quantities are used, perhaps the preparing of a large amount in this manner may be of advantage. But for obvious reasons for the general practitioner it has its drawbacks.

Up to date the amount of 606 which has been injected has varied according to the different reports of different clinicians. Some have had excellent results with a single dose of 0.3 gm., while others believe that 0.4, 0.5, 0.6, or even 0.8 gm. should be used.

Ehrlich believes that for every kilo of weight of the body 0.005 gm. should be used and for the present would be a good rule to be guided by. Thus for a patient weighing 60 kilos, or 120 lb., $60 \times 0.005 = 0.3$ gm., or about 5 grains, would be sufficient. Clinicians who have used this remedy agree that 0.3 gm. should be the minimum amount injected into an adult. The preparation being so powerful and containing about one-third arsenic, care must be exercised in increasing the dose. It is not an indifferent remedy and in certain cases may be attended with some danger. Only the accumulated experience of many practitioners, and after the remedy has had a fair trial in hundreds of cases, will we be able to settle upon the exact dosage for individual cases. Some claim that the earlier the syphilis the larger the dose required, 0.4-0.5 gm., while 0.3 gm. is ample in the late stages. Severe cases seemed to react with the same degree of certainty when only 0.3 gm. were injected as when larger doses were used. My two first cases of late and severe forms responded wonderfully well to 0.3 gm. doses.

From the accumulated reports already published one cannot dispute the fact that by a single dose of the preparation desperate and seemingly hopeless cases not only can be saved but have been saved and their health restored in a very short time. There may be occasionally a case where the spirochetes are not entirely annihilated by a single dose; such may eventually require a second injection; but thus far, of the thousand cases injected very few have been reported in which a second injection was required.

Prof. Ehrlich, in a circular letter dated October 25, 1910, states that the permanent effect depends upon the size of the dose and the method of application, also on the nature of the disease. He states that the intravenous method is better adapted and more intense and quicker for a complete sterilization or annihilation of the spirochetes.

The application is simple and in selected cases without danger and more agreeable for the patient. Alt and Schreiber give as a minimum amount intravenously, 0.3 gm., but more often 0.4 or 0.5 gm. while others give larger amounts, 0.7-0.8 gm. Iversen gives an intramuscular injection, 0.3-0.5 gm. two to three days after an intravenous injection of 0.5 gm., so that in the whole he utilizes 0.8-1.0 gm.

Ehrlich further states that of great importance is the fact that the intravenous injection can be repeated in two to three weeks, especially if the therapeutic effect was not efficient or if after four weeks the Wassermann reaction is still positive. From reports received, it seemed to him that the intravenous injections for permanent effect is superior to all other methods of application.

He strongly advises in the primary lesion to give an intravenous injection of 0.5, and at the same time thinks it advisable, in order to obtain a real sterilization, to institute an energetic local treatment, *i.e.* extirpation or cauterization of the initial sore.

The therapeutic effects of the remedy when introduced intravenously become apparent sooner, but presumably are not as certain because the arsenic is too rapidly eliminated from the system. Alt believes perhaps in the future the method of using the preparation will be to give one intravenously in order to annihilate at once the spirochetes and then follow it up with a second dose after four weeks or more by an intramuscular or subcutaneous injection to anticipate any relapse that may occur, provided, of course, that we can be assured that all of the arsenic has been eliminated from the system. He even states further, instead of a second dose of 606, we may instigate the mercurial treatment again. With the intramuscular or subcutaneous method the therapeutic action proceeds more gradually and lasts for a longer time, for in the muscles or under the skin the preparation is stored, so to speak, and forms a depot as Michaelis describes it, from whence the remedy is gradually absorbed into the system.

Alt (*Münch. med. Woch.*, July 19, 1910) had occasion to autopsy two cases dead from some other causes and found that a considerable part of the preparation injected into the muscle still remained, proving that it remains unchanged for a long time at the site of injection. In obstinate syphilitic cases the slow elimination of the arsenic of 606 is of great value, because the action of the drug is continued over a longer period of time, consequently it would seem more rational to use the subcutaneous or intramuscular method in preference to the intravenous.

Fischer and Hoppe (*Münch. med. Woch.*, July 19, 1910), in examining the urine of patients, found that the arsenic excreted essentially quicker and more completely after intravenous injection and that the elimination was ended by the second or third day. They also observed that in a patient who was autopsied 14 days after an injection for some other cause than the results of syphilis no arsenic was found in any of the organs of the body except in the gluteus muscle, where it was injected and where quite an amount was found, a good illustration of the fact that it remains here in storage for some time. Another case autopsied on the 36th day also showed some arsenic in the gluteus muscle. These

findings are suggestive that more certain results are obtained by the intramuscular or subcutaneous injections.

Outside of the body 606 acts very feebly on parasites. Its highly curative properties in the economy must be due to some changes in its composition brought about by the tissues or fluids of the animal organisms.

In explanation of the specific action of this preparation, Ehrlich assumes that the protoplasm of the *Spirochæta pallida* possesses specific atom groups (chemoreceptors) which link themselves with the fixed atom groups of the chemical substance of 606, thereby extinguishing the life of the parasite. In the elimination of the spirochetes from the organism there may be two processes at work. One a direct annihilation of the parasites, the other an increased phagocytosis. As is well known, phagocytosis is the process principally involved in the production of a natural cure; 606 injected into the body is followed by a considerable degree of leucocytosis, which is very suggestive that the phagocytes play a considerable part in the production of a cure.

Wechselman states that the remedy has a striking and distinct characteristic action on the indurated and compact connective tissue enclosing the spirochetes. Soon after an injection this compact tissue commences to disappear and the spirochetes which were found before the injection have strikingly diminished in number and then gradually disappear altogether. The sclerotic tissue is absorbed entirely and deep ulcers heal over with healthy granulations.

The quickened results are seen in the soft ulcerative forms of the disease while those which are longer in reacting to the remedy are the hard and indurated pathological lesions. This he explains from a study of the histopathological structures of the lesion.

If the infiltrated mass or the metamorphosed connective tissue walling in the spirochetes contain blood vessels as is the case in soft and ulcerative lesions, the spirochetes can readily be destroyed by the preparation brought to them through the circulating blood and a breaking down and absorption of the pathological tissues follows. If, however, the blood vessels are thrombosed as a result of an endarteritis, the remedy cannot be readily transported by the blood to the spirochetes lodged in these masses, but is conveyed by the leucocytes which attach themselves to these pathological structures. In this way can be explained the late disappearance of the hard papular syphilides of the skin and other indurated masses.

From the numerous reports already published the effects of this remedy, especially on the primary and secondary lesions, are simply marvelous. The rapid absorption of the indurated sore and disappearance of mucous patches and the breaking down of condylomata as well as the rapid annihilation of the spirochetes have been observed by all who have tried this remedy. These changes commence and are apparent to the naked eye already after the first 24 hours.

From the results of the cases on record, especially those cases that were not influenced by mercury and iodide, it is more than evident what great therapeutic virtue Ehrlich's preparation possesses. Occasionally there is an increase in the eruption after the injection (Herxheimer's reaction). This is explained as being an indication of the action of the remedy and is attributed to an irritative effect on the spirochetes and perhaps an indication that the dose was not large enough for a fatal effect on the parasites.

As regards the effect on Wassermann's reaction in most cases a diminution in the intensity of the reaction takes place in about four days, some respond earlier and some later. In some cases it only becomes negative after forty or fifty days.

The diversity in time may depend on the difference in the rapidity of the absorption of the remedy. Some trivial after effects are noticed, such as slight rise of temperature with a faster pulse beat; it lasts for three or four days and then drops to normal. The temperature may go in some cases up to 104° Fahr. or more, and is probably due to the absorption of the toxins of the degenerated tissues brought about by the remedy. In the absence of all physical signs accompanying this temperature this seems a rational explanation of the sudden rise. A slight erysipelatous rash may appear on the skin at the sight of injection, but disappears within a day or two. I have not experienced any abscess or necrosis of the skin. These can be avoided by careful asepsis and injecting subcutaneously and not into the skin. No other symptoms develop either in the heart, circulatory system, or digestive tract. When the remedy was not contraindicated in the thousands of cases injected abroad no toxic symptoms have been reported.

So rapidly does the remedy act when injected in the early stages of the disease that as early as after the first day papilla disappear and the roseola becomes paler. The infiltrated masses gradually commence to melt away, so to speak. On the third or fifth day condyloma absorbs and glands become smaller.

In six to twelve days the symptoms are mostly all gone and nearly all the patients gain in weight. This seems to be a characteristic effect of the remedy. Not only do they all increase in weight, but the whole general condition, physical and psychical, improves even on the day of injection. Wechselman thinks that this early feeling of well being may be attributed to the excitation effects of the arsenic. I observed this marked psychical change in the second case I treated. From a depressed melancholic and suicidally inclined individual he became brighter, more cheerful, and happier, which alone was a wonderful achievement.

There have been a few cases reported (Bohac and Sobotta (*Wien. klin. Woch.*, July 28, 1910) in which alarming symptoms arose, such as retention of urine, traces of albumin, loss of patellar reflex, obstipation and rectal tenesmus; they were probably cases in which Ehrlich's remedy was contraindicated or the injection was not properly administered. Ehrlich distinctly and emphatically warns against using it in persons afflicted with any other organic lesions, especially of the liver, kidney, heart, or circulatory system (aneurysms). In the case of the tuberculous, the senile, and heavy drinkers, the remedy should not be used.

In syphilis neonatorum and in children under one year of age the remedy is dangerous, for in these the organism is so overwhelmed with spirochetes that when they are annihilated or killed by the preparation a large amount of endotoxin is generated, the effects of which these young infants in their debilitated condition are unable to withstand and as a consequence will mostly all succumb to its influence. For this reason it was advised to inject the

syphilitic nursing mother and through the milk influence the spirochetes in the syphilitic infant. Two such cases are reported from abroad (*Münch. med. Woch.*, Aug. 30, 1910) with excellent results, although no arsenic was found in the milk of the mother. Ehrlich's explanation was that 606 produced antibodies in the mother and these were conveyed through the milk and thus affected the parasites in the system of the infant.

Opportunity was afforded me to test and confirm this remarkable result. A nursing mother with an infant four weeks old exhibiting the skin manifestations of lues was admitted to the hospital. Both mother and father denied infection and neither presented any manifestations of the disease, although in both a positive Wassermann-Noguchi reaction was obtained. The reaction was also positive in the infant and spirochetes were obtained from several of the skin lesions of the child. The mother was injected with 0.3 gm. of 606 from one of the first tubes I received. Forty-eight hours after the injection about 45 c.c. of the milk from the mother was given to a reliable chemist for examination for arsenic and, contrary to the reports from abroad, traces of arsenic were positively found in the milk.

The lesions on the infant were examined every other day for spirochetes and always found. Wassermann reaction constantly positive in the mother and also in infant until its death ten days after the mother was injected. The skin lesions in the infant did not improve and on the tenth day a temperature of 103° Fahr. developed with exitus. No autopsy allowed. In this case the injection in the nursing mother did not influence the syphilitic infant. How are we to explain this? Maybe the dose was too small or perhaps, as Dr. Meltzer explains, the mother had no manifestations of lues except the positive Wassermann reaction. She therefore did not develop sufficient reaction products from the injection into her system of 606 to be transmitted to the system of the infant with the milk. The arsenic found in the milk had no effect on the spirochetes in the baby. This interesting fact would tend to confirm the theory that it is not the arsenic alone that is directly concerned in the annihilation of the spirochetes, but that the combination of it with the other molecules becomes changed by the tissues and juices of the animal economy into a destructive acting substance which has a special affinity for the invading protozoa.

The precise purpose for which 606 is injected is the complete annihilation of the spirochetes the cause of the disease. We cannot help being sanguine that it accomplishes this. Of the immediate success, many observers can now speak with the authority of adequate experience. Before we can judge of its sustained effects or ultimate results a close study and scrutiny of every case in which the remedy has been used must be made months or even years after in order to speak with confidence of a positive cure. The mere amelioration of the symptoms is by no means all that is necessary to allow us to speak with confidence of a cure. The question of a positive cure can only be satisfactorily answered after the lapse of a long period of time.

What we know thus far from the reports of numerous clinicians who have investigated the therapeutics of this remedy is that in 606 we have a means that without injury to the human body has a specific effect on syphilis and as regards the rapidity and power of action is far superior to any yet known and that we can with one injection or dose accomplish as much, if not more, than several weeks of mercurial injections or inunctions can. It is a remedy which is a wonderful weapon in the treatment of syphilis. The specific action of 606 or mercury on the spirochetes affords conclusive proof that the *Tryponema pallidum* is the etiological factor in syphilis. The spirocheta is not a blood parasite. It flows but once through the circulatory system and then lodges in the tissues, where it either causes reactive changes or becomes imbedded for a longer or shorter time without producing any clinical changes.

It is likely that a single injection of 606 does not reach all the spirachetal foci in the body, and this would explain an occasional relapse. Such recurrence, however, does not detract in the least from the wonderful action of the drug. If up to the present the prescribed dose does not annihilate at once the spirochetes from the syphilis infected body the future may show that perhaps larger doses are indicated or perhaps repeated doses will be necessary. The fact is that in already over 10,000 reported cases no real organic disturbance has been found which could be attributed with certainty to the remedy; it seems obvious that perhaps larger doses or a modified preparation may annihilate at once all the spirochetes without any toxic effects on the system.

A reinjection is allowable and efficacious from the observations made on some of the relapsed cases, because the impression prevails among syphilographers that these relapses are due to the encapsulated spirochetes becoming free. A perusal of the literature shows Ehrlich's remedy to be an excellent and remarkable remedy against syphilitic skin and mucous membrane lesions. On lesions of the internal organs in many cases one injection has shown the same theapeutic effect that is accomplished only by a prolonged mercurial or iodide of potassium course. Of special note is the rapidity with which curative effects take place in malignant cases. Naturally cicatrical changes are not effected. Lost nerve tissue is not replaced by the remedy. Tabes and paralysis are not essentially influenced by it. On account of the rapidity with which it acts and because the treatment is shorter it is far superior to the older methods.

The principal indications for the remedy are malignant syphilis and obstinate affections of the mucous membranes

We can with confidence proclaim the remedy as giving results which are decidedly more satisfactory than those attainable by any other methods. The opinion is gradually becoming widespread and will soon become general that Ehrlich-Hata's preparation is the most powerful antisyphilitic remedy known to-day. One cannot but admit it to be such after observing its rapid action and wonderful effect on the various luetic manifestations, especially such as resisted every other known method of treatment.

It has proven itself harmless to the organs of the body from the thousands of cases already observed and some investigators who have treated many cases go so far as to say that even in diseases of the kidney or the nervous system where arsenic is contraindicated no harmful effects were observed. Through the rapid absorption of the indurated sore and disappearance of mucous patches and breaking down of condylomata as well as the rapid annihilation of the spirochetes there is no doubt that the communicability of syphilis will be lessened. It is obvious if such brilliant results as have been re-

ported continue to be verified lues will in time become exterminated. What remedy promises so much and has done so much already?

The introduction of dioxydiamidoarsenobenzol into our armamentarium has added a drug which has been the means of saving unnumbered lives and restoring to many that enjoyment of health which would otherwise have been denied them.

I have chosen such cases in which the older methods of mercury and iodide of potassium treatment were not efficacious. My personal experience with 606 therefore has been limited because only such cases were selected which did not respond to or were not benefited by other methods. In only one case did I inject 606 in the secondary stage. They are presented as illustrations of the promptness and rapidity with which the remedy acts and what influence it exerts on the resolution of the pathologico-anatomical structures of the disease. Of special note are the first four cases, where mercury and iodide of potassium failed. In these it was astonishing to see the improvement that already occurred on the third or fourth day.

Case I.—H. S., 24 years of age. Visceral syphilis. Contracted initial sore in March, 1907. Was treated by various physicians until June, 1907. From 1907 for three years received hypodermic injections of mercury. Symptoms, a large and painful mass in region of gall bladder with an enlarged liver and enlarged spleen. Exploratory laparotomy showed the tumor to be a gumma about the size of a closed fist and the liver studded with grumatous infiltration. The wound had nearly entirely healed when he was turned over to me for injection with 606; 0.3 gram was injected on September 4.

September 9 marked diminution in tumor mass was evident.

September 14, size of tumor diminished fully an inch from side to side. Liver markedly retracted from the abdominal wall.

October 13, mass entirely gone, gained 9 pounds; Wassermann still positive. November 3, Wassermann weak.

Astonishing and seemingly incredible is

Case II.—H. P., 36 years of age. Case of Dr. John Bullinger. Malignant syphilis. Contracted initial sore in June, 1907, followed by papular eruption. September, 1907, sores on neck and extremities appeared. December, 1907, jaundiced with an enlarged liver and rapidly losing weight. Epiglottis swollen and infiltrated. There followed rapidly ulcers on soft palate, tonsils, and epiglottis; slight improvement under mercurial treatment. June, 1909, relapses of ulcers in larynx and destructive changes in epiglottis. Gumma in the nasopharynx. Left wing of the nose gradually being destroyed by an ulcerative process; ulcerative sores on lips with marked destruction of tissues. In August, 1909, patient was admitted into the German Hospital. He left in October, 1909, very little improved. During all this time he received the most active treatment. He reentered the German Hospital in November, 1909, and remained there until September 5, 1910, when he entered the Lebanon Hospital to be injected with 606.

A large ulcer, 2x3 inches, the result of a broken down gumma, existed over the left malleolus. Another soft gumma on the instep ready to break down. On the upper third of the tibia a hard and painful gummatous mass was developing. A number of small and deep ulcers of punched-out appearance on cheeks, nose, and lips all covered with a nasty, yellowish discharge. (See illustration.) A large defect about the size of a 5-cent piece on the right side of the nose, the result of a broken down gumma and covered with necrotic tissue. He had received all the well-known methods of treatment—mercury in every form, enesol, atoxyl, and arsacetin, without any effect. He was rapidly getting worse. He could not swallow on account of the ulcers in his mouth and on his tonsils. Weight, 99 pounds; gradually failing. Wassermann strongly positive. Injected 0.3 gram on September 7, 1910.

September 14, an astonishing difference in the patient is apparent. The broken down gummas are healing up and covered with healthy granulations. Ulcerations and pustules have disappeared, the face looks clean. Patient is able to walk. The pains have left him. The gumma on the tibia almost entirely disappeared.

By October 20 patient gained 22 pounds. The large and deep ulcer on malleolus almost completely healed and all lesions on the face cured. (See the illustration.)

October 24, complained of slight pain over upper portion of R. tibia, where probably a commencing new gumma is forming. Reinjected October 24 with 0.5 gram. October 28, pain over R. tibia entirely gone. Still a slight swelling.

November 7, all external manifestation entirely healed. Wassermann still positive, but five times weaker than in the beginning.

Exceptionally effective was the remedy in the following two cases of congenital syphilitic interstitial keratitis.

Case III.—George L., age 9 years. Case of Dr. R. Denig. Syphilitic interstitial keratitis of both eyes. Was under the care of Dr. Denig of the German Hospital for five months without any benefit resulting from the usual antisyphilitic treatment. He was not able to open his eyes on account of the intense blepharospasmus. He received 0.15 gram 606 September 21, 1910. Two days later we were all astonished at the improvement. The blepharospasmus was gone, the eyes looked whitish, the infiltration and vascularization less. September 29, eyes absolutely free from injection. October 3, boy discharged from hospital (Bellevue). October 17, absolute cure of his eye lesions. Wassermann still positive October 10; October 23, still positive.

Case IV.—Estelle G., age 12 years. Case of Dr. John Howland of Bellevue Hospital, also one of congenital syphilitic keratitis of right eye. Was treated by inunctions and mercury injections with hardly any improvement.

September 21, 0.15 gram 606 injected. Two days later patient has no shield over the eye. Inflammatory symptoms had nearly entirely subsided. Infiltration decidedly less. September 25, 1910, improvement still continues. October 5, still some slight injection at the nasal side, but the eye looks white and is free from inflammation, tearing, and blepharospasmus. October 17, entirely well. October 10, Wassermann-Noguchi weaker. The boy for five months could not open his eyes on account of the photophobia and two days after the injection of 606 he could see and keep his eyes open. The girl for two months could not open her eye and she also two days after could open the eye without any effort.

Exceedingly interesting because the results were exactly opposite to the two cases published in the German Literature (Taege and Duhot) (*Münn-*

chener med. Woch., August 16, *Münchener med. Woch.*, August 30) is

Case V.—Mrs. D., age 28. A mother nursing an infant four weeks old, who exhibits the manifestations of congenital lues. Running from the nose. Pustular eruptions. Desquamation on palms of the hand and soles of the feet. Mucous patches on the lips, mouth, and around the arms. Mother and father both deny infection and show no evidence of lues. Yet a Wassermann-Noguchi reaction was positive in father, mother, and infant. From the skin lesions on the child spirochetes were found.

October 6 the mother was injected with 0.3 gram 606 to see the effects on the infant through the milk of the mother. Forty-eight hours after the injection the milk of the mother was subjected to a careful chemical examination and arsenic found. (Dr. Oefele.) This is contrary to Duhot's case (*Münch. med. Woch.*, August 30). The infant did not improve. Spirochetes continued to be found up to the tenth day after the injection into the mother, when exitus of infant took place. October 10, Wassermann-Noguchi still positive in the mother. As the mother had no manifest lesions the unsuccessful result might be explained by the fact that sufficient antibodies were not formed when 606 was incorporated into her system, which could be transmitted to the child through her milk.

Case VI.—R. S., age 25 years. Initial lesion three and a half years ago. Received active treatment for a long time with mercurial injections. Was admitted to the hospital with a large indurated mass in the gluteal region about the size of a closed fist and another smaller gumma over the saphenous opening on the thigh. There was an ulcer the size of a 25-cent piece over the hard gumma, which was covered with a nasty and foul discharge; this had existed for many weeks. Injected with 0.4 gram 606 on October 9. One week after the gumma in front of the thigh was soft and half the original size. The hard gumma over the gluteus was melting away and sloughs and necrotic tissue were being rapidly thrown off. October 22, cavity still discharging soft and degenerated tissue. November 1, cavity filling up with healthy granulations. November 3, Wassermann still positive. The patient gained 10 pounds during his stay in hospital.

Case VII.—Charles L., 38 years of age. Case of Dr. Lilienthal of Bellevue Hospital. Initial lesion twenty years ago, was treated by inunctions. Nineteen years ago fell and sprained his ankle. March, 1910, fell and a swelling gradually commenced to appear around his left ankle. It was twice the natural size. Patient could not move joint on account of swelling and pain. The prominent points of the ankle could not be made out. *X*-ray picture showed thickening of os calcis with probably deposits of new bone or gummatous formation. Injected with 0.50 gram 606 October 12. One week after there seems to be already a diminution in size of joint. Pain diminished. October 25, marked diminution perceptible and all the prominent landmarks of the joint can be made out. *X*-ray picture shows absorption of surrounding mass. November 7, pain has entirely disappeared. Patient can walk without cane. Has perfect function in joint. Feels very much better. All infiltration around joint and in tendons disappeared. Walked over a mile without any pain.

Case VIII.—Mr. M., age 41 years. Initial lesion twelve years ago; had active mercury and iodide of potassium treatment for the past three years. Periostitis of both tibiæ. Several indolent ulcers covered with nasty smelling discharge had existed for over a year, which did not heal in spite of all previous treatment. Injected, October 17, 0.45 gram 606. October 25, no more discharge or odor from the ulcers. Look healthy and are rapidly filling up with granulations. November 9, entirely healed. Patient says he has not felt as well in ten years. Has gained 20 pounds in three weeks.

Case IX.—Alice L., 9 years of age, was born with vesicular eruption; both mother and father give a luetic history. When two years of age child became hemiplegic. The lower extremity almost recovered, while the upper extremity became atrophied. Up to two years ago the child was fairly intelligent, but since then became almost idiotic. During the last year has lost her hearing to a considerable extent. During the last three months nose became extremely sore with a discharge of a foul smelling material. In the beginning of October the patient's nose became flattened and a typical saddle nose developed. Wassermann-Noguchi strongly positive. Injected, October 24, 0.3 gram 606. October 28, nose ceased discharging and foul odor gone. Child seems a little more bright and hears better, takes notice of surroundings, and answers when talked to. November 7, Wassermann-Noguchi still positive.

Case X.—O. S., age 44. Case of Dr. J. Bullinger. Infection 18 years ago. Active inunction treatment in German Hospital. No other symptoms until about five years ago, when ulcerations appeared in his throat. He had pain and difficulty in swallowing. Again inunctions and later injections of salicylates. All symptoms disappeared. About three years ago recurrences of ulcerations in throat, dyphagia, pain, and hoarseness. Iodide and mercury have very little effect. Two years ago heavy infiltrations in his tongue and hard palate increased hoarseness and pain on swallowing, loss of flesh. When seen before injection patient was very much run down from loss of sleep; has great deal of pain in throat and neck; turning of head is painful; attacks of spasmodic cough at night lasting often an hour or longer. Patient dreads to eat, as he can swallow only with difficulty, massage often being necessary to facilitate the first few swallows to pass his inflamed throat. It is almost impossible for him to swallow water alone. Status on day of injection: mucous membrane of post-pharyngeal wall nasal space, roof of hard and soft palate thickened and ulcerated, uvula ulcerated laterally, tongue base and sides swollen and granular infiltration, larynx covered with ulcerations and edematous. Only small edematous stump remains of epiglottis. Injected October 29 0.45 gram 606. In the evening patient was already able to partake of eggs, coffee, and bread, which he swallowed without pain or spasm. Next day swallows water without any trouble, all pains have left him. Nine days after injection the swelling of all parts has disappeared. Throat looks clean and mucous membrane has lost its angry redness and infiltrated appearance. Small area of larynx still covered with whitish exudate. Soft palate much shrunken. No more swelling on tongue, but still covered with spots of whitish exudate. Both cords are still thickened. Patient's voice is much clearer; has gained two pounds in weight. Wassermann-Noguchi still positive.

Case XI.—Mrs. E., aged 45. Midwife. Infected with chancre on thumb of right hand in September, 1909, followed by lymphangitis and adenitis. Gen-

eral adenitis after several weeks. Roseola and sore throat followed. During February, 1910, gumma appeared on back of tongue and in region of right tonsil and soft palate. October, 1910, nose became sore and discharged mucoid material. Has pains in all of the limbs. Nocturnal headaches, soreness, and discharge from nose. On left half of tongue several gummata, one the size of small hickory nut. The others smaller. The anterior one nearest tip commencing to break down, leaving an ulcerated area. Tongue swollen and thickened. Cannot roll it around in the mouth. Had received mercury and k.s. for weeks without any effect. Injected November 4, 0.5 gram 606 in lumbar muscles, according to Meltzer's method. Immediately patient experienced the most excruciating pain, which necessitated an injection of morphine. The technique in this case was faulty in that the needle must have penetrated through the muscle and the fluid injected in the connective tissue underlying it instead of in the muscle itself. However, after three days pain had subsided. There was no swelling. Rapid absorption must have taken place from the clinical picture presented, for after the first twenty-four hours the pains in her head had entirely disappeared. The pains in her limbs, also the discharge from the nose, were less. The gumma on the tongue did not inconvenience the movement. She felt better except the severe pain over the site of injection. By the end of the sixth day, November 10, you could not see the ulcerative gumma on the tongue, it had entirely disappeared. The tongue was freely movable. The other gumma had nearly entirely disappeared. All her pains in the face and limbs had dispeared. There was still though a slight sensitiveness over the lumbar region. As regards the clinical manifestations she was entirely cured in one week. Wassermann positive at end of one week.

Case XII.—Mrs. L., age 25. Noticed in the beginning of October a rash all over the body except face. No history of initial lesion. Typical copper-colored macular eruption. In September had pains and headaches with sore throat. Wassermann, November 4, strongly positive. Injected November 6 0.5 gram 606 into ileocostal muscle. Patient experienced almost no pain whatsoever except that produced by the needle. Was free from pain and swelling, except a slight soreness in the back. On November 8 roseola paler. On November 11 roseola still paler and hardly perceptible. Feels very well. This is the only case with secondary lesions that I injected. She was injected according to the method suggested by Dr. Meltzer and experienced no pain and no swelling following the same. As regards the rapidity with which absorption is taking place, the time elapsed is too short to report the effects on the Wassermann reaction.

Case XIII.—William D., age 30. Chancre ten years ago—treated only one week. Four years ago patient had a mass size of pear on right shoulder which broke open and discharged pus. Has had a swelling on knee below tuberosity of tibia size of small hen's egg. About a year ago patient noticed a swelling on inner side of left thigh, which gradually increased in size, was hard and red; swelling broke down and discharged pus and left an ulcer the size of a 50-cent piece. Status on day of injection, November 7, 1910: Gumma on right shoulder. Gumma below patella over the tuberosity of tibia size of small hen's egg. Ulcer on inner side of left thigh covered with a nasty discharge. Injected 0.5 gram 606 according to Meltzer's method. No pain, no swelling—he was free from pain for three days. On November 10 he complained of severe pain in lumbar region when he bent his back. Tumor on left knee smaller. Ulcer smaller and filling up with healthy granulations. Indurated gumma on shoulder practically gone. Wassermann still positive.

The method of injecting 606 into the ileocostal muscles as suggested by Dr. Meltzer leads me to believe that with this method we have a means by which the pain is eliminated, if injected properly. The needle must be inserted into the muscles between its surrounding fascia and not over or under it into the connective, as was done in Case XI.

My experience with the injections has been that of the three—Wechselman's neutral suspension subcutaneously injected, Alt's alkaline also subcutaneously, and Meltzer's with Alt's alkaline solution intramuscular (ileocostal) injection—the latter seems to give the least pain of all. As regards comparing the rapidity with which absorption takes place, as would be evidenced by the quicker disappearance of lesions and the effects on the Wassermann reaction, sufficient time has not elapsed in these last three cases for me to express an opinion. Further observations in other cases that are being made will give sufficient data to come to more definite conclusions on this point.*

To Geb. Ob.-Med. Rath Prof. Dr. P. Ehrlich of Frankfort; to a Member of Honor of the Dutch Red Cross Society and Honorary Life Member of the Lebanon Hospital, and to Dr. S. Flexner of the Rockefeller Institute I wish here to express my best thanks for their kindness in supplying me with tubes of this preparation. To Dr. S. J. Meltzer of the Rockefeller Institute for his valuable suggestions and to Dr. Noguchi for making the Wassermann-Noguchi tests I also desire to acknowledge my indebtedness.

71 East Sixty-sixth Street.

INTUSSUSCEPTION OF THE APPENDIX.

By ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK.

VISITING SURGEON HAR MORIAH HOSPITAL; ADJUNCT ATTENDING SURGEON MOUNT SINAI HOSPITAL.

About one year ago I had the opportunity to observe and to operate upon the following case: B. F., four and one-half years of age, was admitted to the pediatric service of Dr. Koplik, Mount Sinai Hospital, June 22, 1909. The patient's illness began suddenly about three months before admission with severe abdominal cramps which recurred two or three times a day and bore no relation to his meals. These attacks continued with increasing frequency and persisted up to the present. There never was any fever nor vomiting. His bowels moved at least once a day; the feces were normal in appearance, and it is particular to note that blood was never found in the passages.

*Since receiving the proof of this paper for correction I have had the opportunity to use the intravenous method in two cases. The solution injected was made according to Schreiber's method (*Münch. med. Woch.*, No. 39, 1910), and outside of nausea, vomiting, and abdominal pain, which followed about fifteen minutes after the injection, and a slight rise of temperature which showed itself about four hours later, no untoward symptoms developed. The patients experienced absolutely no pain at site of injection, and appeared absolutely well the next day. As only a few days have elapsed since the injections were made, the report of the results on the clinical lesions are left for another occasion.

The physical examination showed a rigidity of the entire abdomen, especially marked over the lower half of the right rectus; there was slight, movable dullness in both flanks; the pain was not localized, and the tenderness was most marked in the umbilical region. No mass was palpable, prob-

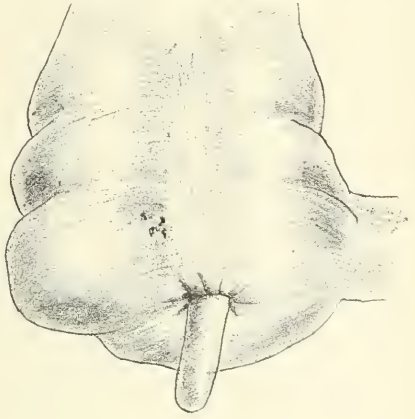

Fig. 1.

ably due to the excessive rigidity of the abdominal muscles. Rectal examination was negative. On the day following his admission distinct visible peristalsis was observed during an attack. He was kept under observation for the next few weeks, during which no change whatsoever was noted. The child felt exceedingly miserable during an attack, but between the attacks was to all appearances perfectly well.

On July 21 he was examined under anesthesia, and during complete relaxation of the abdominal muscles there was to be palpated in the right hypochondrium a mass about the size of an egg which moved with respiration. On July 24 there occurred an unusually severe attack of pain, necessitating the administration of morphine; after this attack a trace of blood was found in the stool.

He was transferred to the surgical service and operated upon July 27. Prior to operation I ventured the opinion that we might deal in this case with a chronic intussusception. Through a short Kammerer incision the mass previously mentioned was brought out of the abdomen and found to be the cecum. The appendix projected for a distance of about half an inch, from a cuplike depression formed by a much thickened cecum. It was recognized as an appendicocecal intussusception and steps were taken to desinvaginate it. After considerable difficulty this was finally accomplished and the appendix removed in the manner usually employed at the hospital (deligation and cauterization). The abdominal wound was closed by layer suture.

The boy reacted promptly and ran a smooth course for seven days, when the house surgeon dressed him for the first time; finding apparently primary union, he removed the silk cutaneous stitches. The child was very obstreperous and during straining burst the entire wound wide open, with resulting prolapse of a large mass of intestines. These were replaced and the entire wound resutured in layers. The child was in considerable shock, but recuperated nicely. Primary union resulted and he was discharged cured August 24.

In approximately 5,000 cases of appendicitis in Mount Sinai Hospital, during the past eleven years, this is the first case of intussusception of the appendix that has occurred. Further evidence of the rarity of the malady is shown by the fact that in the literature I have been able to collect but twenty-four additional cases. In reviewing the reported cases I was struck by the uniformity of the clinical signs, both subjective and objective. In fact the clinical picture, as I have evolved it from the reported cases, is, I believe, sufficiently definite to enable one to make a diagnosis of intussusception of the appendix with a fair degree of probability.

Before reciting the clinical picture of the disease I shall briefly summarize the reported cases.

Monsarrat (*Liverpool Medico-Chirurgical Journal,* Vol. XI, page 68): Child four years of age. History of repeated attacks of severe abdominal pain for one month; between the attacks the child felt perfectly well. At operation there was found a large intussusception, involving the ileum, ileocecal valve, and colon, which was easily reduced. However, there still remained a small mass which was found to consist of an invagination of the appendix into the cecum; all of the appendix but one-eighth inch of the tip was invaginated. Recovery after desinvagination and appendectomy.

Connor (*Lancet,* 1903, Vol. II, page 600): Boy, nine years of age, who had a number of attacks of abdominal pain during the month preceding operation. A large mass, consisting of the readily reducible invaginated ileum, was found; but there still remained a small mass which on examination was found to be the invaginated appendix. Entire appendix was invaginated; on this account desinvagination was impossible and resection of the cecum was necessary. Recovery.

Colman and Kellock (*Transactions Clinical Society,* London, Vol. XXX, page 227): Boy, eight

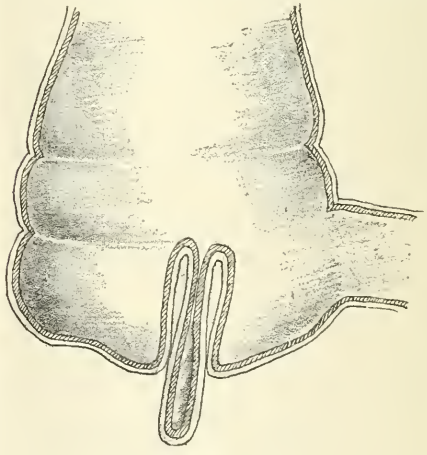

Fig. 2.

years of age. History of fifteen weeks' duration, with repeated attacks of abdominal pain. At operation a large, easily reducible ileocolic intussusception was found. A small mass remained which proved to be an invagination of the appendix into the cecum, and in addition a perforating ulceration

at the junction of the appendix and cecum was found. Excision and suture was followed by death.

Binney (*Australasian Medical Gazette*, 1908, Vol. XXVII, page 358): Child, two years of age. History of fourteen days' duration. At operation a large, easily reducible ileocolic intussusception was

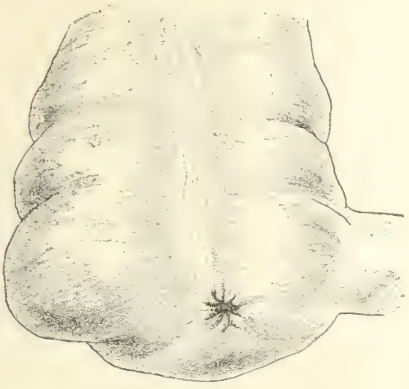

Fig. 3.

found. A small mass still remained, and upon close examination no appendix was to be seen. The cecum and terminal portion of ileum were resected with end to end suture; recovery. Examination of the specimen showed an invagination of the appendix into the cecum.

Rogers (*St. Paul Medical Journal*, 1909, Vol. XI, page 458) reports two cases.

Case 1.—Boy, eight years of age, who was taken acutely ill and gave no history of previous attacks. He was operated upon on the second day of the illness. A partial invagination of the appendix into the cecum was found; appendectomy and recovery.

Case 2.—Adult, eighteen years of age, who gave a history of frequent attacks of abdominal cramps during childhood. His present illness is of over five weeks' duration, with frequently repeated attacks of abdominal pain, culminating once in absolute intestinal obstruction, which was, however, relieved by medication. Operation revealed a partial invagination of the appendix into the cecum, which was so difficult of reduction that resection of the cecum became necessary. Recovery.

Chaffey (*Lancet*, 1888, Vol. II, page 17): Child, three years of age, giving a history of six weeks' duration. A large tumor could be palpated from time to time, which disappeared by enemata and manipulation, with the exception of a small part located in the right iliac fossa. The child died unoperated and autopsy revealed a gangrenous intussusception of the appendix into the cecum.

Lees and Silcook (*Lancet*, 1898, Vol. I, page 1400): Boy, four and one-half years of age. For the preceding few months he suffered from a number of attacks of apparent intussusceptions which were reduced by enemata. This procedure was finally ineffectual and operation became necessary. An invagination of the appendix into the cecum was found, requiring resection of the cecum, ascending colon, and terminal portion of the ileum with end to end suture. Recovery.

Pitts (*Lancet*, 1897, Vol. I, page 1602): Child, two and one-half years of age. History of three and one-half months' duration. In one attack a protrusion appeared outside of the anus, but this was reduced. At operation a large, easily reducible, ileocolic intussusception was found; a small part still remained, which on examination showed an absence of the appendix. Its place was taken by a dimple connected to an intracecal swelling. Incision of the cecum revealed this swelling to be an invaginated appendix. Extirpation followed by recovery.

Wright and Renshaw (*British Medical Journal*, 1897, Vol. I, page 1470): Child, two years and ten months of age. History of one month's duration. Operation revealed a partial invagination of the appendix into the cecum. Reduction was possible only after incision of the cecum and manipulation from within. Appendectomy followed by recovery.

Haldane (*Scottish Medical and Surgical Journal*, Vol. XII, page 333): Child, three years of age, giving a history of at least fourteen days' duration. Operation showed an invagination of the appendix (all but the tip) into the cecum. Extirpation; result not stated.

McKidd (*Edinburgh Medical Journal*, 1859, Vol. IV, page 793): Boy, seven years of age. History of about one month's duration. Patient died and autopsy revealed a complete invagination of the appendix into the cecum.

Enderlen (*Münchner medizinische Wochenschrift*, 1900, page 1021): Child, two and one-half years of age. History of several months' duration. The child was admitted to the clinic August 2 and presented a tumor to the left of the epigastrium; this gradually increased in size and finally (September 23) prolapsed from the anus. The child died September 29 and autopsy revealed in addition to the ileocolic intussusception an intussusception of the appendix into the cecum. No operation was performed.

Brewer (*American Medicine*, Vol. IX, page 67): Female, twenty-two years of age. Patient was taken acutely ill with pain in the right iliac fossa; a diagnosis of appendicitis was made and the patient operated upon by another surgeon; in spite of an extended search no appendix was found. After an operative recovery patient continued to complain of abdominal pain, which continued for the next five

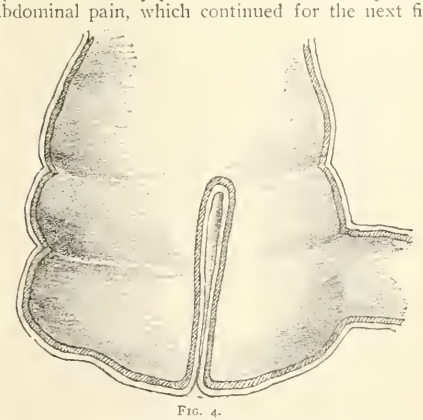

Fig. 4.

months. She was again operated upon, this time by Brewer. Exposure of the cecum again revealed an absence of the appendix; a tumor, however, was felt within the cecum, which, upon incision of this organ, proved to be a complete invagination of the appendix into the cecum. Excision and suture of the cecum was followed by complete recovery.

Hogarth (*British Medical Journal*, 1903, Vol. I, page 850): Child, six years of age. History of six weeks' duration. Operation revealed a large, easily reducible, ileocolic intussusception. There remained a small mass, which could not be further desinvaginated, owing to an invagination of the appendix into the cecum. Extirpation, recovery.

Ackerman (*Bruns Beiträge*, Vol. XXXVII, page 579): Child, four years of age. History of over four months' duration. A large intussusception was palpable in the descending colon. At operation desinvagination was easily accomplished until the cecum was reached. In consequence of this resection of the ileocolic region was performed; recovery. The extirpated specimen showed a gangrenous complete invagination of the appendix into the cecum.

Westerman (*Weekblad van det Nederlandsch Tijdschrift vor Geneeskunde*, No. 24. Original not obtainable, read only in abstract): Child, six years of age. At operation the ascending colon, cecum, and 20 cm. of ileum were resected. The specimen showed a complete invagination of the appendix into the cecum.

McGraw (*British Medical Journal*, 1897, Vol. II, page 956): Child, seven years of age. History of five months' duration. At operation an intussusception of the appendix into the cecum was found. Excision of the appendix and adjoining portion of cecum; recovery.

Waterhouse (*Transactions of the London Pathological Society*, Vol. XLIX, page 108): Child, four years of age. Operation showed that all but five-eighths of an inch of the distal extremity of the appendix was invaginated into the cecum. The invaginated part was gangrenous and irreducible. The cecum was resected but patient died thirty hours after operation.

Kuss and Guimbellot (*Bulletin et Memoires de la Société Anatomique de Paris*, 1907, Vol. LXXXII, page 487): Male, seventeen years of age. History of about one and one-half months' duration. A small mass was to be felt in the right iliac fossa and patient was operated upon for a supposed appendicitis. At operation the appendix was found to be completely invaginated into the cecum. Amputation; recovery after the temporary formation of a fecal fistula. On microscopic examination a primary tuberculosis of the appendix was also found.

Haasler (*Langenbecks Archiv*, Vol. LXVIII, page 826) reports two cases:

Case 1.—(Case 4 of Haasler's series): Patient forty-two years of age. History of six weeks' duration. A tumor was to be felt in the abdomen and a carcinoma of the intestine was diagnosed. The cecum, ascending colon, and 10 cm. of the ileum were resected; recovery. Examination of the specimen showed an invagination of the valvula Bauhinii and of the appendix into the cecum.

Case 2.—Case 9 of Haasler's series): Child, four years of age. History of four and one-half months' duration. At operation a large, easily reducible, ileocolic intussusception was found, leaving only a small irreducible portion in the cecal region, necessitating resection with end to end suture. Recovery. The specimen showed a complete invagination of the appendix into the cecum.

Greig Smith (*Abdominal Surgery*, Vol. II, page 678) in speaking of the treatment of intussusception says that in one of his cases of intussusception treated by insufflation, that died, the appendix was found to be invaginated into the cecum and unreduced.

D'Arcy Power in discussing the case reported by Waterhouse says that his last case of intussusception showed a beginning intussusception of the appendix into the cecum.

I am of the opinion that the above abstracted twenty-four, or, including my own case, twenty-five, can all be looked upon as authentic cases of complete or partial invaginations of the appendix into the cecum, with or without invaginations of the ileum and colon. In addition I find the following three cases, which are occasionally referred to by some writers as examples of this malady, which, however, on reference to the original publications, do not appear to me to be perfectly valid. I abstract them for the sake of completeness and shall indicate at the proper place the reasons which have prompted me to exclude them from my compilation.

Knight: Case of acute intussusception of cecum and appendix. Mortification. (*New Zealand Medical Journal*, Vol. IV, page 106). Child, thirteen months of age, which was taken ill very acutely, so that the time elapsed from the beginning of the illness to the operation was only one and one-half days. The major part of a large intussusception had been reduced prior to operation, leaving only a small unreduced part. At operation a small mass was found from which the appendix protruded. It being impossible to reduce it, the bowel was incised and valve exposed to view, which was found to be gangrenous. The child died within one hour. I believe this case should be excluded, because it is not stated distinctly in the description that the appendix was found to be invaginated; and furthermore, the presence of the gangrenous ileocecal valve leads me to the belief that this, and not the appendix, was probably the apex of the intussusceptum.

Rolleston: Prolapse of the mucous membrane of the vermiform appendix into the cecum (*Edinburgh Medical Journal*, 1898, Vol. IV, page 21) reports an interesting autopsy finding in a man thirty-two years of age who died of peritonitis caused by a perforated duodenal ulcer. A prolapse or projection of the mucous membrane of the appendix into the cecum, containing a coprolith, was found. This case, while undoubtedly of great interest as "possibly" explaining the earliest surgical pathology of the malady in question, should, however, not be included in this compilation, inasmuch as not all of the coats of the appendix were involved.

McFarland: A case of intussusception of the vermiform appendix and cecum, with recovery and subsequent passage of the invaginated tissues per rectum. (*Proceedings of the Philadelphia Pathological Society*, New Series, Vol. IV, page 163). Child eight years of age. History of an acute abdominal trouble, which was diagnosticated as intussusception. The case was not operated upon, as the symptoms relieved themselves spontaneously. During the convalescence two pieces of tissue were passed per rectum. One was a flat piece of intestine about the size of a half dollar, to which was attached a tube, 10 c. m. long, which was the appendix. It was not inverted. The author concludes that it was an intussusception of the appendix. I believe this case is to be excluded for the following reasons: First, that the intussusception was not seen; second, that the occurrence described can very readily happen in an ordinary gangrenous appendicitis with perforation into the cecum, and finally, that the appendix was not inverted. I believe it is impossible for an intussuscepted gangrenous appendix to reinvert itself.

Surgical Pathology.—It is evident that in any form of intussusception, which occurs in the neighborhood of the ileocecal valve, the appendix may be involved in one of the following five ways: 1. In any extensive intussusception, no matter whether it began as an ileoileac, ileocecal, or ileocolic form, the appendix will form a part of the entire mass. Inasmuch, however, as the appendix bears its normal relations to the cecum, such an appendix can not be classified as an intussusception. 2. There is also the possibility that the tip of the appendix may become invaginated into the lumen of the appendix, and this might progress until more or less of the appendix becomes inverted. No case, however, of this lesion, which may be called an appendiculo-appendicular intussusception, has to my knowledge ever been observed. 3. The intussusception may start at the junction of the appendix and cecum, or at the so-called Gerlach's valve. More and more of the appendix becomes inverted, and the process only ceases by swelling of the coats, or adhesions between the apposed serous surfaces. We then have what I have termed a "partial" intussusception of the appendix, as illustrated by the following diagrams, Fig. 1 seen on the flat and Fig. 2 seen on cross section. A greater or less portion of the appendix usually projects from the cecum. If a longitudinal section is made through the cecum and intussusception the intestinal coats will be cut six times. Of this variety of intussusception there are reported six cases, namely, two cases of Rogers, those of Wright and Renshaw, Haldane, Waterhouse, and myself. The process may end here, or it may go on to the formation of: 4. The entire appendix becomes inverted into the cecum, and we obtain a picture which is typical of the glovefinger eversions. As a rule no vestige of the appendix is visible, but its cecal attachment can always be found by tracing the teniae of the colon. On closer examination the appendix is found in the form of a mass within the lumen of the cecum. This form of intussusception may be designated as "total," and is illustrated by Fig. 3 as seen on the flat, and Fig 4, seen on cross section. In contradistinction to the preceding variety there are visible only four layers of the various coats of the intestine on longitudinal section of the cecum. Of this variety of appendiceal intussusception I have found only four cases recorded, namely, those of McKidd, Brewer, McGraw, Kuss, and Guimbellot. 5. The process may stop short with any one of the last two forms; it appears, however, that the inverted appendix acts as a foreign body, and in the efforts of the intestine at expulsion more and more of the intestine is drawn into the intussusception, in some cases even to the point of protrusion from the anus. In these cases we obtain, of course, the usual clinical picture of an ileocolic intussusception. At operation it is noted that after the comparatively easy reduction of the major portion there still remains a small tumor-like mass in the cecum, which is difficult of reduction and which is found to be either a partial or total inversion of the appendix.

It is manifest that the cases must begin either as a partial or total inversion of the appendix; owing probably to failure of diagnosis or from tardy operative interference the true condition is not recognized until the larger intestinal intussusception becomes evident. This is probably also the reason why the majority of cases of intussusception of the appendix belong to this group; in fact, in my series fifteen are of this variety, namely, those of Monsarrat, Connor, Colman and Kellock, Binney, Chaffey, Lees and Silcock, Pitts, Enderlen, Hogarth, Ackerman, Westerman, Haasler (two cases) Greig Smith, and D'Arcy Power.

Clinical Picture.—1. Race and Nationality. It is an interesting fact that of the twenty-five cases here recorded twenty were reported by American and English observers. The significance of this large Anglo-Saxon percentage I am unable to discern. It is particularly interesting in the light of the large statistics collected by Clubbe in Australia and Erdman and others in New York, which show that intestinal intussusception as a whole is far more prevalent among Anglo-Saxon peoples than among others.

2. Age. The oldest patient on record is Haasler's, who was 42; Kuss' and Guimbellot's was 17, Brewer's was 22, and Rogers' second case was 18. The remainder belonged to the first decade, varying from 2 to 9 years, with an average for the 18, in which the age is recorded, of about 5 years. We may safely say therefore that the age incidence is the middle of the first decade.

3. Pain. This is, to my mind, the most diagnostic symptom of appendicular intussusception. The pain is intense, cramp-like, and is usually localized around the umbilicus. The distinguishing feature of the pain, however, is its remitting character. The pain comes in paroxysms, during which the patient behaves as if in abject misery. These paroxysms are followed by an interval of remission, during which the patient feels perfectly well, and the little patient acts and behaves as though nothing had happened. The periods of pain and well-being alternate and their frequency varies from one or two to many a day. It is needless to add that this description applies only to partial or total invaginations of the appendix, uncomplicated by intussusception of the larger bowel. When this complication has supervened the clinical picture of intestinal intussusception dominates.

4. Duration. The duration of the disease is also rather characteristic. We find in most instances that the history spans a considerable period, varying from a few weeks to even several months. In a measure, the long duration is principally due to failure of recognition of the malady. It is a fact, however, that a longer or shorter period elapses before operative treatment becomes indicated either as an exploratory measure in the total or partial invaginations of the appendix or as an urgent measure when the primary invagination of the appendix is complicated by an intestinal intussusception. In other words, an interval of several weeks as a rule elapses before a pure and simple appendiceal intussusception becomes converted into, or, better said, complicated by an intussusception of the ileum into the colon.

5. Tumor Formation. While in many instances the palpatation of a distinct mass may be difficult from excessive rigidity of the abdominal muscles, I believe that in suspected cases every means should be taken to afford the best possible relaxation. I refer especially to the use of the water bath immersion method or to the administration of a general anesthetic. In my case a general anesthetic enabled us to demonstrate beautifully a swelling the size of an egg. The characteristic sausage-shaped swelling of cases accompanied by ileocolic intussusceptions requires but a passing mention.

6. Darmsteifung. This phenomenon has been noted in a few cases, but is not characteristic of the disease.

7. Stools. In pure and simple appendiceal intussusceptions the bowels move as a rule spontaneously or readily do so with cathartics; in other words, constipation is not the rule. It is needless to mention that in the more advanced ileocolic cases absolute constipation prevails.

8. Gross blood and mucus in the passages is, as a rule, almost pathognomonic in the more advanced cases of ileocolic intussusceptions. In the purely appendiceal intussusceptions this symptom has not been reported as occurring frequently; but I have little doubt that blood is probably present in nearly all the cases, if it is only looked for by chemical and microscopic tests. Blood was present in my case, and it was the presence of blood in the passages, directly after an attack, though only in minute amounts, ascribable to no other cause, which tempted me to make a tentative diagnosis of an intussusception.

To recapitulate briefly, the points upon which a diagnosis might be based would be the following: Given a child in the first decade of life with a more or less protracted history of repeated attacks of severe abdominal cramps occurring remittently with periods of wellbeing; who has a small palpable tumor in the right iliac fossa and blood in gross or minute quantities in the passages, I believe a diagnosis of chronic intussusception of the appendix to be justifiable. If manifest ileocolic intussusception is present and the above clinical picture has been previously in evidence the diagnosis that the larger intussusception originated in one of the appendix may be hazarded.

Treatment.—I do not wish to enter here into the question of the operative treatment of intussusception as opposed to the mechanical treatment, though I well know that good results have been reported, particularly from England and the Continent, from the insufflation of air and water. In the United States the operative treatment is deservedly recognized as that of choice, and I believe the presence of irreducible appendiceal intussusceptions, be they ever so rare, adds strong additional arguments for the correctness of this view. (See cases of Chaffey and Greig Smith.) If open operation is done for an intussusception, we can readily see whether the entire intussusceptum has been reduced, and if not, we can take steps to overcome it or act upon indications. I shall not discuss the operative treatment of ileocolic intussusception which is well known, but shall confine myself briefly to the operative treatment of appendicular intususceptions proper.

In the simplest cases of partial intussusception an attempt, frequently successful, is to be made to desinvaginate the entire appendix and then to remove it. If this is impossible its excision with the adjoining part of the cecum is indicated.

In total intussusceptions of the appendix I doubt whether desinvagination is ever possible. Three methods would appear to be feasible. 1. to incise the cecum and to desinvaginate the appendix from within and then extirpate it; 2. to incise the cecum and to extirpate the appendix from within; and 3. to resect the cecum with the appendix in one mass; this should, however, not become necessary except in the rarest instances.

Bone Formation in a Laparotomy Scar.—P. J. Sabijakina describes a case in which two and a half months after a laparotomy a bone 5 cm. long and 1 to 1½ cm. broad was removed from the scar. This bone had been formed partly from the connective tissue direct and partly from an intermediate cartilaginous stage.—*Russki Vratsch.*

TYPHOID SPINE:

REPORT OF A CASE, WITH RADIOGRAMS; COMPLETED BIBLIOGRAPHY.

By NATHANIEL BOWDITCH POTTER, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE NEW YORK CITY, THE FRENCH AND THE RUPTURED AND CRIPPLED HOSPITALS; ASSOCIATE IN CLINICAL MEDICINE, COLUMBIA UNIVERSITY.

The accompanying radiogram, taken for me by Dr. L. G. Cole, is so striking and confirms so completely the accepted view of the nature of the lesion in this comparatively rare complication of typhoid fever that I have considered it fitting to publish it with an account of the case.

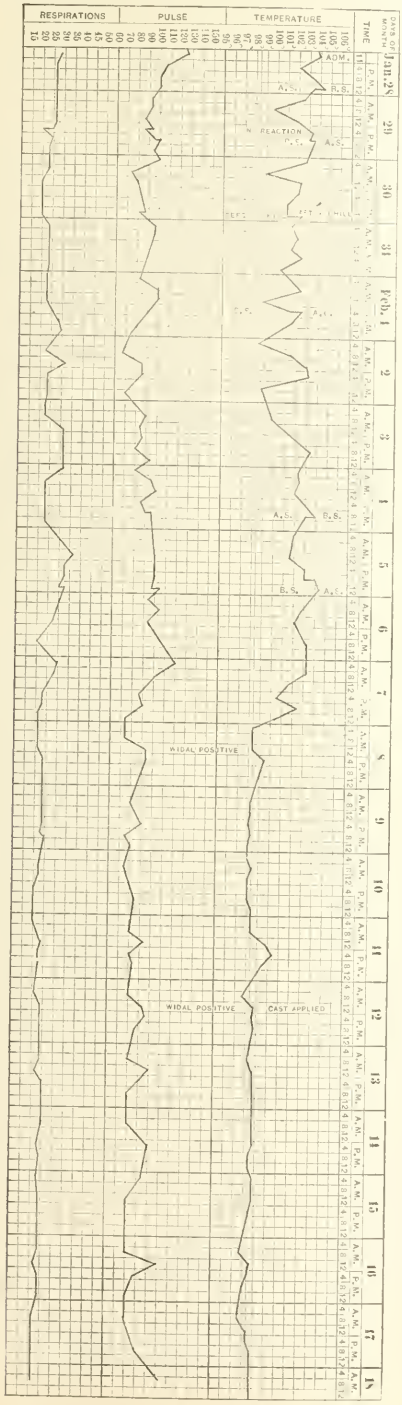
A. E. S.—French Hospital, No. 2344; admitted January 28, discharged February 21, 1910; services of Doctors Ferrer and Potter; house physician, Dr. Bernstein. Male, 30 years, chemical engineer, married, born in Austria, has lived in America several years. Family history: Mother had chronic rheumatism, otherwise unimportant. Patient's history: Acute articular rheumatism at fifteen; pericardial effusion and diaphragmatic pleurisy; sick for five months; patient noted no circulatory disturbance following. Specific and secondaries denied. Gonorrhea at nineteen, mild, no complications.

He was treated for typhoid fever at the French Hospital, under Dr. Birmingham, August 11 to October 11, 1909; a prolonged intercurrent relapse, febrile from before entrance to September 19 (140 days). Von Pirquet reaction negative, January 15; Widal positive, August 28; dilution 1:50. Urine showed diazo positive on entrance, pus cells towards middle, numerous motile bacilli September 7 for several days.

Treatment: A few cold baths which were not well borne. Alcohol sponges. Well till January 1, except occasional attack of pain, right side of back just below costal margin near spine, coming on at 4.00 A.M., and awakening the patient. These attacks persisted till January 18, though the patient was able to work despite pain which gradually continued during the day. Six hours' railroad trip in following week. On arrival, attack of severe pain which disabled the patient. He returned home in intense pain and fever and entered the hospital again. The pain was located in the right side of the spine below and over the last two ribs: it was so severe as to induce rigidity of the abdominal muscles and cause extreme pain about the umbilicus. No frequent urination or other symptoms on the part of the genito-urinary tract. No trouble with the legs or arms.

Physical examination: Fairly well nourished, slender male. Pupils: Moderately dilated, react normally. Skin: Warm, no eruption. Breath: Fetid. Tongue: Heavily coated, red edges, no deviation, no tremor. Pharynx: Slightly congested. Lymphnodes: Not palpable. Heart: Dulness extends from 5 cm. to right to 14 cm. to left of midsternal line. Apex beat: Slightly heaving, diffuse. P. M. I. 12.5 cm. to left of midsternal line. Murmurs: Loud, blowing, prolonged diastolic murmur heard with maximum intensity over left edge of sternum and at apex, also plainly audible over base and toward neck; shorter systolic blowing murmur heard at apex, over mitral and transmitted to left. Second sound clear, synchronous, no accentuation. Arteries: Visible pulsation in carotids, brachials and iliacs; abdominal aorta palpable; very slight thickening of peripheral arteries. Pulse:

Regular, rapid, increased tension; "Corrigan" type. Capillary pulse evident. Lungs: Normal. Broad-



bent sign: Marked. Abdomen: Slightly distended and tympanitic, held rigidly in upper quadrant; palpation there resisted by patient. Extremities: Normal, except for much exaggerated knee jerks. Spine: Held rigid; motion of lower lumbar and dorsal region impossible; any attempt causes excessive pain and is limited by muscular spasm. Tenderness to pressure along last three dorsal spines and along tenth and eleventh ribs on right side.

(See temperature chart for remaining details.)

February 1: Pains in back have persisted intermittently. The least movement brings on a paroxysm, in which the patient's suffering seems distressing. Except during paroxysms, patient is rather somnolent. Treatment has been rest, local heat, quinine in full doses, diaphoretics, and morphine to quiet pain. Chill on January 30 and February 1, the latter severe, lasting more than a quarter of an hour.

February 2: Tenderness seems more sharply localized over spine of eleventh dorsal and along tenth and eleventh ribs for two or three inches to right of spine; examination still very difficult and unsatisfactory. Knee jerks much exaggerated. Abdominal rigidity less marked. Edge of spleen felt. No spots detected. Medication changed to urotropin, grs. t.i.d.

February 4: Patient was taken to hospital, X-ray department. Definition of picture unsatisfactory. Renewed access of pain in back and abdomen, and rise of temperature after return to room.

February 7: Blood culture, sterile, Dr. Krumwiedie. Pains have been much less severe, less constant, and less frequent. Tenderness over tenth dorsal spine less marked.

February 9: Professor Gibney examined the patient and confirmed the diagnosis of "typhoid spine."

February 11: Paroxysm of pain recurred.

February 12: Dr. Townsend. "Any motion of back is complained of as painful. Is weak; effort to stand causes pain. No sign of posterior deformity; but there is a slight curve to the left of entire spine, beginning in upper dorsal and extending to the sacrum. No spinal tenderness on pressure. From mid-dorsal to sacrum spine is held rigid, no motion whatever permitted, either anteroposterior or lateral. Solid plaster of Paris jacket applied with assistance of Sayre extension apparatus."

February 14: Patient has been nearly free from pain. Drove to Dr. Tousey's X-ray laboratory; plaster jacket interfered with perfect definition of radiogram.

February 19: Jacket made into corset. Radiogram taken by Dr. L. G. Cole and he reports as follows: "From a careful study of three plates I am able to detect a very definite lesion in the intervertebral disc between the tenth and eleventh dorsal vertebrae. The spacing between these vertebrae is reduced to about one-half the size it is between the others. There is a lack of clearcut contour of the upper surface of the eleventh vertebral on the left side."

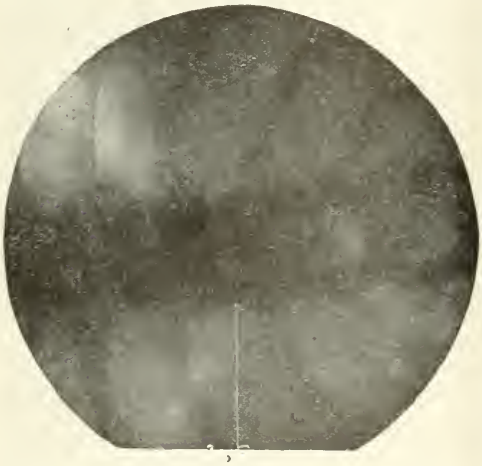
May 16: Patient resumed his occupation soon after discharge from hospital. Has worn his corset continuously. Pain has been slight from time to time, but was relieved by application of cautery. General physical condition markedly improved; weight 150 lbs.; cardiac signs as upon entrance; spleen not felt; knee jerks still increased. R—L;

no disturbance of cutaneous sensibility; back as before, but no tenderness, except to very strong pressure. Wassermann reaction negative (Dr. Noguchi). Urine normal.

May 21: Dr. Townsend. "Has worn no apparatus for past twenty-four hours. Spine rigid as before; lateral curvature severe. No tenderness."

May 24: X-ray picture. Dr. L. G. Cole. "Ribs, bodies of the vertebrae, and transverse spinous processes of the vertebrae show very distinctly. The spacing between the tenth and the eleventh dorsal vertebræ is very much less than between the other vertebræ. The edges of the surface are not as smooth and clearcut as they are above and below, and there is an increase in the density of the lower part of the tenth and upper part of the eleventh dorsal. These radiographic findings correspond exactly with the previous findings and from a study of these plates compared with those previously made I am absolutely certain of a pathological lesion corresponding with the above findings."

The literature upon this very interesting complication has been so thoroughly and recently re-



viewed by Fluss,[1] Silver,[2] and Halpenny[3] that the records of but few cases are needed to bring it up to date. Some of the previously reported cases have been excluded in one or both of the two last named compilations.

Guyot's[4] case, despite Halpenny's and Silver's objection to his brief report, seems to me worthy of being included among the authentic cases. A child of six years who had presented the symptoms of typhoid with a temperature of from 39° to 40° C. every afternoon for eight days developed great pain and hypersensitiveness in the lumbo-sacral region. Neither edema nor fluctuation was made out. Incisions were made through the aponeurosis upon both sides of the spinous processes; a large amount of pus was evacuated and the two cavities were drained. Nothing abnormal was made out in the cord. Two days later a focus of osteomyelitis at the lower end of the left fibula had to be drained; a few days subsequently another focus in the right thumb (a rare situation). The child recovered after sequestra were discharged without any special deviation. At the same meeting Chavannaz reported that he had seen an osteomyelitis of the vertebral column in a woman forty years of age, which occurred after a relapse. She showed certain nervous complications and died. This is the only fatal case which I have been able to find. It is a pity that the report is not more in detail. Crittenden[5] merely mentions that he has seen only one case of typhoid with Gibney's typhoid spine in a young woman who suffered a great deal from menstrual difficulties. It should be omitted from the list. As Silver has stated, Freiberg has reported but one case, not two, as credited to him by Fliess.

The case reported by Schanz[6] was also reported by Hertz[7] and is Zenker's[8] second case. The latter's description of his first case reads more like a case of myelitis than of typhoid spine and should properly be excluded.

Pahl[9] has no case of his own, but refers to three cases of typhoid spine seen in the last two years by Dr. John Ridlon of Chicago. There are hardly sufficient grounds on which to include these cases.

I agree with Halpenny and also include Herrick's two cases, Vickery's case, Arapov's[10] two cases, Gibney's Tyrolean case, Eskeridge's case, as well as the two cases of Osler, which were omitted from the list by Silver. White[11] has added still another case and refers to an early one by Schmitz,[12] and to two by Le Briton.[13] In addition to my case reported above in full, we may add one reported by Halpenny[14] in a footnote; one by Berry,[15] one by J. C. Wilson[16] (not the same referred to in Halpenny's article), and one by Sweet.[17] Trozzi's[21] case of typhoid spondylitis affecting the coccyx seems to merit inclusion, despite the location, the subsequent suppuration, and the lack of a radio-

	Age	Sex	Duration of Fever	Time of Onset of Symptoms	Cause of Onset	Mode of Onset	Location	Pain	Fever	Sensory Symp.	Tenderness	Inc. knee jerks	Deformity	Duration Acute Stage	Recovery due to Fixation	X-Ray Finding
Halperings 2d case	50	M	N	2 wks		sudden	Lower dorsal & lumbar	+ +	+		+			16 wks.	To rest	Refused
White	16	M	N	6 wks	Bicycle	sudden	Upper lumbar	+ +	+	+	+			3 wks.	Yes	
Schmitz	12	F	N	At end of fever		sudden	Lumbar iii & iv.	+ +		+	+		Kyphosis		rest

Le Breton	40	M	Severe	At end of fever		grad'l	Lumbar	+ +			+	+	Obliteration of *I* n. curve.	sev. wks.	yes	
Berry	19	M	N	During convales		grad'l	Lumbar	+	+		+					
S. Wilson Larat	28	M	N	3 mos	Exertion	grad'l	Lumbar	+ +	+		+			4 mos.	To rest	+
Sweet	19	M	Severe	2 wks		grad'l	Lumbar iii & iv.	+ +	+		+	+	Kyphosis	6 wks.	yes	+
Potter	30	M	Severe	4½ mos	Travel.	grad'l	Dorsal x & xi.	+ + +	+		+	+	Curvature	2 wks.	yes	–

gram. This brings the number to eighty-four, if we include Guyot and Chavannaz.

Following the analysis of Halpenny and Silver, I have constructed the table on p. 1094.

Radiography: J. C. Wilson's case showed much narrowed intervertebral discs; signs of necrosis in the vertebrate bodies, many osteophytes. Sweet's case showed an obliteration of the disc between the fourth and fifth lumbar vertebrae, with signs of new bone formation and scoliosis at this point. Of the fourteen cases in which radiograms are mentioned, only those of Cutler and Peltesohn showed no evidence of a pathological process in the bone or cartilage. In view of the uniform results in the positive cases and of the difficulty we encountered in our first two trials, it seems fair to assume that most examples of this complication of typhoid fever will present a similar lesion. The picture in Lovett and Withington's[20] case report is not a radiogram, but the reproduction of a photograph showing the patient in profile view, nude, with a crutch under his left arm. "As may be seen in the picture, the projection was of considerable size, the spinous processes could be easily made out, and their angular projection could only be accounted for by the giving way of some part of the weight-bearing portion of the vertebral column."

So far as treatment is concerned, a study of the cases reported more recently suggests that prompt fixation, whether by a plaster bed, extension apparatus, or corset will relieve or arrest the process.

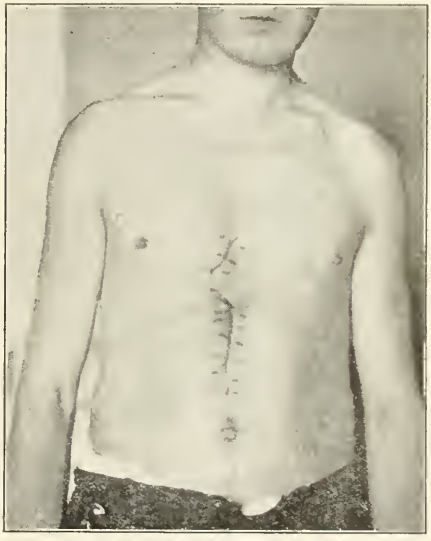
A CASE OF STAB WOUND OF THE HEART.*

By JOHN F. ERDMANN, M.D.,

NEW YORK.

S. H., male, age twenty-one, at 7 o'clock on the night of August 22, 1910, received a stab wound in the chest, made by a knife three-quarters of an inch wide by 6 inches long that would correspond to a fruit knife or one used for paring potatoes. The puncture—three-quarters of an inch long—was on the right side of the chest, one and three-quarter inches to the right of the median line, penetrating the fifth costal cartilage obliquely, and splitting its lower three-quarters. The distance from the left nipple was six inches to the right of the median line and on a line one and a quarter inches below the right nipple.

The patient was received at the hospital shortly after the injury, stating that he had been stabbed in an altercation at the restaurant in which he was employed as a waiter, and that he struck the man a blow and knocked him down subsequent to his being stabbed. I saw the patient at 10:30 or 10:45, practically three and a half hours after the injury, and was told that in the interval between his entering the hospital and my seeing him he had had a transfusion of 500 c.c. of salt solution. His condition at the time I saw him was one of profound shock,



The angle at the extreme right of the scar as the patient stands represents the point of entrance of the knife.

marked pallor, the pulse uncountable and almost imperceptible, dyspnea, rapid and shallow breathing, cold perspiration, and semiconsciousness. The heart sounds were distant and almost imperceptible. The patient complained of constant abdominal pain and upon palpation he was found to be exquisitely tender on the right half of the abdomen. On percussion dullness and flatness extended over this entire region, particularly marked in the upper half. As a result of the pain, dullness, and flatness, and the marked tympanitis on the other side, it was suspected that the liver might have been punctured or transfixed to such a degree that a hemorrhage had taken place into the peritoneal cavity, in addition to an injury in all probability to the outer edge of the pericardial sac.

An exploration was begun at the angle between the seventh costal cartilage and the ensiform process. Upon reaching the peritoneum a deep blue-black appearance such as is seen in extrauterine pregnancy with rupture was observed. The exploration was then extended two inches further in the abdominal wall, and the peritoneum opened, when

*Reported at a meeting of the Surgical Section of the New York Academy of Medicine, November 4, 1910.

the dark blue mass was seen to be the liver, driven downward four inches below the costal margin. It was deeply cyanotic. The peritoneal cavity and the dome of the liver were explored and nothing found to indicate puncture. The seventh costal cartilage was then raised, the diaphragmatic musculature was detached, and the cartilage cut at its juncture with the rib. The sixth, the fifth, and the fourth were also cut through. A retractor was placed on the cartilages, the skin raised from the sternum at the upper limit of the incision, and the sternum cut through at the upper limit of the incision with a pair of bone-cutting forceps. The cartilage and bony flap were raised to the left by forcibly dragging upon the retractor previously placed upon the cartilages. Upon raising the flap a hole admitting the index finger was found penetrating the pericardium. This was enlarged by a transverse incision one-half inch long toward the median portion of the mediastinum. The index finger was inserted and explored the contour of the heart, when a hole was found in the right ventricle admitting the gloved index finger. The pericardium was then incised upward and downward in the median portion of the mediastinum, so that an exposure was made for four inches in length. Upon making this opening in the pericardium an immense amount of clot was expelled, with some liquid blood. At this point the heart slipped from my fingers. The finger was again rapidly introduced, and the palm of the hand above and the thumb below grasped the heart, while the index finger was retained within the ventricle. A curved needle, threaded with No. 2 plain catgut, was then placed down to the heart, and during a systole puncture was made, irrespective of penetrating the cavity or not. As soon as the needle had pierced one side of the incision, the finger was withdrawn and the needle made to make its exit from the opposite side. A knot was tied and the heart held dangling from this suture. The subsequent stitches—eight or ten in number—were readily placed, one more being placed in the line of the heart wound proper, and two more rows placed after the manner of Lembert. A long cigarette drain was placed in the pericardial cavity, the incision in the pericardium closed up to the emergence of the drain, which was led out at the angle of the seventh costal cartilage and the sternum. Catgut stitches were taken in the costal cartilages between them and the ribs. Nothing was done to the sternum except to hold it in place by the dressings after the skin wound was sutured. The patient was back in bed in about thirty minutes.

The subsequent condition, while followed by a period of anxiety for four or five days on account of a lobar pneumonia and a pneumothorax, was such as to cause us to feel that a recovery was in order.

The patient was out of bed on the fourteenth day and was discharged on September 30, having been kept in the hospital simply to prevent his undergoing any undue exercise or labor.

Lymphocytosis in Basedow's Disease and Simple Goiter.—M. Kappis finds a relative and absolute lymphocytosis of the blood as a constant manifestation of Basedow's disease, and as a frequent one in simple goiter. This lymphocytosis bears some relationship to the lymphatic foci present in the enlarged thyroid. In Basedow's disease the degree of lymphocytosis is not proportionate to the severity of the clinical manifestations.—*Mitteilungen aus den Grenzgebieten der Medizin und Chirurgie.*

SPONTANEOUS RUPTURE OF A GLAUCOMATOUS EYEBALL.*

By BURTON CHANCE, M.D.,

PHILADELPHIA, PA.

Ellett's report of a case of "Spontaneous Rupture of the Eyeball, as a Phenomenon of Glaucoma," read at the meeting of the American Medical Association in 1910, recalls a case of my own which it may be of interest to record.

In March, 1902, I was asked by a colleague to see his aged mother whose sight had been lost for some time past. As he resided at a distance the history was vague; what I could gather was as follows: About two years before the left eye became inflamed; there was intense pain, with visual symptoms which I judged to have been those of glaucoma. The sight failed rapidly and for some time past yielded only light perception. Within the preceding two months symptoms resembling those of glaucoma had set in in the right eye and it too became blind.

I found the right cornea steamy and insensitive, a shallow anterior chamber, the pupil dilated irregularly, and the iris inactive. No details could be obtained through the greenish-yellow fundus glare. In the left there was a large dense leucoma involving the lower half of the cornea—the result, apparently, of an ulceration which had been active at the time of the first period of inflammation—indeed, it was the family's belief that the disease of the eye had been that of ulceration of the cornea. There were iridocyclitic signs in both eyes, and about each cornea there was injection as well as congestion of the sclera. The eyes were not tender, although the tension was fully +3. There was but doubtful light perception. The picture was one of hopeless and complete inflammatory glaucoma.

Eserine was instilled and a strong solution was prescribed and to be used several times a day. After three days the pupils were seen to be somewhat contracted. The patient begged that no more of the solution be used because it gave great pain whenever instilled, the pain lasting about an hour.

After three weeks the lady was brought to my office in response to a request which I had made for the physical effect of being out of doors. The left eye had been less uncomfortable than formerly, though the pupil had continued dilated. The right eye had been very painful. The pupil was dilated and had resumed the ovoid shape. The corneal center was hazy and steamy, its substance edematous. The iris had been caught to the capsule by a synechia down and out. No view of the fundus could be obtained through the red glare made by the mirror, neither could any view of the fundus of the left eye be obtained. There was no light perception in any field of either eye.

Eserin in a weaker solution was prescribed, yet it too was painful. Sodium salicylate was administered thrice daily for several weeks. About six months later the lady fell and broke her right wrist, and later her general health declined, because of the inaction occasioned by her blindness. She had been a most active and self-dependent person, despite her 84 years.

The corneæ remained quiet for several months. About the first of March, 1903, the right eye became painful and on the 11th I noticed a shallow erosion near the center of the cornea.

*Read before the Section on Ophthalmology, College of Physicians of Philadelphia, Thursday, October 20, 1910.

and in two days there was marked hypopyon. These symptoms regressed, the erosion healing over and the condition remained stationary until early in April, when there was a rapid change and an abscess formed which pointed into the anterior chamber. All treatment was unavailing and I advised the removal of the eye. This was refused, but I was allowed to perform paracentesis. As the tension was so great I determined to insert a broad flat keratome into the cornea at the lower limbus. This was done most cautiously and then with forceps a dense fibrous slough was withdrawn from the aqueous chamber. The next day there was a rapid filling of the anterior chamber with a thin purulent fluid, which soon became absorbed and the wound of incision healed. The lady's general health did not fail perceptibly and in time she became strong enough to be able to go about the house again.

On April 18, at 10 P.M., while stooping, she was seized with frightful pain in the right eye and she became greatly agitated. A few moments afterward there was a burst of blood from the right eye and the protrusion of what to the family appeared to be the contents of the globe. When seen early the next day the lids were puffed and ecchymotic, and a mass of oozing clot and débris protruded from between them. The cornea had burst and the contents of the globe hung out through the rent in the center of the membrane. I abscised the mass and applied a firm bandage. When seen late at night the oozing had ceased and the patient was comfortable.

In the weeks following the ball continued to be painful and the anterior segment rapidly became staphylomatous, while the posterior was shrunken. As nothing gave relief I was entreated to remove the eye, which I did on May 5, 1903, without further accident and with but scant hemorrhage. The ether was borne well, the recovery was prompt, the wound in the socket healed favorably, and the left eye remained quiet.

An examination of the ocular tissues showed a matting of the iridociliary structures in a blood clot into the cornea, together with distortion of the posterior elements. The specimen was not examined microscopically, unfortunately having been mislaid and lost.

While the cornea in this case had been weakened by disease, it is without doubt that the rupturing was caused by an increase of the intraocular tension, and it is presumed that there was a distinct augmentation of the pressure when the patient stooped over while preparing for bed. As she was a woman of remarkable intelligence, her extreme agitation together with the pain she experienced prior to the actual rupture safely may be taken to indicate that something must have happened within the globe, and that this something led to the rupturing. My own thought is that a blood vessel ruptured and the increase of pressure was caused from the infiltration of the tissues by the effused blood. The cornea had undergone no visible changes since the abscessing; the wound of incision had become as firm as ever one sees after paracentesis, and, moreover, the rending of the cornea was centrally located.

The lady continued in fair health for several months, but died on September 8, 1904, after a brief illness.

A BRIEF COMPARATIVE STUDY OF HEART STIMULANTS USED DURING FEVERS WITH A RECOMMENDATION OF THE PRECORDIAL COMPRESS.

By WILLIAM LEE SECOR, PH.D., M.D.,

ST. PETERSBURG, FLA.

RECENTLY HEAD OF THE DEPT. OF PHYSIOLOGY AND PROFESSOR OF THERAPEUTICS IN THE CHICAGO COLLEGE OF MEDICINE AND SURGERY.

The proper support of the heart during the course of a more or less prolonged fever is a problem often of the greatest importance to the physician. The administration of heart stimulants or tonics in the case of various heart conditions indicating them but uncomplicated by fever is a very different matter from the use of agents to support the heart during a febrile course if the temperature is at all high. In these febrile conditions we usually find a rapid and weakened heart action so that the agent indicated would be one that would produce a slower, stronger heart's action, and if at the same time it stimulated the nutrition of the heart muscle it would approach the ideal.

Theoretically we have just such an agent in digitalis. It stimulates the vagus center and the inhibitory fibers of the vagi, thus producing a slower heart action and at the same time the force of the heart beat is increased by its stimulant action on the heart muscle and its intrinsic ganglia. It is held by some (Hare, "Practical Therapeutics") that the vagi are trophic nerves of the heart; if this be true digitalis not only stimulates the heart to do more and better work, but also aids in providing the extra nutrition needed by the heart muscle. Theoretically digitalis would be a very satisfactory agent and would meet the various indications nicely, but in practice we find that digitalis is a very unreliable drug *when administered during high fever,* and we cannot depend upon it.

Strychnine is a drug used by many throughout the course of febrile conditions. It stimulates the heart's action, increasing the rate and force of the pulse. It also stimulates the cord and increases reflex activity. Its action on the nervous system would contraindicate it in conditions where the nervous system is already in a high state of irritability due to the action of toxins. Hare claims that it should never be used throughout the course of a prolonged fever and sounds a strong note of warning against its use in this manner. He claims that its place in these conditions is that of an emergency remedy only to be used in time of special need to bridge over a crisis. In this same class of emergency remedies we would place nitroglycerin, ammonia, ether, etc.

The value of alcohol as a heart stimulant is very questionable, to say the least. Personally I am of the opinion that it does no good and often a great deal of harm and I know that I am not alone in this opinion.

Caffeine is used by some, but its excitant action upon the brain would contraindicate it in cases where there is hyperexcitability, insomnia, or delirium.

Strophanthus may give satisfactory results, but when used alone is often unreliable and such drugs as cactus and sparteine cannot be depended upon at all under these conditions.

The fact is that we have no drug that fully meets the requirements of a heart supporter during the

course of a fever. And in this connection I desire to call special attention to the precordial compress as a procedure giving results which meet the indications nicely.

In applying the precordial compress a rubber or aluminum coil, prepared for the purpose, is wrapped in moist gauze and placed over the precordial area. Through this coil ice water is kept flowing continuously. I have found that a large sized ice bag may be substituted for this coil without detracting from the value of the procedure.

This cold application should be kept on continuously except that every three hours it should be replaced, for fifteen minutes, by a fomentation and brisk friction made over the area. This will prevent damage to the skin and maintain the proper reflex activity of the nerves.

We find that the effect upon the heart and circulation of a prolonged cold application to the precordial area is very similar to that produced by digitalis and the action is not altered by fever. The heart's action becomes slower and the rate of flow of blood through the body is diminished, but the force is maintained with some rise in arterial tension. If continued for some time there is apparently an improvement in the nutrition of the heart muscle.

So we have here an agent readily accessible which possesses all of the advantages of the drug heart stimulants with none of their disadvantages, a procedure the study and application of which will well repay the physician in positive results.

CHANCROIDS DUE TO A PECULIAR CAUSE.

By WILLIAM J. ROBINSON, M.D.,
NEW YORK.

Mr. X. Y. applied to me for treatment for chancroids. That was his and his doctor's diagnosis. It was, according to his statement, a very bad case and they kept on constantly recurring. The first time he had them was about a year before he got married, but they were completely cured. And now they kept on coming back in spite of the fact that he avoided all extramarital relations, as all good men should. He had been six years married, had two children, the last three years old. The first attack since marriage he had over two years ago. The chancroids would heal in five to ten days, and sometimes they became confluent. The doctor gave him a wash, which from the description was lotio flava, then he gave him iodoform, but as he objected to the odor, he gave him some aristol powder. The chancroids would heal in five or ten days, and would remain well as long as he would keep away from intercourse; but almost invariably after intercourse with his wife, the chancroids would break out again. I suspected that the *causa peccans* was to be looked for in the woman, and I said so. He rejected this surmise with indignation. His wife was the purest woman in the world. I told him that I did not at all impugn her purity, but that she might have an irritating vaginal secretion, or leucorrheal discharge. This was also impossible, as she was very healthy, very clean, and he was sure that he alone was the guilty party.

When I examined him I found three small ulcers, one in the sulcus, one on the side, and one near the root of the penis. They did not look like chancroids to me. They looked like ordinary superficial ulcerations, due to some irritation or a burn. There was no adenopathy on either side. And careful microscopic examinations of the scrapings from each ulcer failed to disclose the presence of the Unna-Ducrey bacillus. Nor were there any streptococci. In fact, the field was singularly free from bacterial flora. I cleaned the ulcers thoroughly with hydrogen peroxide and gave him the following ointment to be applied twice a day:

Zinci oxidi	4.0
Bismuthi subnitr.	2.0
Bals. Peruviani	1.0
Petrolati albi	20.0

and I told him to abstain from intercourse for two or three weeks. In five days the ulcerations, or the chancroids, as he persisted in calling them, were completely healed. A month later the man came back with the same ulcerations, almost in the same situations. I gave him the same treatment, but told him that if his "chancroids" broke out again I would not treat him until I had examined his wife. They did break out, and reluctantly he agreed to send her to my office. I examined her, found the vaginal mucosa harsh, dry, and shining, but no evidence of any disease or any uterine or vaginal discharge. Still I felt that here was the etiological factor to be looked for. A little parleying disclosed the fact that each time before intercourse, without the husband's knowledge, she was in the habit of inserting some antiseptic tablet. She had been doing it for over two years, as she did not want to have any more children. And she considered it too delicate a subject to speak about to her husband. I analyzed the tablets and found the principal ingredients to be citric acid and a small quantity of corrosive sublimate. And I consider the latter responsible for my patient's chancroids. The susceptibility of many people to mercuric chloride is well known, some being unable to use it on their hands without getting an eczematous eruption, etc. I advised her to leave those tablets alone, suggesting a milder remedy, and since then my patient's chancroids have not returned. Which is proof positive that those tablets were the only cause of the trouble.

And in this connection it is not out of place once more to sound a warning against the use of the highly toxic mercuric chloride as an anticonceptional remedy and as a vaginal injection. Some druggists in their ignorance advise the use of the 7.7 grain tablets! Of course, several cases of poisoning from the vaginal use of corrosive sublimate have been reported, some of them with a fatal issue. That more cases are not on record is a matter of great luck and is to be looked for probably in the slight absorptive power of the vaginal mucosa.

12 Mt. Morris Park West.

Primary Epithelioma of the Urethra.—J. Tanton says that this tumor is extremely rare. Its etiology is obscure. Predisposition and chronic irritation play a part in it. Symptoms are at first slight; they are a diminution of the stream of urine, spontaneous hematuria, purulent secretion, tumor in various parts of the urethral passage. It appears in old subjects with the manifestations of urethral stricture. It destroys the tissues and infiltrates the neighboring structures. It may cause a perineal phlegmon or abscess after the urethra has been opened by the growth. In females it causes the same symptoms, and there is a tendency to confound the symptoms with those of metrorrhagia. Spontaneous pain is severe and violent, irradiating down the thighs. Coitus becomes very painful. In the females the growth begins at the opening of the meatus. The diagnosis is not easy. The prognosis is unreservedly bad. Treatment is of no avail as far as removal of the entire growth. Only palliative operations can be undertaken.—*Gazette des Hôpitaux.*

New York, December 17, 1910.

THE ACTION OF LIME SALTS.

It has been suggested that the toxic action of oxalic acid is to be attributed to its combining with calcium in the body tissues and fluids. The hypothesis has recently been confirmed by Januschke working in the laboratory of Professor Hans Meyer of Vienna. At the meeting of the Section of Pharmacology and Therapeutics of the British Medical Association, held July 22 to 29, 1910, Meyer reported that Januschke had shown that not only the cardiac depression but also the general toxic symptoms of oxalate poisoning can be relieved by the administration of calcium or of its physiological equivalent, strontium. The essential element in relieving the poisoning consists in the replacing of the calcium withdrawn by the oxalic acid from the protoplasm, and not in combining with and rendering inactive the acid itself. The symptoms of oxalate poisoning, namely, the marked flow of saliva, the alternate maximal contraction and dilatation of the pupil, the alternate rise and fall of blood pressure accompanied by a corresponding acceleration and slowing of the heart-beat, all point to an increased irritability of the autonomous and sympathetic nervous systems due to the withdrawal of calcium. The administration of calcium counteracts this hyperirritability.

It has also been found by Chiari and Januschke that animals to which calcium has ben administered do not give inflammatory exudates as normal animals do in response to chemical and bacterial irritants. This is attributed to the diminished permeability of the vessel walls, owing to the increase in their calcium content. These results correspond closely with those obtained by Wright in the prevention or weakening of serum exanthemata by the administration of calcium. Meyer believes that the following facts have been demonstrated: First, calcium has a sedative effect on the vegetative nervous system; and, second, it diminishes the permeability of the walls of the blood-vessels.

In the light of these experiments there is added strength to the theory of eclampsia, as advanced by J. R. Mitchell in the MEDICAL RECORD, November 19, 1910, that this disease of pregnancy, similarly to tetany, is to be attributed to a calcium starvation of the patient. Eclampsia of pregnancy is a complex symptom of the mother's need for calcium. The growing fetus is a calcium parasite, and will have this element even at its mother's expense, causing in the latter carious teeth, headaches, and nervousness. In pronounced calcium deprivation, the "nerves writhe in protest," first with intermittent, tetanic twitchings, later with frequent tetanic convulsions. The administration of calcium salts quickly relieves these manifestations.

This theory ingeniously explains in a most simple manner the causation of the toxemia of pregnancy, about which the theories already published have been legion. The edemas of gravid women receive a further rational interpretation in Meyer's hypothesis of the diminished permeability of the walls of the blood-vessels resulting from the withdrawal of calcium. The theory advanced by Mitchell and supported by his clinical experience explains better than any other the manifold phenomena of eclampsia, namely, its greater frequency in twin pregnancy and at term, the nervous excitability and convulsions, the delayed coagulation time of the blood, the decayed teeth, the urinary findings, the associated edema, the eclampsia of lactation and that of the newly born, and the cessation of convulsions under milk diet. It is hoped that a thorough trial will be accorded to the therapeutic administration of calcium lactate, as recommended by Mitchell, in the toxemia of pregnancy.

SPECIALISM OF TO-DAY.

In the presidential address delivered by Dr. Andrew MacFarlane at the meeting of the Third District Branch of the Medical Society of the State of New York on October 4, 1910, the subject of present-day methods of the practice of medicine was dealt with. Special pursuits specialism is the feature of the age. Individual effort has gone by the wall and the worker of to-day is no longer, as formerly, a good all-round man, but merely a part of a huge machine in which he takes his part and no more. Formerly a man was a trouser maker or a shoemaker, as the case might be, and this term meant that he was competent to make a pair of trousers or a pair of boots throughout. Now all that is past and the trouser maker has to do with the manufacture of but one small part of the trousers and the shoemaker one part of the shoes and so on with the other trades. The professions are becoming specialized in a similar manner, and the modern physician or surgeon busies himself with but one part of the human body. Thus if an individual goes to a certain physician complaining of certain symptoms, he is as likely as not to be passed on to another physician whose specialty is the treatment of the complaint which induces such symptoms.

Whether, on the whole, this state of affairs is for the weal or woe of the human race, the fact remains that specialism in medicine and surgery holds the field. As Dr. MacFarlane remarks, "This must be so, as one man could no more cover the field of medicine to-day than a single worker could master all the details of a huge manufacturing plant." However, when it has been freely granted that modern medicine has made tremendous advances

because investigation has been substituted for speculation and knowledge has driven out mystery, MacFarlane doubts if with all our added knowledge corresponding improvement has been made in our methods of diagnosis over those of fifty years ago. For instance, it may happen now that a patient, the cause of whose symptoms is obscure, will be bandied about from one specialist to another without a correct diagnosis being made until the patient has lost confidence altogether in the medical profession. Again, a patient may diagnose his own case and select his specialist. The specialist will limit his examination, observations, and treatment to his own field without knowing or trying to know anything about the condition of the other organs of the body. Further than this may not a medical man become so obsessed with his specialty that he neither can nor will see anything beyond it?

MacFarlane suggests as a remedy for this somewhat haphazard fashion of diagnosis that a conveniently situated house should be chosen to which obscure and complicated cases could be sent for observation and examination—a diagnostic house, in short. This house thoroughly equipped for the purpose would be in charge of a well-trained and experienced house officer. Thither might be sent the patient with the obscure lesion, whose history would be taken by the house officer who would in addition make the routine laboratory examinations. The patient having undergone at the hands of the attending physician a thorough physical examination it would then be decided what further examinations might be of assistance. By such means, thinks the author, "the diagnosis would then be more nearly the real resultant of medical science and not a hit-or-miss."

That prompt and accurate diagnosis is by far the most important factor in the treatment of disease requires no argument. In some diseases correct diagnosis is a matter of life or death. If the disease be quickly and properly diagnosed treatment can be initiated that will have the most successful results and vice versa. Therefore, any means which will assist to bring about this end is deserving of notice. The diagnostic hospital might be feasible and might be very valuable.

The Caloriscope.

Infant feeding on a calorie basis is a comparatively new resource as compared with caloric feeding of adults. The old plan of a properly balanced ration with the checks of proper utilization, good health, and natural gain in weight has generally been and still is regarded by many as all sufficient for infants. Even those who believe in infant feeding by calories limit the method to the mere prevention of overeating and obesity. It is probable, however, that the calorie plan will come more and more into use, and it may be well that it should. The infant who can do very well under the old plan may furnish some arguments against the relatively new one. When we apply calorie feeding to the individual we find great variations; and the experience of gastroenteric specialists is such that they almost to a man repudiate it in the diseases of the digestive organs. Certain men claim that they can do hard work without fatigue or loss of weight on about one-half the calories which, according to tables, are "coming to them." We have for some time had concise tables for the calorie feeding of infants, but the instrument in question, which was devised by Mettenheimer (*Münchener medizinische Wochenschrift*, November 15), represents a celluloid disk, or rather two semicircular disks, one of which is divided into sectors of different colors upon which are printed the chief articles for infant feeding, with a scale of calorie values for each quantity to be used—the lowest at the center. The other disk contains formulæ for mixtures of the said nutrient materials, and for recording the weight of the child. The first disk is made to revolve upon the other, so that a given colored sector may be brought flush with the second disk, on the free margin of which are inscribed calorie values from 100 to 1,000, an arrangement which facilitates the reading of the total number of calories in a mixture.

The Nature of Pellagra.

Dr. Sambon, the distinguished Italian investigator connected with the London School of Tropical Medicine, was one of the first, if not the first, to throw doubt upon the long held belief that pellagra is due to the consumption of damaged corn. He preached his doctrine with such earnestness that a fund was raised to enable him to make a study of the subject in the heart of an Italian pellagrinous district. The results of his investigations have been embodied in a preliminary report (*Journal of Tropical Medicine and Hygiene*, September 15 to November 1, 1910) which, whatever may be an individual's views, provides very instructive reading. Of course, this report is, in the nature of things, inconclusive, but enough material has been collected to prove that Sambon's opinions are founded upon sound premises. The reason why he first doubted that corn was the cause of pellagra "was based principally upon the striking differences existing between the distribution of the pellagra endemic stations and that of the areas of maize consumption, as well as on the irrefutable fact that true pellagra was known to occur in people who had never eaten maize. Spanish experience was overwhelming on this point." Arguing from the analogy of many insect-carried diseases and pellagra Sambon looked for an insect host and thinks that he has found it in a Simulium. His arguments in this direction are strong if not wholly convincing. As yet all endeavors have failed to demonstrate a parasitic agent in pellagra, but up to the present time experiments have not been sufficiently exhaustive. The research work, indeed, has only been partly accomplished. It seems that further and more lengthy investigations would be necessary to demonstrate the presence of the causative organism, if such exists. Sambon has possibly shown the way, and it is to be hoped that he may be enabled to place the honor of the final discovery to his name. There are many, however, who are not in accord with the London scientist's views, and among these is Captain H. J. Nichols, U. S. Army, who thinks that Sambon has been perhaps too ready to jump at conclusions from somewhat inadequate data. On the other hand, several well known authorities now regard his theory of pellagra as deserving of close study; among these is Dr. Sandwith. The report is full, interesting, and logical, and will well repay a careful perusal by all who are brought into contact with this peculiar disease.

Vaccination Against Typhoid Fever in the United States Army.

Vaccination against typhoid fever has been conducted on a considerable scale in the army of the United States according to the most recent report of the Surgeon-General, a total of 11,771, of whom completed cards have been received, having been thus operated upon. The number of moderate and severe reactions was quite small, while of the total number vaccinated there have developed to date three cases of typhoid fever, with no deaths. It must be borne in mind that the Widal reaction as a means of diagnosis among persons who have been vaccinated is worthless, since the reaction appears immediately after immunization and persists for a variable length of time. Among such patients the only rational way of confirming a clinical diagnosis by laboratory methods is by using Wood cultures. Among the unvaccinated of the army the case of typhoid fever rate per thousand was 4.11 and the case rate among the vaccinated was .26 per thousand, seemingly a convincing argument in favor of the method. Somewhat roughly speaking, the incidence among the unvaccinated was nearly sixteen times higher than among the vaccinated. Thus the harmlessness of the procedure has been clearly demonstrated and its efficacy appears to have been proved also in a sufficiently satisfactory manner. The Medical Department has now done all that can be done in the direction of voluntary vaccination against typhoid fever in the army and it remains for the War Department to decide whether the time has come to require it as a routine procedure.

News of the Week.

In Honor of Dr. Weir.—On Saturday evening of last week Dr. Robert F. Weir was entertained at a dinner given in his honor at the University Club by his former house surgeons at the New York, Roosevelt, and St. Luke's Hospitals. The dinner was the outcome of the desire of Dr. Weir's old house surgeons, numbering two hundred or more, to manifest their affection for their former chief, to whose teaching and example they as surgeons owed so much. Because of the limited capacity of the banquet hall it was found necessary, however, to restrict the number of Dr. Weir's hosts to about seventy-five. Dr. Robert Abbe, the toastmaster, read a number of letters and telegrams from old house officers, now scattered over the country and regretfully absent, and then presented to Dr. Weir a beautiful répoussé chalice, which had been concealed in oriental fashion beneath a square of Japanese embroidery. This cup, it was said, had not two handles or three, as the ordinary loving cup, but a thousand invisible handles which all the friends of the recipient were eager to grasp with him. Dr. Weir delivered a reminescent address, referring to the New York surgeons of the middle of the last century, with whom and under whom he had worked, and mentioning incidentally that his total years of hospital service were seventy-six—this figure resulting from some overlapping double services. Addresses were also made by Drs. Maurice H. Richardson of Boston, W. L. Rodman of Philadelphia, and W. S. Halsted of Baltimore.

Health of the Canal Zone.—The report of the Department of Sanitation gives the total number of deaths among employees in the Canal Zone, during October, as 42, 23 being from disease and 19 from external causes, giving an annual rate per 1,000 of 10.19. In Octobers of other years the annual rate per 1,000 was as follows:

1904	20.31
1905	32.85
1906	46.68
1907	25.97
1908	12.93
1909	9.95

The annual average rate of death during October in Panama, Colon, and the Canal Zone, including both employees and civil population, was 23.61. During previous years the rate was:

1905	56.62
1906	46.40
1907	30.19
1908	27.91
1909	16.62

The increase in the rate for October, 1910, over that for October, 1909, was due to the increased number of deaths among infants from intestinal disorders in the city of Panama. A comparative statement of the death rate among canal employees on the Isthmus of Panama under the original French company from 1881 to 1888, eight years, and the American Commission from 1904 to 1909, six years, is included in the report. It shows that if the American employees had worked under the same sanitary conditions as did the French, there would have been 1,279 more deaths per annum than have occurred under American control. This means a saving of 7,674 lives in the six years of the American occupation, and a reduction of 70 per cent. in the annual death rate from disease, when the average numbers of deaths per 1,000 among the French and the American employees are compared.

October Death Rate.—The monthly bulletin of the New York State Department of Health gives the death rate for the entire State during October as 14.5, the total number of deaths being 10,942, while in New York City alone the rate was 14.0, and the total number of deaths 5,597. In the rural districts the rate was 15.8. About 21 per cent. of the deaths were of children less than one year of age. The total mortality was 464 less than during October, 1909, the reduction being fairly well distributed throughout the State.

More Typhoid Fever at Annapolis.—The twenty-ninth case of typhoid fever among the cadets at the Naval Academy developed on December 9. The authorities still attribute the epidemic to contaminated milk which was received at the academy prior to November 9. Since that date the supply of milk from the suspected source has been discontinued.

Pasteur Institute Burned.—A dispatch from Paris tells of the burning of the branch of the Pasteur Institute at Garches, near Paris, on December 7. The branch was located in the Chateau Villeneuse l'Étang.

National Red Cross.—The sixth annual meeting of the National Red Cross was held in Washington on December 6, when President Taft was reelected president of the society. The other officers elected are Mr. William W. De Forest of New York, vice-president; Mr. Charles A. Magee, secretary; Mr. A. P. Andrew, Assistant Secretary of the Treasury, treasurer. President Taft announced that New York City had already pledged $500,000, its quota of the

two million dollar fund which the society is endeavoring to raise, and that he considered this an earnest that the entire amount would be forthcoming. The Red Cross now has about fifteen thousand members in the United States. Announcement was also made that the society intends to prosecute those concerns which continue to violate the act of Congress of June 23, 1910, protecting the Red Cross insignia from manufacturers.

National Health Bureau.—In his recent message to Congress, President Taft renews the recommendation contained in his message of last year that a bureau of health be created "in which shall be embraced all those Government agencies outside of the War and Navy Departments which are now directed toward the preservation of the public health or exercise functions germane to that subject." President Taft further says: "I greatly regret that the agitation in favor of this bureau has aroused a counter agitation against its creation, on the ground that the establishment of such a bureau is to be in the interest of a particular school of medicine. It seems to me that this assumption is wholly unwarranted, and that those responsible for the Government can be trusted to secure in the personnel of the bureau the appointment of representatives of all recognized schools of medicine, and in the management of the bureau entire freedom from narrow prejudice in this regard."

Open-Air Classroom.—Plans have been filed with the Building Department of New York City for the erection of an open-air room and diet kitchen on the roof of the two-story public baths and gymnasium in the rear of Hudson Street Park, at a cost of $6,000. The roof room will be used as an open-air classroom for children inclined to tuberculosis, accommodations being provided for not more than fifty.

Cholera in Madeira.—A dispatch from Funchal, dated December 11, states that the cholera continues to rage there, 422 cases with 136 deaths having been reported since the outbreak began. All the physicians in the island have been impressed into the public service by the health authorities.

Measles on Ship.—The steamship *Pannonia*, which arrived in New York on December 10, was held at quarantine because of the large number of cases of measles on board.

Pasteurized Milk.—In reviewing the work of the recent milk conference in New York, Dr. Charles E. North of the New York Milk Committee says that the conclusion was reached that the only raw milk fit for human consumption is that produced under sanitary conditions from tuberculin-tested cattle, and that all other milk should be thoroughly pasteurized. The conference as a body adopted Meigs's classification which provides for these two kinds of milk only, this action being taken as the result of testimony given by many experts in the subject.

Hospital at Aix-les-Bains.—The gift of $40,000 for the improvement of the hospital at Aix-les-Bains from Mr. J. Pierpont Morgan is announced by Dr. Paul Guyenot of that city, who sailed for home on December 8. Dr. Guyenot has been in America for several months studying our hospital methods.

New Sanatorium.—The State Commissioner of Health has approved the application of the Tupper Lake Sanatorium Corporation for permission to establish a private sanatorium for the treatment of tuberculosis at Tupper Lake.

Prof. Frederic S. Lee.—The trustees of Columbia University on December 5, on the recommendation of the Faculty of the College of Physicians and Surgeons, appointed Frederic S. Lee, Ph.D., now professor of physiology, to be head of the Department of Physiology in succession to Prof. John G. Curtis, who retired on June 30, 1909. Dr. Lee has been connected with the College of Physicians and Surgeons since 1891, when he was appointed a demonstrator of physiology.

Dr. Louis H. Mutschler of Philadelphia has been elected visiting surgeon to the Episcopal Hospital in that city. Dr. Mutschler has already served the hospital for fifteen years as assistant surgeon.

Dr. Edward Martin of Philadelphia has been elected John Rhea Barton Professor of Surgery in the Medical Department of the University of Pennsylvania in succession to Dr. William White resigned.

Public Health Lectures.—Dr. H. L. Wheeler of New York and Dr. W. A. White of Phelps, N. Y., have been appointed by the State Commissioner of Health as lecturers and consultants on hygiene in the Department. They will deliver a series of lectures throughout the State on subjects pertaining to the public health.

Philadelphia Medical Examiners' Association.—At the annual meeting, held on December 6, the following officers were elected: *President*, Dr. A. T. Gaillard; *Vice-President*, Dr. F. S. Ferris; *Secretary*, Dr. J. D. Farrar; *Treasurer*, Dr. J. D. Morton.

American Society of Sanitary and Moral Prophylaxis.—A meeting of this society will be held at the New York Academy of Medicine on Thursday, December 22, at 8:30 P.M. Papers will be presented by Professors E. R. A. Seligman and Felix Adler on the Sanitary Supervision of Prostitution. The subject of the Control of Venereal Diseases by the Health Department will be discussed by Drs. Abraham Jacobi, Stephen Smith, Thomas Darlington, and Eugene H. Porter, State Commissioner of Health.

Medical Association of the Greater City of New York.—A stated meeting of this association will be held in the New York Academy of Medicine on Monday, December 19, at 8:30 P.M. A paper on "Morbific Processes Controlled by the Hypodermatic Use of Aseptic Chemical Solutions" will be read by Dr. J. Blake White. This will be followed by a discussion on "The Question of Reflex Disturbances."

Taylor County (Texas) Medical Society.—At the annual election of officers of the society held in Abilene on December 6 the following officers were elected: *President*, Dr. M. M. Carrick, Assistant Superintendent State Epileptic Colony, Abilene; *Vice-President*, Dr. J. A. Adkisson, Merkel; *Secretary-Treasurer*, Dr. J. M. Estes, Abilene. Dr. J. M. Alexander entertained the society at a banquet, fifty guests being present. Dr. M. M. Carrick acted as toastmaster.

Eau Claire District (Wisconsin) Medical Society.—At the annual meeting of the society, held on November 28, the following officers were elected for the ensuing year: *President*, Dr. R. R. Chase, Eau Claire; *Secretary-Treasurer*, Dr. E. L. Mason.

Gila County (Arizona) Medical Society.—At the organization meeting of this new society, held on November 22 at Gila, the following officers were elected: *President*, Dr. John Bacon, Miami; *Vice-President*, Dr. R. D. Kennedy, Globe; *Secretary-Treasurer*, Dr. J. L. Wales, Globe.

Black Hills (South Dakota) Medical Society.—The following officers were elected at the annual meeting held at Deadwood on November 22: *President*, Dr. F. S. Howe, Deadwood; *Vice-President*, Dr. A. S. Hoon, Nemo; *Secretary*, Dr. W. L. Vercoe, Lead; *Treasurer*, Dr. F. E. Clough, Lead.

Montgomery County (Ohio) Medical Society.—The annual meeting of the society was held in Dayton, on December 2, when officers were elected as follows: *President*, Dr. A. L. Light; *Vice-Presidents*, Dr. Charles Hunt, Dr. Harry B. Harris, and Dr. C. W. Salisbury; *Secretary*, Dr. H. H. Hatcher; *Treasurer*, Dr. William Prather.

Hancock County (Ohio) Medical Society.—The following officers were elected at the annual meeting held on December 1: *President*, Dr. W. N. Yost; *Vice-President*, Dr. L. E. Todd; *Secretary*, Dr. E. H. Cooper; *Treasurer*, Dr. J. A. Kimmell.

Elkhart County (Indiana) Medical Society.—At the annual meeting held on December 1 the following officers were elected: *President*, Dr. C. W. Frink; *Vice-President*, Dr. G. W. Kirby; *Secretary*, Dr. E. M. Hoover

Mr. Isaac Stern.—In the death of Mr. Isaac Stern of New York, which occurred on December 5, Mt. Sinai Hospital loses the president of its Board of Directors, and one who for many years had been actively devoted to the service of the hospital. Mr. Stern was also a member of the Board of Directors of the Mt. Sinai Hospital Training School for Nurses and vice-president of the Hospital Saturday and Sunday Association. His will provides for a bequest of $10,000 to Mt. Sinai Hospital, to be known as the Isaac and Virginia Stern endowment fund, the income to be applied as the directors may determine.

Deaths of Foreign Medical Men.—Dr. Henri Huchard of Paris died on December 11. He was well known for his original work on arteriosclerosis and diseases of the heart and arteries. Professor Angelo Morro, the eminent Italian physiologist, died the early part of this month at the age of sixty-four years. He had made a special study of the phenomena of fatigue, being the inventor of a well-known form of ergograph. He was a senator in the Italian Parliament.

Obituary Notes.—Dr. JOHN C. DA COSTA of Philadelphia, Pa., died at his residence on December 6, of kidney disease, aged 76 years. Dr. Da Costa was born in Philadelphia and was graduated from the Jefferson Medical College in that city in 1878. At the time of his death Dr. Da Costa was emeritus gynecologist at the Jefferson Medical College, chief gynecologist to St. Agnes' Hospital, and president of the Philadelphia Obstetrical Society. He was also a member of the American Medical Association and of the Pennsylvania State and Philadelphia County Medical Societies, and a Fellow of the College of Physicians of Philadelphia and of the American Surgical Association.

Dr. WILLIAM WATSON of Dubuque, Iowa, a graduate of the Rush Medical College, Chicago, in 1854, a veteran of the Civil War, died at his home on November 21 aged 74 years.

Dr. HENRY HUTCHINSON of St. Paul, Minnesota, a graduate of the Hahnemann Medical College of Philadelphia in 1874, formerly professor of the theory and practice of medicine in the College of Homeopathic Medicine and Surgery of the University of Minnesota, a member of the staffs of St. Luke's, St. Joseph's and the City and County Hospitals, president of the Minnesota State Board of Health since 1901, a member of the Minnesota State Institution of Homeopathy, the Minnesota State Anti-Tuberculosis Society, the American Public Health Association, and the American Institute of Homeopathy, died suddenly at the Hotel Mustapha Superieur in Algiers on December 1 of heart disease, aged 61 years.

Dr. OLIVER ROLAND of Lancaster, Pennsylvania, a graduate of the Medical Department of the University of Pennsylvania in the class of 1875, for many years a member of the School Board and of the Board of Health, physician to the Children's Home, and a trustee of the Stevens Industrial School and the Lancaster Free Library, a member of the American Medical Association and the Pennsylvania State and Lancaster County Medical Societies, and consulting physician to the Lancaster General Hospital, died at his home of apoplexy on November 21, aged 60 years.

Dr. EMILY PARDEE-DISBROW of South Norwalk, Connecticut, a graduate of the New York Medical College and Hospital for Women in 1875, a member of the American Institute of Homeopathy and of the Connecticut State Homeopathic Society, died at her home on November 30.

Dr. JOHN FREDERICK HALLER of Brooklyn, N. Y., a graduate of the medical department of the University of Buffalo in 1888, examining physician of the Department of Charities, New York, visiting surgeon to the Swedish Hospital and consulting gynecologist to the Jamaica Hospital, a member of the New York State and Kings County Medical societies, and of the Association of Military Surgeons of the United States, died at his home on December 3, of pneumonia, after a brief illness, aged 44 years.

Dr. JOHN CUMMINGS MUNRO of Boston, Mass., a graduate of the Harvard University Medical School in 1885, consulting physician to St. Luke's Home, consulting surgeon to Quincy Hospital, and surgeon-in-chief to the Carney Hospital; formerly lecturer in surgery in the Harvard University Medical School; a member of the American Medical Association, the Association of American Anatomists, the American Surgical Association, and the Massachusetts State and Suffolk County Medical Societies; president of the Society of Clinical Surgery, honorary member of the Vermont Medical Society and of the Canadian Medical Association, and honorary fellow of the Philadelphia Academy of Medicine, died at his home, on December 6, aged 52 years.

Dr. HORACE BABCOCK of Gowanda, N. Y., a graduate of the Medical Department of the University of Buffalo, surgeon in the 2d Wisconsin Regiment during the Civil War, died at his home, on December 5, aged 86 years.

Dr. FRANK E. MCGANN of Mount Sterling, Ill., a graduate of Barnes Medical College, St. Louis, in 1904, a member of the Illinois State and Brown County Medical Societies, and coroner of Brown County, died at his home of typhoid fever, on November 28, aged 30 years.

Dr. Benjamin Franklin Spurgeon of Chico, Cal., a graduate of the University of Louisville, Medical Department, in 1874, a member of the California State and Butte County Medical Societies, died at his home, on November 24, aged 57 years.

Dr. Felix F. Porter of Paris, Tenn., a graduate of the Medical Department of the University of Pennsylvania in 1859, died at his home on November 27.

Dr. Frederick William Van Slyke of St. Paul, Minn., a graduate of the Minnesota Hospital Medicine Medical College in 1883, a member of the American Medical Association and of the Minnesota State and Ramsey County Medical Societies, died at St. Joseph's Hospital, St. Paul, on November 23, aged 54 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

GENERAL MEDICAL COUNCIL.—RAT PLAGUE, OFFICIAL CIRCULAR.—FRACTURES NEAR JOINTS.—ALTERNATING ANESTHETICS.—ENDOMETRITIS.—OBITUARY.

London, November 25, 1910.

The General Medical Council met on Tuesday, when the president, Sir Donald MacAlister, gave an address. He said he had reason to believe that a bill now before Parliament would remove the disabilities of midwives trained in Ireland. He had official authority to state that the inquiries of the Local Government Board into unqualified practice would be published in a Blue Book in a few days. A more important memorial would be laid before the council, supported by a letter from the Colonial Office, concerning instruction as to tropical diseases. It was desired that a certificate or diploma, such as that given in Public Health, should be obtainable from the various examining bodies and registered by the council. Sir Donald had ascertained that, if desired, a clause to effect this would be proposed by the government at an early date. All this sounds fairly optimistic but takes no account of the fact that we are in the midst of a general election with its uncertainty, and even if the same party should be returned, the present government holds the record for making promises and evading them when fulfillment is due.

As to the Blue Book mentioned, it was issued yesterday and officially confirms the frightful amount of quackery that is a familiar fact to all practitioners. The board find it difficult to say, categorically, whether unqualified practice is increasing, though in some districts the evidence is said to be in that direction. London does not seem quite so bad as some provincial towns. Counter prescribing by chemists is shown to be general and diminishes by delay the chance of cures. Bonesetters flourish most in the northern districts and in Wales. Quack medicines are sold largely to the poor and also in enormous quantities to the well-to-do and many are said to contain powerful poisons. When the General Medical Council has digested this Blue Book they might well reflect on their own negligence in making no effort to effect a change. Established to prevent practice by unregistered persons, they have contented themselves all those years in taking fees for registration and talking about the duties they have not performed.

The Local Government Board on Saturday issued a further statement as to rat-plague in which it is said that one of the inspectors has been inquiring for several weeks into the extent of the disease in East Suffolk with a view of securing concerted action by the various authorities. With him are associated three of the board's medical inspectors to investigate over a wider area. Further, Dr. Martin of the Lister Institute is investigating the outbreak on a large scale, the kinds of rodents predominating in the districts, and the flea parasites of these rodents. Other inspectors have been instructed to make inquiries in various parts of England, but up to the present infected rats have been found only in five districts. Valuable help has been rendered in East Suffolk by Dr. Heath, who has accordingly been specially appointed to deal with the matter by the County Council and other authorities are co-operating. The official statement adds that although cases of plague in man are unlikely to arise arrangements are being made by the various authorities for the early recognition and isolation of any such cases should they occur.

The Surgical Section of the Royal has allotted two evenings to a discussion on "Fractures in the Neighborhood of Joints." The opening paper was by Mr. Robert Jones of Liverpool, whose experience as hospital surgeon and university teacher gives great authority to his views. It is well they should be fully considered and I greatly appreciate a remark with which he began as to the way in which a broken bone is often left from first to last to the house surgeon, as if it were of slight importance. It is true, too, that every practitioner is expected to be able to treat a fracture, though many stiff and useless joints confront us and give occasion to serious misgivings.

Mr. Jones recognized that students nowadays are taught to rely too much on a radiograph for diagnosis, the interpretation of which is by no means free from difficulty. During the last twenty-five years he said he had treated many fractures involving the functions of the joints and a large proportion were not recent and had given rise to deformity or disability, or both. Patients suffer far more from disability than mere appearance and so he regarded every fracture as a potential cause of disability. In all fractures near a joint the mechanical function of that joint must be considered even more than its anatomy. Common disabilities in the shoulder after neglected fractures are deficient abduction and rotation; in the hip diminished range of these and often of extension; in the elbow fixation at an inconvenient angle; in knee, genu valgum and sometimes flexion. The special deformities and disabilities of injuries should be studied, anticipated, and so prevented. Mr. Robert Jones then proceeded to lay down his method of dealing with the fractures connected with the several joints and this at sufficient length to constitute a valuable clinical essay founded on his exceptional experience. Summarizing, he pays more attention to function than appearance, considering correct alignment to be more important than meticulous care in reposition of fragments, holding that pain is always an indication for physiological rest and, therefore, depreciating early forced passive movements.

If in some cases he prefers manipulation and fixation when others would prefer an open operation, he admits it may, perhaps, be because the increasing proportion of his work has been in the treatment of deformities and disabilities, whether of traumatic origin or not, has given him more con-

fidence in carefully graduated force in cases where some might hesitate to use it.

Mr. Rushton Parker said in any fracture between the clavicle and elbow it was of greatest service for diagnosis and treatment to sling the arm to the neck and flex the elbow to a rather acute angle. The upper limb was thereby bent into two portions, one containing hand and forearm suspended from the neck; the other only suspended from the shoulder. An upper arm was thus relieved of the weight of the forearm, which, if left loose, caused pain and deformity. In the lower part the tendency to adduction of the condyles could me met by a twist given to one of the lower splints, if of sheet metal.

Mr. R. Warren said the greatest accuracy was required when the cartilage-covered bearing surface of the joint was involved and in such open operation was more likely to be needed than when the fracture was in the vicinity but outside the capsule.

Mr. R. H. A. Whitelocke thought in all cases of fractured patella with much separation the open method was the only satisfactory one. Since the recent legislation the public was not satisfied with good functional results. He said Mr. Jones had struck the right note in emphasizing the important rôle of correct alignment especially in the lower limbs.

When prolonged anesthesia is required the plan of maintaining it by alternating the agents has recently been tried, ether being first given, or ethyl chloride at first, and afterwards nitrous oxide being employed to keep up the anesthesia. The method seems to have been due to the fact pointed out by Crile, that collapse was less frequent after nitrous oxide and oxygen than after other anesthetics and that overstimulation by the ether might partly be to blame. Mr. Flemming brought the subject before the section of anesthetics in a paper reporting eighty-six cases in which the plan was used, the prevailing idea being to decrease the amount of ether by alternating its exhibition with gas. In many cases there was no nausea and in none was there postoperative collapse. The numbers did not exclude the possibility of coincidence but Mr. Flemming thought them worth submitting to the section. He said the method demanded minute attention to decide just when to change from ether to gas, or vice versa. This usual routine was to induce anesthesia with ethyl chloride and ether, maintain it by ether (open or closed plan) for 15 or 20 minutes, in fact, till the operation was well under way, then substitute nitrous oxide and oxygen, with frequent breaths of fresh air, for from 3 to 5 minutes, then change back to ether and so on throughout. Thus gas anesthesia was, as it were, superimposed on the ether intoxication and generally it was found possible as the operation progressed to shorten the times of ether and lengthen those of gas. Mr. Flemming was satisfied that a perfecely smooth anesthesia could be maintained in this way and among the patients who proved favorable subjects were some for whom gas alone would not have been suitable, *e.g.* alcoholic men, very stout persons, and senile subjects.

Mr. Gill said he had given ether and gas alternately for short operations. He was glad stress was laid in the paper on limiting the dose and maintaining as light as possible a degree of anesthesia.

Dr. Blumfield had had similar experience in short operations and asked if reflex phenomena had been met with.

Dr. Silk did not consider rapid recovery wholly advantageous as the period of analgesia masked postoperative pain. The plan would require great skill and consume much gas.

Mr. Boyle said why not induce the anesthesia with gas. He thought it must be difficult to maintain level anesthesia by alternating.

Mr. Flemming, replying to this and to others who rather supported it, said he was himself surprised both by the ease with which level anesthesia was maintained and at the satisfactory after results.

In the Obstetrical Section a paper was read dealing with the clinical aspects of chronic endometritis, employing the term as a matter of convenience, although it was admitted that real inflammation was probably rare. Drs. Donald and Shaw were the authors and they comprised in their summary cases in which there were menorrhagia, metrorrhagia, leucorrhea, dysmenorrhea, and pain in the lower abdomen, associated with a moderately enlarged uterus which was tender on palpation. So far pathology had given little help. The chief object of the paper was to state the results of curetting in different types. Notes of 267 cases were taken and the condition of the patients ascertained twelve months after treatment. The general result was 230 were relieved and 37 not. The large majority did not get full benefit until some months after the operation. In dysmenorrhea the results were very good, and this supports the view that this symptom is often due to an abnormal condition of the endometrium. In leucorrhea the results were not quite so good; only cases in which the discharge was certainly uterine were included. In sterility the results were good—pregnancy following in one-third of the cases.

Surgeon-Major-General James Sinclair, A. M. S., Honorary Physician to King Edward, died on November 21, aged 78. He served in Ceylon, Malta, Gibraltar, Bombay, Abyssinia. He was at Magdala in 1868. Was mentioned in despatches and after holding a number of home appointments retired.

Brigade-Surgeon Lieutenant-Colonel J. M. Murray, M.D. Ed., F.R.C.S., died on Thursday, 17th inst. He served in New Zealand in 1860 and was present in several engagements, for which he received a medal. He retired in 1892.

Mr. Mitchell Henry, F. R. C. S., whose death was reported yesterday, was once on the surgical staff of the Middlesex Hospital but he abandoned the profession for a mercantile career in 1862 and subsequently took also to politics. He was first M. P. for Galway but later held a division in Glasgow, 1885-6.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

MANILA MEDICAL SOCIETY.—INFECTED AERATED WATERS.—ANTI-TUBERCULOSIS WORK.—DIFFICULTIES IN CONNECTION WITH THE NEW WATER AND SEWER SYSTEMS.—606 IN YAWS.—PERSONAL.

MANILA, October 26, 1910.

THE regular monthly meeting of the Manila Medical Society was held at the Philippine General Hospital on the evening of October 3, 1910. A paper was read by Major Brookes of the Army Medical Corps entitled "The Report of Recurring Abscess of the Liver." The next paper was a "Report of a Probable Case of Pellagra," by Dr. D. Willets of the Philippine Medical School. Dr. Willets, while on a hookworm commission in the Province of Isabela,

found a case which presented the typical clinical manifestations of this disease, but he had some hesitancy in making a positive diagnosis because it is the first reported case in the Philippine Islands.

The necessity for constant vigilance and frequent inspections in connection with health matters was forcibly demonstrated recently by the inspection which was made by the Bureau of Health of the aerated water factories. While the routine inspection of these was being made monthly for a number of years and the use of sterile water made obligatory, yet upon more careful examination it was found that it was the custom of many of the factories as soon as the inspector had left to disconnect their sterilizing plant and use the raw water from the city mains which is, of course, ameba infected and undesirable in every way for bottling purposes.

The Anti-Tuberculosis Society still continues to make considerable headway in organization. Branches of the society were recently started in Zamboanga and Cebu. Through the aid of the Anti-Tuberculosis Society the Bureau of Health was enabled to open its sanatorium and night camp at San Juan del Monte upon an elevated sanitary site and within street car distance of Manila. Two weeks ago the sanatorium was made ready for the care of thirty patients and all this available space has already been occupied; in addition, tents have been provided for a night camp which will accommodate one hundred persons. The interest of the public has been thoroughly aroused. A number of public meetings have been held; large quantities of literature for public distribution have been prepared; a number of local theaters have held benefits for the society and a general awakening with regard to combating this disease has been manifested.

At the time the new water system for the City of Manila was put into operation it was thought that the watershed from which the supply was obtained could easily be freed of human habitation; it now develops, however, that in addition to the town of Boso Boso, which was recently depopulated, some 20,000 hectares of land still remain in the possession of private individuals, and at least 1,500 hectares of this is excellent farming land. The owners of one of the farms have held out such inducement for settlement that many of the persons who heretofore lived at Boso Boso and whose rights were bought out at considerable expense are now settling down on this new site which is still on the watershed. In the little towns which they have established large numbers of horses and carabaos and other animals are quartered close to the banks of the principal stream and the drainage from the stables flows directly into it. There is also considerable danger of the water being contaminated by the latrines which are used in connection with the dwelling houses. This land is rapidly advancing in value and it is feared that it will soon be beyond the resources of the Government to purchase the same.

During the past few months considerable difficulty has been experienced from the odors which arose in connection with the Calle Herran pumping station of the new sewer system. Persons who live in the vicinity complained bitterly of the nuisance created. A board was finally appointed composed of the city engineer, the chief of the department of sanitation and transportation and the director of health. After a thorough investigation it was found that the trouble arose from bags, dresses, stockings, and other foreign matter found in pails being dumped into the sewer and thus clogged the inlet pipes of the pumps which resulted in the fluid contents being pumped away and the solid matter being left behind, and that in order to remedy this condition of affairs the native attendants who are in charge of the pumps opened the manholes and forced the solid matter onward. The agitation caused by this process was directly responsible for the odors which arose. Steps were taken to prevent the introduction of these foreign substances and no further trouble has been experienced.

Considerable success has been had recently in treating cases of yaws with Ehrlich's new preparation 606. One patient who had extensive eruption on the face and arms was completely cured within a period of ten days. Other cases are now under treatment and a result of the same will be furnished later.

Dr. M. Reichard, formerly of Philadelphia, who was appointed to the Coast and Geodetic Survey, has arrived in Manila and has been assigned to duty on the S. S. Fathomer. Major Lyster of the Army Medical Corps is doing the eye work at the University and at St. Paul's Hospital.

Progress of Medical Science.

Boston Medical and Surgical Journal.

The Doctrine of Vitalism in Medicine. M. G. Seelig.
Present Knowledge of the Laws of Heredity. W. P. Graves.
Postoperative Psychoses. J. G. Mumford.
A Case of Myxofibrosarcoma Originating in the Great Omentum with Involvement of the Bladder and Small Intestine. H. Cabot.

Vitalism in Medicine.—M. G. Seelig states that vitalism concerns itself solely with the abstract thought that there is inherently resident in living matter a directing element or force that is not under the control of the known laws of physics or chemistry. Vitalism is the *testimonium paupertatis* of the scientist, his credo expressed in terms of honest agnosticism. Antipodal to this doctrine of the inscrutability of the fundamental basis of life stands the dogma of the nonvitalist; that since many of the phenomena of life conform with the laws underlying the properties and actions of inorganic bodies one has every reason to assume that the sum total of activities constituting life is as much subject to the laws of chemistry and physics as is the sum total of activities of gunpowder or of the threshing machine. According to this view the human body is a machine, not only in the sense that its activities are directed toward a purposeful end, but also in that each step toward the accomplishment of this end is predicated upon a definite axiom. The sum total of these axioms constitutes the great body of natural law. There are, says the nonvitalist, many axioms still in the crucible of proof, many still unguessed; but the result of the final assay will invariably be the disclosure of a principle as essentially mechanical, physical or chemical as are the already established laws of the inorganic world. The assumption of an intangible, immeasurable vital force is, according to the doctrine, unnecessary and, to say the least, uninspiring.

Laws of Heredity.—W. P. Graves discusses this subject under the following headings: germinal continuity; physical basis for the laws of heredity; proof that the nucleus is the bearer of heritable characteristics; heredity and variation; modifications; inborn variations; discontinuous variations or mutations; telegony and maternal impressions; transmission of acquired characters; heredity in disease; law of filial regression; the law of ancestral inheritance; Mendel's law, and eugenics.

Postoperative Psychoses.—J. G. Mumford states that experience teaches that many persons subject to physical

and mental assaults—to what one calls traumatism and to shock—receive serious mental impressions, which can be demonstrated clinically through searching our records, and can be demonstrated anatomically through the examination of the brains of experimental animals and of patients who have died as a result of some form of physical or mental shock. The clinical evidence of disturbed mental equilibrium is familiar to all surgeons, and the author's researches show that such mental disturbance is especially liable to ensue after operations on the generative organs of both men and women when those organs have not been actually removed, but have been tampered with that the patient lives on in dread of their loss at some future time. For example, operations for varicocele and hydrocele are followed by more pronounced and prolonged neuroses than is the operation of castration. The operations of suspension of the uterus or repair of the perineum frequently leave behind them traits of mental depression more serious than does the operation of ovariotomy, or even of hysterectomy. The explanation in this case seems to be that those deprived of important organs are able to readjust themselves to a positive calamity more readily than are those patients who continue an existence of anxiety regarding a possible future calamity. In view of this situation it behooves surgeons to provide in every way possible against adding physical and mental traumata to their patients. This proposition in itself opens a field of wide speculation and interest and of the greatest practical importance. One must endeavor to guard against mental shock by surrounding the patient with appropriate psychic influences, and to guard against physical shock by limiting operative manipulations to the least possible traumata of the parts involved, and one must employ anesthetics judiciously and appropriately. The conduct of convalescence must be made more painstaking, more optimistic, and more prolonged. One must impress upon the patient the certainty of his return to perfect health; one must eliminate a needless repetition of painful dressings, which so frequently lead through summation to a depressing dread of the surgeon's visit; and after the wound is healed and the patient leaves his bed we should continue, through ourselves, our associates, and the patient's family physician, a constant and sustained attitude of optimism and encouragement to take up and practise the familiar duties and experiences of a well regulated and normal life.

Myxofibrosarcoma.—H. Cabot reports a case of this condition originating in the great omentum, in which the tumor involved the bladder and small intestine. The patient was successfully operated upon. The case is reported on account of its rather unusual character, and as showing how apparently hopeless growths may at times be found curable by operation.

Iodine.—F. T. Woodbury, on the basis of wide experience, advocates the use of iodine as the sole antiseptic throughout operations for sterilizing hands, instruments, and suture material (at the time of operation without previous preparation), and for its local application in the full strength of the tincture throughout the extent of all wounds and suppurative cavities and on every raw surface infected or likely to be infected, and as an irrigation, in varying, suitable strengths, in all phlogistic conditions where the drug may be brought in contact with the bacterial cause, and as he cannot find in standard textbooks on pharmacology and therapeutics and surgery any reference to iodine as an antiseptic except in a vague way as being liberated from iodoform in the cavities of tuberculous abscesses or as used in the Claudius method of preparing catgut, he believes that he is the first to introduce this very valuable action of iodine to the profession.

Regulation of Prostitution.—F. Bierhoff refers to the protest made by the committee representing various women's clubs against the new statute providing for the medical examination of convicted prostitutes and their subsequent detention and treatment. He states that prostitution is a product of social conditions and economic causes which no legislation can abolish. No laws can force men and women to be all alike in their natural impulses, nor in their powers to resist these. While society may—and should—try, by educational means, to lead men and women to a better understanding of their moral obligations toward each other and toward the community, no laws can compel this understanding and its observance. Prostitution will continue to exist, and with its existence there will be a continuance of the ills consequent upon it. It cannot be legislated out of existence, nor can the ills. The most that legislation can do is to attempt to decrease, in a measure, open and flagrant solicitation upon the streets; to protect the young, innocent, and inexperienced from contamination by hardened offenders, and to protect the health of the community, guilty and innocent alike.

Hypernephroma.—L. W. Blackburn in reporting two cases of hypernephroma of the kidneys and one of what may be designated as adrenal hyperplasia with fatty infiltration of the adrenal cells, states that the term hypernephroma is one given to an epithelial cell growth now known to be derived from adrenal tissue, whether of the gland itself or aberrant hypernephric tissue situated elsewhere; being most frequently met with in the kidney, the term usually implies a renal tumor if unqualified. Knowing that there is in the adrenal gland only mesodermic epithelium, mesodermic connective tissue, and a few ganglionic nerve cells, one must acknowledge that in this neoplastic derivative there is a potentially or actually malignant combination tumor, the essential elements of which are mesodermic epithelial cells. The growth is, however, not essentially different from the mesoblastic malignant epithelial growths of the kidney and other organs of known mesoblastic embryogenesis. It differs from those tumors, however, in several respects which entitle it to a recognition as a special tumor though closely allied to so-called ordinary mesoblastic cancers.

Cystourethroscopy.—L. Buerger describes the operative technique of this procedure, stating that the cystourethroscope has a still wider scope of utility in the execution of therapeudic procedures than the older instruments. As for the ease and exactness with which even complicated operative measures can be performed, one can say without hesitation that the irrigation instrument surpasses the direct vision types.

A Case of Hypernephroma.—J. A. Jackson reports a case of this condition occurring in a patient who had pulmonary tuberculosis with an enterocolitis; the tumor was found at the post-mortem examination. There were no evidences of metastasis, the adrenals were free, and the growth was confined to the right kidney; a brief description of this organ comprises the body of the report.

Arsenic and Syphilis.—S. C. Runnels states that from a theoretical standpoint sodium cacodylate has several

advantages over dioxydiamidoarsenobenzol. The latter cannot be obtained in this country at present, while the former is at hand, and it is only necessary to test its purity before using. 606 will probably be very expensive, while the cost of the other is merely nominal. 606 causes pain on injection, while the cacodylates do not. Of the two the instability of the dioxydiamidoarsenobenzol is the more marked, for while the cacodylates break down in a few months, giving off poisonous products, it is necessary to ship the other in hermetically sealed vacuum capsules to prevent immediate decomposition. The maximum dose of the cacodylates, for safety, 0.3 gram per kilogram, is twice the size of that of 606, 0.15 gram per kilogram, proving that in the experimental animal it is much more safe. The arsenic content of 606 is 34 per cent., while that of sodium cacodylate is 46.8 per cent.; the latter, therefore, is capable of delivering, weight for weight, 38 per cent. more arsenic. Theoretically there seem to be some grounds for belief that sodium cacodylate should be more than a third more efficacious The entire dose of sodium cacodylate is dissolved in the blood, whereas a large percentage of 606 remains unabsorbed and therefore unacted upon at the site of injection. This means that those who have been treated with 606 afterward carry around in their persons indeterminate amounts of arsenic. This has in no way had any therapeutic action and is worse than wasted. It is said in favor of Ehrlich's compound, however, that that portion of it which enters the blood possibly breaks down with more ease and therefore delivers its arsenic content more readily than does sodium cacodylate.

Centenarians.—J. Knott believes that the production of centenarians has become a much more familiar feature of the accepted records of human existence within the past few decades. Some observers of the undoubted fact would explain it by the more accurate registration of births and deaths, which embalms facts that were formerly allowed to perish—either by negligence or scepticism, or a combination of both. Others, who happen to be optimistic believers in the efficacy of the methods of modern hygiene and sanitation, would attribute the prolongation of the span of human existence to the results obtained under their combined preventive and preservative influences. All the evidence which is now before the scientific world goes to show that the span of average human life is lengthening; so that one has this consoling consideration to offer its small contributory item of comfort to the wearied in an age of hurry and worry—universally expanding, as regards both national and individual progress, as these detestable features of modern existence unquestionably are. The additional physical comforts, the sanitary improvements, and the almost universal diffusion of some of the sound elementary facts and concepts of hygiene and allied sciences have more than compensated, upon the whole, for the excess of wear and tear produced by the increased speed which is now so necessary for competition in the race for material success, and the progressive emulation which the growth of numbers and the gradual elevation of the altitude of the higher test standard of skilled labor—mental as well as physical—have necessarily created in every locality and in every profession and occupation of life.

Cholelithiasis.—C. M. Stimson reports a case the interesting points in which were the existence conjointly of three pathological conditions, namely: cholelithiasis, primary carcinoma of the liver, and chronic fecal obstruction, and also the presence of almost continuous intense pain from the time the patient was confined to bed.

Cocaine Intoxication.—N. S. Yawger describes the symptoms and treatment of acute and chronic cocaine poisoning.

Etiology of Ptoses and Their Relation to Neurasthenia.—E. Reynolds presents this paper which was reported in MEDICAL RECORD, July 16, 1910.

Recruiting and Preventive Medicine.—W. H. Rennie states that the one essential requirement for the best results in selecting recruits is the strict adherence to a fixed, invariable, systematic routine method of examination. He gives instances of the influences brought to bear on recruiting surgeons, both for and against enlistment, by friends and states the requisites of an efficient recruiting surgeon as follows: Good powers of observation, a keen eye, mental alertness, considerable knowledge of human nature, complete understanding as to service conditions, and the calls that are made in each rating and, with all this, a proper interest in the service. Landsmen surgeons have been found repeatedly not to obtain the best results in recruiting on account of their lack of the special training required under actual service conditions.

Conservative Utilization of Wassermann Reaction.—D. M. Kaplan reaches the following conclusions: When a serum is submitted for diagnosis the laboratory report should read "negative" or "positive." No qualifications as to degree are necessary. For diagnostic and therapeutic purposes the laboratory report should always be collated with clinical findings. Negative reports are of value in therapy. Treatment should be stopped for from four to six months after the patient becomes clinically and serologically normal, and at the end of this period the test should be repeated. All patients having been cured of syphilis ought to have for preventive purposes a test performed twice a year. Some patients who have had syphilis never lose the positive reaction in spite of any therapy. A negative report obtained on a serum from a suspicious case should defer treatment until the course of the disease decides the etiology, provided there is no danger in delaying treatment. With a positive report one must not lose sight of the possibility of another disease being present beside syphilis. Advanced scleroderma and old leprosy are more positive than old syphilis, quantitatively and qualitatively. In active tabes 88 per cent. and in quiescent tabes 44 per cent. of positive reactions were obtained.

The Colonoscope.—H. Stern describes an instrument for the inspection of the sigmoid flexure which he claims possesses a number of advantages over other instruments intended for the same purpose.

Exophthalmos in Brain Tumor.—T. H. Weisenburg alludes to the small attention that has been given to the subject of exophthalmos in connection with brain tumor in the literature of the subject. His attention was particularly directed to it by a number of cases which he has observed during the last few years. Eight of these are briefly reported. In five a necropsy was made. The neoplasms were located in nearly every part of the cranial cavity and varied in their nature so that there appeared little connection between the character of the tumor and its location and the exophthalmos. In some cases the or-

bits were examined and in others the nature of the growth was such as to preclude any metastasis to the orbital cavity. Basedow's disease was excluded in all. The exophthalmos was bilateral in all the cases of internal hydrocephalus and those in which the tumor involved both sides of the brain, with the exception of a basal tumor. In the unilateral growth it was on the side of the lesion. The conclusions which he draws from the study of the subject are: Exophthalmos accompanies brain tumor more frequently than is generally supposed. It occurs only in those cases in which there is great intracranial pressure, especially when there is, in addition, direct interference with the normal flow of the cerebrospinal fluid. Exophthalmos is produced by direct pressure on the cavernous sinus. Its presence is of some clinical value, inasmuch as unilateral exophthalmos is nearly always indicative of an intracranial lesion on the same side. In those cases in which the protrusion is bilateral there is nearly always a greater exophthalmos on the side of the greater intracranial pressure or lesion.

Brain Tumor of Psychomotor Area.—F. W. Langdon and S. P. Kramer report a case of tumor in the left psychomotor area with visual hallucinations, somatic delusions, astereognosis, and right hemiplegia, but without the usual symptoms of headache, vomiting, vertigo, and papilledema to any extent manifest. Recovery followed operation and removal of a tumor imbedded in the brain, adherent to the pia and involving the middle third of the left precentral convolution, growing downward and diagonally backward across the Rolandic fissure and displacing but not invading the post-central convolutions. It was encapsulated, presenting numerous small protrusions and cysts on its buried or subcortical surface. Its weight was 26 grams, and on microscopic examination it proved to be an endothelioma, starting from the pia mater. The case is considered worthy of report on account of the peculiar mental symptoms and somatic disturbances without the usual general symptoms of brain tumor. There were no speech disturbances other than those due to mental condition.

Cerebellopontile Tumor.—J. Grinker reports three cases of tumor in the cerebello-pontile angle. In the first case three operations were performed before the tumor was detected and a portion of it was removed. The patient afterward died and at the autopsy the entire left hemisphere was found occupied by a gliomatous consolidation. The history of the case brings out prominently the following points: 1. The presence of pulsation does not necessarily mean absence of tumor underneath. 2. Once a patient has become blind and other symptoms such as severe headache, vomiting, and vertigo are not troublesome, a radical operation may possibly verify a doubtful diagnosis but is of no service to the patient. This fact should lead to the performance of decompression before blindness comes on. Lumbar puncture may occasionally prove beneficial in such cases, with due care to prevent sudden escape of fluid. In this patient the removal of only about an ounce of cerebrospinal fluid relieved a headache which had resisted all other treatment. The second case, in which the patient also died but in which there was no autopsy, emphasized the importance of unilateral sensory disturbances as a suggestion of organic disease, and the fact that focal symptoms of cerebellopontile tumors often precede the general symptoms by a considerable period of time. In the third case the symptoms were rather characteristic, but a diagnosis of cerebral hemiplegia had been made because of a sudden appearance of right-sided weakness combined with facial involvement. This symptom occurring in tumors in this location has been differently accounted for by authorities, some claiming it to be a real motor paralysis and other explaining it as a sign of cerebellar asthenia. Among the latter is Luciani who described three symptoms as characteristic of cerebellar lesion produced experimentally, namely, atonia, asthenia, and abasia. Clinicians have found this triad of symptoms in disease of the cerebellum, and particularly in tumor of that region. In this case the headache was principally in the frontal and parietal regions instead of in the occipital, but this symptom has little localizing value.

Subtentorial Brain Tumors.—H. H. Hoppe states that one cannot lay too much stress on the early diagnosis of tumors of the cerebello-pontile angle, since in their early stages they are very amenable to surgical treatment, though later little is to be hoped for from it. The aurist should be the first to recognize them, because of the prominent ear symptoms and impairment of hearing. Tumors of the cerebello-pontile angle show a predominance of unilateral focal signs on the part of the fifth, sixth, seventh, and eighth nerves, whereas tumors of the pons and medulla show bilateral focal signs with a clear indication of alternate hemiplegia. In both the focal signs may precede the general signs of brain tumors. Pons and medulla tumors, being small, produce less marked signs of brain tumor, whereas angle tumors have, later on, well-marked general signs. Choked disk is usually absent in pons tumor, but in angle tumors is almost invariably present, together with headache, vomiting, and vertigo partly due to an associated hydrocephalus. Not only is it difficult to say whether the disease is unilateral or not, but it is often difficult to rule out growths of the frontal lobe or to say certainly whether the symptoms are caused by tumor, or acquired internal hydrocephalus, or whether there is no tumor at all, but only a case of pseudotumor of the brain. The author takes up separately cerebellar ataxia, which is typical probably only in tumors of the vermiform lobe; the hemiataxia, hemisynergy, and tremor which may be of topographic diagnostic importance as indicating the side affected; the atonic paresis of one side, the vertigo which is invariably present, but not of much localizing value, the nystagmus which is a sort of nystagmic jerking when the eyes are turned to one side or the other, and is frequently seen in subtentorial growths. He also calls attention to the fact that the position of the head and the position of the body have a marked influence in bringing out signs of cerebellar tumors that may be latent. General or unilateral convulsions of the cerebellar type, viz., opisthotonos, momentary loss of consciousness with a general clonic spasm of very short duration, are indicative of subtentorial pressure and irritation of the pons rather than of intracerebellar tumor. Probably one of the most valuable signs indicating the site of the lesion is adiadokokinesis to which Babinski has called attention. By this is meant a slowing of movement of alternating character, and is best illustrated by successive pronation and supination of hand and forearm. In lesions of the cerebellar hemispheres there is a marked slowness in these movements of the homolateral side. It sometimes manifests itself as a slowness of speech due to the inability of the patient to rearrange his lip and tongue muscles rapidly. Other speech disturbances have been ascribed to cerebellar lesions, such as a jerky staccato speech. Other symptoms have been noticed by various authors, but not confirmed by others. Oppenheim says he finds a dulness on percussion on the side of the lesion, and Bruns calls attention especially in children to tenderness on percussion and the cracked-pot sign on the side of the lesion.

Ehrlich's Biochemical Theory.—L. H. Marks in expounding the work that Ehrlich has accomplished in the past seven years states that the latter has done far more than merely lay the foundation of a new science. His most valuable contribution to science is the basic idea that a specific chemical affinity exists between specific living cells and specific chemical substances. In his work on the trypanosomes Ehrlich studied the drugs that enter into

this chemical affinity. Of these drugs there are three groups: 1. The arsenic group, examples of which are arsenious acid, atoxyl, and later the new atoxyl substitution products, such as acetylatoxyl, arsenophenylglycin and dioxydiamidoarsenobenzol. To this group can also be added the antimony compounds. 2. Certain azo-dyestuffs, such as trypan-red, discovered by Ehrlich and Weinberg, and trypan-blue and trypan-violet, discovered by Mesnil. 3. Certain basic triphenylmethan dyestuffs, such as parafuchsin, methyl-violet and pyronin. The mode of action of these different drugs varies, according to Ehrlich, as follows: 1. Some substances have no effect on the parasite in test-tubes and possess no curative properties; in other words, the trypanosomes possess no receptor which fits into the atom grouping of the substances. 2. The substance has a highly destructive action on the parasites outside the body; but has absolutely no curative effect. This is best illustrated by the experiment of Koch with anthrax bacilli and bichloride of mercury. 3. The substance has absolutely no effect on the parasites outside the body, but shows a highly or completely curative action when within the body. This is an indirect action and under this category can be placed most of those drugs which are of practical interest.

Torsion of the Great Omentum.—W. W. Richardson reports a case of this condition belonging to the group of intrahernial and intraabdominal torsion about two points.

Fly Larva Infection.—R. T. Miller reports a case of infection of the skin with one of the ox-warble flies, a parasite of cattle almost exclusively.

Wright's Blood Stain.—J. H. Wright revises his directions for making and using the Wright blood stain

The Progress of Infection in Phthisis. Containing a Plea for the Treatment of Early Cases by Absolute Rest. L. Cobbett.
The Preparation 606; the Treatment of Syphilis by Ehrlich's Method; Indications and Contraindications; Observations Made in Germany. E. Emery.

Thrombotic Softening as a Cause of Acute Myelitis.—H. C. Bastian concludes that the evidence seems to be overwhelming that in the great majority of cases of acute myelitis, and also of acute poliomyelitis, the affection is caused not by an inflammation, but by thrombosis of some of the vessels of the spinal cord (where, in the latter disease, it is not due to a special acute degenerative process). Certainly, in the former affection one has in the great majority of cases to do with thrombotic softening rather than with a true myelitis. This latter conclusion is rendered obvious (1) by the similarity of the morbid changes in question to those occurring in the brain which are due to thrombosis, as well as to the absence of any reason why a primary inflammation should be rare in the brain and common in the spinal cord. These strictly logical reasons are strongly reinforced by (2) the fact of the existence of special conditions favoring the occurrence of thrombosis in the vessels of the spinal cord, and in just such parts of the cord as are most frequently affected; (3) by the fact that the disease is most commonly met with in just such persons and under just such conditions (as to heart's action, blood-vessels, and quality of blood) as are known to be favorable to the occurrence of thrombosis; (4) by the fact that the mode of onset and the early symptomatology of the affection are wholly different from what they would be had an inflammation of the cord actually existed; and finally (5) by the fact of the absence of any reasonable cause of inflammation, certainly in the majority of those in whom the malady makes its appearance.

Diseases of Elephants' Tusks.—J. B. Sutton contributes a humorous essay upon this subject, which can be valued only in the light of comparative pathology.

Diffuse Lipoma.—Sir J. Hutchinson states that the occurrence of fat tumors on the nape of the neck in the human subject has been observed by many. Sometimes disease may be located chiefly in the hair follicles or glands, sometimes the structures of the true skin may undergo hypertrophy, and in others a tendency to overgrowth may appear to be almost exclusively expended in overdevelopment of fat. It is from the latter condition that the enlargements with which the author deals originate. They are paleogenetic aberrations in the human subject of the base of the mane in animals. Until recently they have been supposed to occur only in the human subject, but recent observations have led the author to think that, as might have been expected, they occur also in some of the domestic animals. Nor must one, although he attach great importance to the region of the mane as giving to these growths their special location, narrow his observations to that region only. Wherever there are deeply placed hair follicles embedded as they always are in fat, there such hypertrophies may occur. These conditions occur very definitely in the region of the pubes.

Progress of Infection in Phthisis.—L. Cobbett discusses this subject and presents a plea for the treatment of early cases by absolute rest. Tuberculosis in man confers a certain degree of immunity, and it is on the acquisition of the new or improved powers of resistance which are the cause of this immunity, slight though they be, that the hope of recovery mainly depends. Certain observations on the lesions of calves injected with tubercle bacilli of the human and bovine types respectively lead the author to believe that the powers of resistance which develop during infection, and which lead in favorable cases to cure, are partly local and partly general. Experiments made many years ago on the cause of the local immunity caused by erysipelas lead the author to think that it is not improbable that the local powers of reaction become quickened and improved; possibly the endothelial cells become less sensitive to the poison, owing, it may be, to the development of an antibody, so that they now react by multiplication to a concentration of poison which originally would have caused necrosis. But whether the local powers of defence undergo improvement or not, one must believe that they hold the disease in check until new or improved constitutional powers, whatever they may be, have had time to become evolved, and so far perfected that the disease is arrested. In man, as in the ox, the severity of a tuberculous infection is largely determined by the number of bacilli which gain entrance at the start. As tuberculosis runs its course and the capacity of resistance increases it will require as time goes on an increasing number of bacilli to infect any new region of the patient's body. The author comes to the final conclusion that resistance to tuberculosis like resistance to other infections, is a very specific matter, and does not necessarily go hand in hand with what one regards as the general bodily health. We commonly assume that the two go together, and do everything to encourage the general well-being. We prescribe the most nourishing food, recommend fresh air, and are not adverse, in what we deem suitable cases, to moderate exercise. So far good, but the author thinks we should ever bear in mind in phthisis the menacing danger of the infection of new areas and do all we can to avoid it, or to postpone it until the patient has become more immune. And if we can do this in the early stages by absolute rest in bed, he does not think we should be deterred therefrom by the fear that the general bodily health will suffer.

Treatment of Syphilis by 606.—E. Emery, who, at the instance of Professor Alfred Fournier, was the first

Frenchman to visit the laboratory of Ehrlich and the various clinics of Germany to study the value of 606, comes to the following conclusions: 1. That the Ehrlich method up to the present is contraindicated as regards elderly men; for all persons having non-syphilitic visceral lesions —renal, cardiac, hepatic, splenic, pulmonary, and vascular affections, such as advanced aneurysm of the aorta, again particularly as regards patients who have not a normal condition of the fundus oculi. Toward patients who suffer from a severe syphilitic affection of the brain, such as recent hemiplegia, acute or subacute meningoencephalitis, it is necessary to observe the utmost caution, and, awaiting more ample information, to intervene only in very grave or desperate cases when mercury has ceased to be efficacious. Constitutional weakness and cachectic conditions are not always contraindications. 2. That the Ehrlich method is formally indicated: (a) for all patients in whom the lesions do not yield to mercury; (b) when a relapse takes place following immediately on an apparent cure with mercury; (c) in cases of repeated relapses; (d) when a total mercurial idiosyncrasy contraindicates the use of all mercurial forms of treatment; (e) for all patients attacked with malignant syphilis, with secondary or tertiary syphilides deeply destructive and mutilating, or most serious on account of their position and the disorders or dangers that they occasion; (f) again, for attacking syphilis when the chancre first appears, on condition that one adds to this the initial treatment of the spot attacked by an intermittent and prolonged mercurial course. 3. That in every other case one may, according to the circumstances and fitness, independent even of the infection, use either Ehrlich's method or the old mercurial methods. The author thinks, as do a number of writers on syphilis, these two methods of treatment assist and supplement each other in a certain number of cases. A long comparative study of the two kinds of treatment, of their advantages, their inconvenience, and their efficiency, will allow one to determine within narrower limits the precise indications for one or for the other. Whatever may be the fortunate future of Ehrlich's discovery, one cannot withhold an unreserved admiration from this sympathetic *savant* whose whole scientific career is a model and an example of ingeniousness, of logic, and of perseverance. No link is wanting in the unbroken chain of his experiments, all directed toward one end. From the very beginning of his studies Ehrlich set himself the task of determining the elective affinities of certain chemical substances toward the various organic tissues. After having shown the affinity of the granulations in blood corpuscles toward certain coloring matter, after having proved the existence of chemical substances which are fixed by the living microorganisms in the human body, he discovered this elective action shown by certain arsenical compounds toward spirilla. One can state, therefore, that the discovery of 606 is not due to mere chance, but, on the contrary, is the ultimate result of a whole series of researches conducted with scrupulous care and admirable certainty of deduction. It is better than the spontaneous creation of a purely intuitive genius: it is the crowning point of a splendid scientific career and the work of a lifetime.

Elastic Traction and Elastic Pressure in Surgery.—G. A. Wright after reviewing some of the many uses to which elastic pressure has been adapted gives a somewhat detailed consideration of the use of rubber as an orthopedic agent. In cases of flexion deformity where no actual ankylosis is present, but immediate straightening by force is undesirable, no more valuable means of rectification exists than elastic tension. At this point the author notes the advantages which rubber possesses over other means of employing tension. First rubber has the advantage over steel springs in that its tension can be employed through a much wider range, as the strength of the tension is capable of more ready adjustment. It is much easier to apply slighter degrees of traction or pressure, much easier to arrange for the exact degree of traction required, and, in addition, any apparatus needed may be readily and cheaply improvised. The appliances are indeed exceedingly cheap, easily manufactured, and easily replaced. A little ingenuity and some rubber cord is the stock-in-trade, though patience and care are, of course, also necessary, as living tissues cannot, as some surgeons seem to suppose, be dealt with quite as if it was a question of cabinet making or upholstering. Pressure sores are a possible result of mismanagement or neglect, and are easier to make than to repair.

High Blood-Pressure in Arteriosclerosis.—R. D. Rudolf states that when in a case of arterial thickening a raised blood-pressure is detected such a rise may be due to one or more of the following causes: 1. Toxemia; such toxemia being at the same time the direct cause of the arterial disease by directly poisoning the vessel walls. A good example of such a poison is nicotine which directly raises the blood-pressure, and according to many authorities, also acts directly upon the vessel wall as a poison. Probably there are very many such toxins manufactured in the alimentary tract or in the tissues of the body. 2. Some toxin which has nothing to do with the associated arteriosclerosis, but is directly raising the pressure. One might theorize that in an arteriosclerotic patient the adrenal tissues might be from time to time overactive, and might thus produce periodic rises in pressure, as might occur in individuals not arteriosclerotic. 3. Compensatory. It is well known that if some vital tissues, such as those in the medulla, be rendered anemic—say, by the pressure of a new growth—the blood pressure rises enormously, seemingly with the object of forcing blood at all hazards into the part. If such a part of the brain be supplied by a vessel the lumen of which is much narrowed by disease, it is likely that the blood-pressure will rise from the same cause. 4. Simple nervousness. It is very common to find the pressure high from nervousness, and if an arteriosclerotic happens to be also a neurasthenic his pressure may be high from this cause alone. 5. Lastly, the raised pressure may be due to the arterial disease alone, and in this case probably the splanchnic vessels, or the aorta leading to them, are extensively diseased.

Reaction of Heart to Digitalis.—T. Lewis states that the case for which he pleads—that digitalis slowing is a result of heart-block when the auricle is fibrillating—is very materially strengthened when the following facts are considered: The type of case in which, with the normal or coordinate contraction of the auricle present, heart-block is readily provoked by digitalis administration, is the advanced rheumatic heart, and *a fortiori* the heart affected by mitral stenosis. It is a striking fact that of all cases of clinical auricular fibrillation those which are of rheumatic origin, and *a fortiori* those affected by mitral stenosis, show the characteristic slowing of digitalis to most advantage. This is the type of case in which digitalis acts in so magic a fashion, and in which the rate of the ventricle is set by the dosage employed; it is the type of case in which the ventricular rhythm may be sometimes reduced to regularity, and in which the rate may be reduced to that consistent with a true ventricular

rhythm. On the other hand, there is the type of patient in whom no reaction ensues upon the exhibition of the drug. Now Mackenzie has shown that digitalis produces heart-block in those patients in whom a previous defect of conduction exists. The proposition the author advances is a parallel one, namely, that the ventricle is retarded in auricular fibrillation by digitalis when there is a preexisting damage of the junctional tissues, a damage which is frequently demonstrable in cases of rheumatic heart affection. The complete evidence in support of this proposition will require observations upon patients in the early stages of the affection. It is requisite that it be demonstrated that a large proportion of the cases which react to digitalis had a deficiency of auriculoventricular conduction before the onset of fibrillation. The author presents the facts in regard to three cases in which the heart-rhythm was observed before the onset of fibrillation, or during the intervals of rest between attacks. The cases were thoroughly tested with digitalis during the stage of fibrillation. Two cases, in which no previous defect of conduction could be demonstrated, failed to show a trace of reaction to the drug. The third case in which deficiency of conduction was clearly established reacted repeatedly and in the most typical manner.

Fermentation Properties of Typhoid Bacillus.—W. J. Penfold finds that cultures fresh from the blood or excretions of typhoid patients show an almost absolute conformity to type in respect of fermentation characters, whereas the agglutination tests, when applied to freshly isolated strains, not infrequently break down. It seems, therefore, that, in the recognition of these organisms, fresh from the body, the fermentation characters take a preeminent position. In conclusion, the author puts in a plea for the value of the fermentation tests in elucidating the laws of bacterial variation. They are easily applied, and if once understood would probably explain many of the most difficult problems in connection with virulence and other properties of microorganisms.

Diaphragmatic Hernia.—E. Ringrose reports a fatal case of this condition occurring in an adult. The large omentum had passed partially through the hernia into the thorax. About one-quarter of the small intestines was in the thorax, and together with the fundus of the stomach and omentum had compressed the left lung against the vertebral bodies. The transverse colon was empty, but still passed horizontally across the abdomen a little below the level of the umbilicus. The hernia was situated on the left side of the diaphragm, and admitted the whole hand; its edges were formed of distinct muscular bands, the free edge being smooth and rounded; the upper edge formed a well-defined falciform border reaching from the middle arcuate fibers to the attachment of the diaphragm to the twelfth rib. There was no evidence of any tear or laceration; in fact, the condition strongly suggested a long duration, if not a congenital deficiency of the substance of the diaphragm between the middle arcuate fibers and the external acruate band. There was no sac. It was of interest to note that after reducing the hernia, that is, pulling back the fundus and intestines into the abdomen, the condition at once recurred, being highly suggestive that this migration into the thorax had been of some considerable standing.

Supersensitiveness to 606.—Wechselmann discusses briefly supersensitiveness, both local and general, to the Ehrlich-Hata remedy. This is naturally a difficult subject, for the apparent supersensitiveness may be due not to the drug, but to the liberated endotoxins of the disease. Local supersensitiveness, excluding the possibility of accidental infection from pyogenic germs, doubtless explains the occasional occurrence of local necrosis at the point of injection. This necrosis appears to result from the unabsorbed drug, which may produce a dense nodule, with death of the tissues in the central portion. Much of this nodular formation is due less to hyperergy on the part of the drug than to the medium of solution. The excess of acid may either irritate ordinary tissues, or tissues supersensitive to acids. Manifestly such additional irritation must be excluded as far as possible. Orth has recently made serial sections of these nodules and has found them sterile as to germ life; the sole irritant, as already stated, being the unabsorbed arsenobenzol acting on supersensitive tissues. In regard to the general reaction, cases of paresis in which liberation of endotoxins should be negligible in degree have shown a supersentiveness suggesting idiosyncrasy to arsenic. Further study appears to show that in a small percentage of cases the remedy sets up a symptom-complex of a definite type, due neither to the necessarily liberated toxins nor to the arsenic in the molecule—high fever, angina, exanthems and enanthems, nephritis; in short a condition closely resembling serum disease. To patients with weak heart such an outbreak might prove very dangerous. The author seems to connect this supersensitiveness with antigen formation in connection with liberation of toxins. We have thus far been told that liberation of toxins was a necessary step in the action of the remedy and that a reaction should be in proportion to the toxins liberated. This phenomenom is not dependent on supersensitiveness. The reaction due to the latter should be a different phenomenon —should occur when endotoxins are not liberated, as in paresis and in nonsyphilitics. The author in his brief sketch does not sufficiently differentiate between the two sets of phenomena.

Optic Neuritis Following Use of 606.—A few cases of opticus lesion have come to light in connection with the use of the Ehrlich-Hata remedy, but these are not of a character to discredit the latter; with the rapid spread in the use of the remedy, a case now and then is bound to occur as a mere coincidence. Kowalewski describes a case which well illustrates the point. His patient had at the outset a severe case of recent syphilis which yielded promptly to one injection of the remedy. However a relapse occurred, which assumed the shape of intolerable headache persisting some days, and followed by typical optic neuritis. The mechanism of the case was simple enough. The relapse took the form of a meningitis which was propagated along the sheath of the opticus with eventual neuritis. Not caring to inject 606 a second time, patient was placed on an inunction cure (Hg) and promptly recovered—so promptly, in fact, that the author believes that the disease had been all but cured by 606. He suggests as a matter of prudence that one should follow up the single injection of 606 with an inunction cure.

Internal Secretion of the Generative Glands.—Münzer concludes his long serial article on this subject. He ends with a study of the results of castration on the psyche. Our information along these lines is scanty. No one seems to have studied the development of the brain in castrates—at least since the time of Gall, who found the cerebellum undeveloped; a sequence also claimed to be constant for all castrated animals, both by Gall and his school and by various moderns. We know empirically that in the miniature individual, as well as in those who were castrated early in life, sexual desire is in abeyance—is extinct. When the generative glands reach their maturity, they exert a certain action on the brain, giving rise to the sexual impulse. Changes in character and personality are even more in evidence. Man is believed to owe his courage, energy, industry, etc., to his generative glands.

Women after castration are believed to be irritable, moody, and combative. The mental state is one of depression. The psychical alternations in both sexes after castration are believed to be due to a species of autointoxication. In one predisposed to psychosis castration would intensify the condition.

Münchener medizinische Wochenschrift.

November 22, 1910.

On Caution in the Use of Iodine Internally.—Krehl would always examine the thyroid before pushing iodine or iodides. He would consider enlargement of the thyroids a contraindication to the use of the drug in arteriosclerosis. The patient should also be investigated as to the possible presence of thyrotoxic symptoms, which also contraindicate iodine. The author believes further that indiscriminate use of iodine causes both enlargement and hyperactivity of the gland. If iodine is given when thus contraindicated, the condition set up appears to resemble the so-called "iodine cachexia" as described by others.

Intermittent Limp.—Professor Erb writes briefly of a condition which he long ago helped to make known. He touches first on the so-called "tobacco etiology" of the condition which has recently been put in evidence by himself and others. His personal and other available figures appear to sanction such a view. In fact, the more he sees of the condition the more he is inclined to recognize tobacco as a causal element, to the same degree that it is a cause of arteriosclerosis. Another element is the natural tendency to cold feet, including traumatic coldness of extremities (from special exposure). In the last dozen or so cases examined Erb could feel no femoral pulse, although the stethoscope revealed a faint arterial murmur. This symptom is unilateral as a rule and brought out by comparison with the sound side.

On the Question of Marriage of Girls with Heart-Disease.—Jashke discusses this problematic subject in much detail. He is concerned chiefly with the effects of pregnancy on the mother. In regard to childbearing by women with valvular lesions he cites many figures to show that the danger is exaggerated. Women with such lesions continue to bear children. The type of case described by obstetricians as contraindicating pregnancy and as furnishing a special obstacle to delivery is an extreme one and leads us to another type of case, to wit, that with impairment of the myocardium, with actual chronic insufficiency. The diagnosis of the intimate nature of this lesion is difficult at best. Many varieties are to be found under this head, for chronic insufficiency of the heart is not necessarily due to degeneration of the myocardium. Fatty infiltration, goiter-heart, congenital stenosis of the arteries, pressure lesions, etc., may cripple the normal action of the heart and must be separated from actual disease of the myocardium, which latter, when in evidence, is sufficient to contraindicate marriage and pregnancy. In regard to pure neuroses of the heart, these not only do not contraindicate marriage, but may at times be improved by it.

Extensive Poisoning by Hyoscyamus Niger.—Phillipi and Muhle report an episode of this sort, said to be rare in literature. A number of people partook at once of roast meat, potatoes, and blackroot. Within two hours all exhibited evidences of poisoning by some member of the solanaceæ family. Mydriasis was present. The blackroot *(scorzonera hispanica)* could not in itself be toxic, but was evidently mixed with or replaced by a weed containing hyoscyamus *(h. niger)*. This was evidently a result of careless harvesting, the blackroot having been accidentally mixed with the toxic plant. The symptoms induced were of the type caused by the solanaceæ, with the differential marks which distinguish hyoscyamus from other members of the group.

November 27, 1910.

Action of the Ehrlich-Hata Remedy on the Eye.—Wechselmann studies this subject from the point of view of the effects of the remedy on patients with syphilis of the eye. The material, therefore, comes largely from ophthalmological sources. In a series of 250 cases the eye was examined before the injections were practised. In none of these cases did the injection of "606" give rise to any alteration of the eye. The author has now controlled over 1,400 cases, and has yet to note any evidence of injury to the eye as a result of the treatment. It is, however, probable that an optic nerve rendered supersensitive by previous injections of some of the more toxic arsenical compounds may be unfavorably influenced by 606. Even in untreated syphilis or syphilis treated with Hg. optic neuritis may occur as a rare phenomenon. Some authorities have so much confidence in the innocuousness of 606 in causing optic neuritis that they would not hesitate to prescribe it if that condition were actually present. The author regards this course as unwise.

Etiology and Treatment of Detachment of the Retina.—Horstmann believes that this condition cannot occur save as a result of disease of the vitreous. This depends for its nutrition on the choroid plexus and ciliary body. All cases thus far recorded which have been subjected to microscopic examination confirm this teaching. Hence a variety of intraocular affections may give rise to the retinal lesion (space does not suffice to enumerate them). In regard to treatment, rest is of the first importance and very many recoveries have resulted from this resource alone. Only when this fails completely should we proceed to operative measures. Most of those advocated are of no value. The author contents himself with recommending but one, to wit, scleral puncture, to lessen the amount of fluid beneath the retina.

Functioning Muscle Substitution.—Kron enumerates many instances of this character from general and personal records. He deals in part with congenital defects of muscles, and in most of the cases cited the defects were in the muscles of the neck, chest, shoulders, etc. Cases are also cited of replaced paralyzed muscles, such as result from neuritis. Thus the author replaced a paralyzed deltoid (from poliomyelitis) with the clavicular pectoralis, which had already undergone compensatory hypertrophy. The lower extremity yields results greatly inferior to those of the upper part of the trunk in this connection.

Paratyphoid Osteoperiostitis.—Osteoperiostitis due to Eberth's bacillus and a small number of other germs is well enough known, or is at least to be found mentioned in standard works. The paratyphus germ has hardly yet been mentioned in this connection but Jensen and Kock of Copenhagen have placed a case on record. Of great interest is the apparent fact that a period of latency of 20 years occurs in this case. In 1889, long before the isolation of paratyphus fever, patient had a typhoidlike fever, which ran a protracted course. A tender area appeared on one of the femurs, and while relative recovery took place the locality occasionally gave trouble. At the expiration of 20 years, patient now being 40 years of age, the old lesion lighted up in the form of an osteoperiostitis, from the pus in which the paratyphus B. bacillus was found. Unusual cultural and inoculation tests were made which left no doubt as to the nature of the germ.

Prevention of Air Embolism in Placenta Prævia.—Peters alludes to the danger of air embolism in the operation of extracting a placenta prævia. This danger may be obviated by performing all operative procedures necessary for the detaching of the placenta while the patient is under water. This may be accomplished with the aid of a sterilized bathtub and sterilized water.—*Zentralblatt für Gynäkologie.*

Book Reviews.

THE PHYSICIAN'S VISITING LIST (Lindsay and Blakiston's) for 1911. Sixtieth Year of Its Publication. Philadelphia: P. Blakiston's Son & Co.

THIS edition of the popular Lindsay & Blakiston Visiting List, used by so many practitioners for so many years, differs in no wise from its predecessors. It contains a calendar for 1911 and 1912, directions for treatment of certain emergencies, the usual dose table, and blank pages for twenty-seven patients a week. It is of convenient size for the pocket and conveniently arranged.

STUDENTS' AIDS SERIES. AIDS TO MICROSCOPIC DIAGNOSIS (BACTERIAL AND PARASITIC DISEASES). By ERNEST BLAKE KNOX, B.A., M.D., (Dubl. Univ.) Diplomate in Public Health (Honors), Royal College of Physicians and Surgeons, Ireland; formerly Assistant to Lecturer in Pathology and Bacteriology, Trinity College, Dublin; late Demonstrator of Anatomy in the University of Dublin; late Secretary and Member of the Standing Committee on Enteric Fever, appointed by the Government of India; Captain, Royal Army Medical Corps. New York: William Wood and Company, 1910.

THIS little handbook of 156 pages is designed to enable students and others preparing for examinations to review the essential features in microscopic diagnosis. It is not intended as a substitute for a textbook, but it covers its ground thoroughly, and is strictly up to date. The chapters on the protozoal diseases are particularly admirable, and embody the results of most recent researches. The methods of isolating, staining, and identifying the common pathogenic bacteria are succinctly stated, and presented in a manner suitable for ready reference.

L'AÉROPHAGIE, PAR LE DR. H. MAUBAN, Ancien Interne des Hôpitaux de Paris, Médecin Consultant à Vichy. Preface du DR. ALBERT MATHIEU. Paris: G. Steinheil, 1910.

EVER since Mathieu, in 1901, showed that aerophagia, associated with digestive troubles, is one of the most frequent causes of so-called flatulent dyspepsia, this condition has been generally recognized in the pathology of digestion. In this small volume of 160 pages the author reviews the clinical forms of aerophagia, their mode of production, and their symptomatology. Among the measures recommended in the treatment are to advise the patient to keep his mouth open, to wear a tight collar so as to make swallowing painful and attracting the attention of the patient to this act, the use of gastric sedatives and absorbents, lavage, the prone posture, massage, electricity, and respiratory gymnastics.

PRÉCIS DU TRAITEMENT DES FRACTURES PAR LE MASSAGE ET LA MOBILISATION. PAR LE DR. JUST LUCAS-CHAMPIONNIÈRE, Chirurgien Honoraire de l'Hôtel Dieu, Membre de l'Academie de Médecine, President de la Societé Internationale de Chirurgie. Paris: G. Steinheil, 1910.

THIS little volume presents a résumé of the use of movements in the immediate treatment of fractures. The indications and limitations of this mode of treatment, its mode of application, with the precautions to be observed, are presented in a general manner. The details of this treatment as applied to the special fractures are fully given.

DIFFERENTIAL-DIAGNOSTISCHE TABELLEN DER INNEREN KRANKHEITEN. Von J. CEMACH, in Wien. München: J. F. Lehmanns Verlag, 1910.

THIS little volume comprises 37 schematic tables covering the differential diagnosis of the principal internal diseases. Considering the difficulty which this subject presents to the average student of medicine, these compact and at the same time complete synoptic comparisons of the various groups of diseases cannot fail to be helpful. At the same time they may serve to aid the general practitioner in moments of uncertainty, enabling him to review rapidly the chief points in differential diagnosis. The author has succeeded in crowding an unusually large amount of material between the covers of this book.

OPOTHÉRAPIE. Par Le Dr. PAUL CARNOT, Professeur Agrégé à la Faculté de Médecine de Paris, Médecin des Hôpitaux de Paris. Avec 90 Figures dans le Texte. Paris: Libraire J.-B. Baillière et Fils, 1910.

THIS useful volume is a comprehensive textbook of opotherapy, a subject that has taken front rank among the many systems of therapeutics. The first part deals with organotherapy in general, the nature of its remedies, the internal secretions, hormones, kinases, cytolytic and anticytolytic antibodies, and the anaphylactic substances, the toxicity of the organotherapeutic products, the indications and contraindications in their employment, and their various modes of preparation and pharmaceutic forms. The second part of the work deals with the special applications: hematic opotherapy, comprising blood transfusion, and the use of hemoglobin, fibrinogen, and leucocytic extracts; digestive opotherapy, including the use of the various digestive juices, and the ferments, pepsin, kinase, secretin, etc.; genital opotherapy, including the study of the testicular, interstitial, and prostatic juices, ovarian extracts, and extracts of the corpus luteum, placenta, mammary glands, and their many therapeutic applications. The subject of the internal secretions of the thyroid and parathyroids, and their administration in myxedema, cretinism, infantilism, chronic rheumatism, scleroderma, dermatoses, migraine, nocturnal enuresis, and asthma is exhaustively covered, as is that pertaining to the internal secretions of the hypophysis and suprarenal capsule.

MENTALLY DEFICIENT CHILDREN. Their Treatment and Training. By G. E. SHUTTLEWORTH, B.A., M.D., etc., Medical Examiner of Defective Children to the Willesden Education Committee, and formerly to the School Board for London; Consulting Medical Officer, National Association for the Feeble-Minded, late Medical Superintendent (now Hon. Consulting Physician), Royal Albert Institution for the Feeble-Minded of the Northern Counties, Lancaster; formerly Assistant Medical Officer, Earlswood Asylum, and Medical Expert, M. A. B. Institution for Improvable Imbeciles, Ealing; and W. A. POTTS, B.A., M.D., etc., Consulting Medical Officer, National Association for the Feeble-Minded; Chairman of the After-care Committee, and Member of the Special Schools Committee, Birmingham; late Medical Investigator to the Royal Commission on the Care and Control of the Feeble-Minded: formerly Resident Medical Officer, Yorkshire East Riding Lunatic Asylum. Third Edition. Philadelphia: P. Blakiston's Son and Company, 1910.

THAT one per cent. of all school children belong to the class of mental defectives is a fact whose importance cannot be ignored by physician or educator. Since the publication of the first edition of this book in 1895, there has been a growing interest in the welfare of the defective child which has been greatly stimulated by the general introduction of medical school inspection. The present volume may be used as an accurate guide by all those who are directly or indirectly brought into contact with these unfortunates. It comprises chapters on the history of this subject, the discussion of the term feeble-minded, defective and epileptic children, special instruction, pathological classification, etiology, diagnosis, and prognosis, the medical examination of children, treatment, education, industrial and moral training, and results and conclusions. There is an excellent bibliography at the end.

PHYSICAL EXAMINATION AND DIAGNOSTIC ANATOMY. By CHARLES B. SLADE, Chief of Clinic in General Medicine and Instructor in Physical Diagnosis in the University and Bellevue Hospital Medical College, New York. Illustrated. Philadelphia and London: W. B. Saunders Company, 1910.

THIS book presents the technique, fundamental principles, and methods of physical examination, in order to prepare the student for the study of the more comprehensive works upon the subject. The diagnosis of specific disease conditions is avoided, as the work deals chiefly with the normal subject. The illustrations contain only those lines that are essential to the subject-matter. The book may be safely placed in the hands of the beginning student as a reliable primer of physical diagnosis.

A PLEA FOR THE HOME TREATMENT AND PREVENTION OF SCARLET FEVER. By ROBERT MILNE, M.D., Ch.M., Medical Officer of Dr. Barnado's Hospitals and Homes for Thirty Years, etc., etc. New York: William Wood & Company, 1910.

THIS little book of eighty pages is an exposition of the author's strikingly original method of treating scarlet fever. The patients are not isolated from other children. They are frequently and thoroughly anointed with eucalyptus oil, and their throats are frequently swabbed with a 10 per cent. carbolized oil. The results of this plan of treatment are said to be exceptionally good, particularly in preventing the spread of the infection. The main advantage apparently lies in the fact that it is not necessary to isolate the patients, and even in the hospital these are treated in the same ward with surgical cases. It certainly indicates an unusual amount of courage for anyone to advocate such a method of handling these cases, in direct variance with current practices and teaching. At any rate, the book is a most interesting and suggestive one, particularly in awakening the thought that possibly some of our apparently settled convictions may yet be considerably modified or even overthrown.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Fourth Annual Meeting, Held at Nashville, Tennessee, November 8, 9 and 10, 1910.

THE PRESIDENT, DR. W. W. CRAWFORD OF HATTIESBURG, MISSISSIPPI, IN THE CHAIR.

AN address of welcome was delivered by Dr. W. D. Haggard of Nashville, which was responded to by Dr. Seale Harris.

President's Address.—Dr. W. CRAWFORD spoke approvingly of the advances that had been made in the system of medical education during the past decade. He said the profession must be made to appreciate that an over-production of medical colleges meant an over-production of poorly equipped doctors. The laymen must be brought to realize that there was a difference in medical degrees, so that he might demand higher standards. State legislatures must be awakened to their responsibility. The medical student himself must be convinced that the best was not too good for him.

Safeguarding Society from the Unfit.—Dr. A. B. COOKE of Nashville said that vasectomy was not specified as the method of sterilization in the Indiana law, but its advantages over other methods were obvious. Orchidectomy was a mutilating operation, and one of considerable gravity, yet he was persuaded that it should be recognized and specified as the only method permissible in a certain class of criminals. As a preventive, particularly in the South, where this monstrous evil was most prevalent and most abhorrent, it could not be doubted that the legal infliction of one such penalty would have a more salutary effect than many lynchings or even burnings at the stake. It was as yet too early to point to definite results from the operation of these laws; but when the crucial test of time shall have been applied he thought it was reasonable to predict that crime and degeneracy would be largely decreased and the world would be correspondingly better and happier.

Dr. GEORGE H. PRICE of Nashville said it was a difficult matter to secure legislation because there had been a lack of uniformity on the part of the medical profession looking to this great problem of safeguarding the public; nevertheless he thought the medical profession should be foremost in advocating restrictive measures.

Dr. FRANCIS DOWLING of New Orleans said the people in various sections of the State of Louisiana were interested in securing such legislation as would safeguard the public. Some had suggested that gonorrhea and syphilis should be among the diseases reportable to boards of health, the same as cases of diphtheria or scarlet fever.

Dr. JOHN H. WHITE of New Orleans said there was one difficulty growing out of the particular remedy advocated by Dr. Sharp of Indiana for this class of defectives, and that was the operation of vasectomy would be utilized by the roué as fitting him to practice his nefarious life without risk of being caught, and he believed that that was a thing which should be carefully considered before resorting generally to this operation, and a law providing against men voluntarily submitting to this operation for that very reason.

Dr. JERE L. CROOK of Jackson, Tenn. said the time had arrived when the medical profession should take active steps towards bringing about the consummation of the ideas embodied in Dr. Cooke's paper.

Dr. ISADORE DYER of New Orleans said that in the last few years this particular question had been discussed as one of supreme moment in connection with the general subject of eugenics. He believed that professors of eugenics, criminologists, and scientists, who were interested in the solution of this problem, were all satisfied that the aphorism of Oliver Wendell Holmes, that a man should begin to take care of himself by taking care of his great grandfather, was very pertinent, and that we ourselves for the sake of our own people should establish a law protecting our descendants from the possibilities to which they had been exposed in regard to criminals and defectives.

The association then passed a resolution to the effect that it concurred in the laws of Indiana regulating marriage and providing for the sterilization of habitual criminals and other degenerates.

Exophthalmic Goiter.—Dr. WILLIAM D. HAGGARD of Nashville spoke of the four cardinal symptoms of this disease, and said that surgical treatment had proven superior to any other form of treatment. It simply showed statistically it offered the best results, and at the present time early operation was the best treatment.

Dr. B. L. WYMAN of Birmingham, Ala., said the medical treatment of hyperthyroidism had been practically a failure in the majority of cases, and this agreed with his experience in the treatment of this disease, so that in recent years he had referred his cases to a surgeon. He emphasized the importance of early diagnosis.

Bones and Joints.—Dr. JOHN B. MURPHY of Chicago gave an address on this subject, and, among other things, said that when there was a lesion in the neighborhood of a joint which caused inflammation or thickening, or adhesion of the capsule, if the surgeon wanted to overcome deformity the capsule must be dealt with as one would deal with bones or with any other inelastic material. The outer fibrous capsule had a feeble vascularity. It practically never became inflamed; it was never the seat of a primary lesion. It never became tuberculous. It had an inner lining which was known as the synovial lining. The surface was represented by endothelial cells, which were arranged close to each other, and they sealed up the surfaces of both the synovial membranes just as the epithelial cells sealed up the surface of the skin. He had found in his experiments on dogs that if he wanted to infect a joint with the most virulent type of pneumococci, if he injected half a syringe full of the virulent microorganisms into a joint with a very fine needle, it would produce no effect whatever in that joint. On the other hand, if he took the other half of the same syringe barrel of infective material and injected it into another joint in the same dog, using a fine hypodermic needle, it would tear out the endothelial cells that covered the surface, and this would be followed by infection and death. This meant that if surgeons were going to do work on joints one of the things they must observe was that the joint had an enormous resistance against infection, and they must become the greatest respecters of this endothelial layer in all work that involved the surgery of the joints. He found that if he injected a joint with turpentine a day or two days in advance, or if he injected the joint with tincture of cantharides a day or two in advance, then injected the joint with formalin and glycerine, and afterwards injected the virulent microorganisms, the dog would die. Again, if he injected the joint six or twelve days before, then he could inject the joint and tear it up and not the slightest effect would be produced, because the chemical inflammation produced a cofferdam of all the lymph spaces beneath, making it impossible to infect the surface. He could render the joint surface, therefore, immune by injecting it with some chemical irritant two weeks before he operated. The time to attack a joint was when nature or the surgeon had artificially prepared the joint in rendering it immune against easy infection. Speaking of ankylosis he said it could be avoided in practically every case of acute infection of joints. The moment the practitioner spoke of draining joints that were infected, he was assuming re

sponsibility for an ankylosis. If there was an infection in a joint, to save it from destruction, it was necessary to relieve the joint of tension and the products of infection. This could be done by aspiration. But what one could do to give the patient more relief than a hypodermic injection of morphine was to put on Buck's extension and separate the pressing surfaces that were inflamed. Dr. Murphy reported several cases on which he had operated with gratifying results.

Education of the Specialist.—Dr. S. C. Ellett of Memphis said that with the establishment of a department of health it might be feasible to map out a course of study and hospital work which a man must satisfactorily complete before he could appear before the world as a specialist in any department of medicine.

Treatment of Trachoma.—Dr. H. H. Martin of Savannah, Ga., said in order to effect a complete cure in chronic trachoma surgical and medical treatment must be combined, as neither was sufficient in itself. On the surgical methods the one which he called attention to was the Coover plan, which was the most satisfactory from all points of view. For local application a five to ten per cent. solution of copper sulphate had no rival, but it must be begun soon after the operation and continued for eight weeks.

Malarial Manifestations in the Eye.—Dr. M. H. Bell of Vicksburg, Miss., stated that his observations were made from the symptoms found in thirteen cases of eye trouble due to malarial infection. Corneal ulceration was present in eleven cases, and two entirely distinct types of ulceration were noted. In seven cases the common dendritic ulceration was present, and in the other four the ulcers were of the simple round variety which he had designated acute herpetic. The acute type of dendritic ulcer he had found only in an acute malarial infection, and it had always responded readily to appropriate antimalarial treatment in combination with the application of tincture of iodine to the ulcerated area, and the usual local treatment employed for any corneal inflammation.

The Artificial Leech in Acute Mastoiditis.—Dr. U. S. Bird of Tampa, Fla., said that his experience included some nine cases. Clinically they were all instances of typical acute mastoid infection, middle ear disease, temperature, mastoid swelling, and pain. In every case the middle ear had been freely opened without relief. In all of the cases operation seemed probable and in one case the patient was sent to a hospital for that purpose. In some heat was used, but in most it was unnecessary after the leech. Calomel was given at first as a routine measure. An improvement was noted at varying intervals after leeching. In every case relief was permanent, no further active treatment being necessary.

Turbinectomy.—Dr. G. E. Vaughan of Clarksville Tenn., pointed out the chief indications for this operation, described the method of operating which is usually practiced, and reported cases.

Episcleritis.—Dr. O. Dulaney of Dyersburg, Tenn., detailed the symptoms of this disease, and discussed the prognosis and treatment.

The Heath Mastoid Operation.—Dr. M. M. Cullom of Nashville, Tenn., said the operation was safer than the radical operation. There was less danger of intracranial involvement following the operation. There was practically no danger of injuring the facial nerve. There was no injury to the hearing and the operation was often followed by marked improvement in hearing power. Suppuration diminished rapidly and postoperative healing took place sooner than after the radical operation. It could be easily converted into the radical operation, if desired.

Inguinal Hernia.—Dr. John Smyth of New Orleans related some experiences in operating on cases of inguinal hernia. After reporting three cases he drew the following conclusions: 1. The sac in one case was probably a variety of the pantaloon sac reported by Dr. Eisendrath and others. This kind of sac might account for some of the failures to cure hernia by operation. 2. The condition in another case was an artificial one, and was evidently the result of a failure to securely close the neck of the sac in the previous operation, and it showed the necessity of extreme caution in operating on cases which have already been subjected to operation. 3. The condition in another case was the result of an effort at reduction of the hernia, in which the position of the testis was lost sight of or ignored. The truss applied at that time caused sufficient traumatism to produce adhesions which imprisoned the testicle in the upward reflection of the sac, and the enterocele, or hernia proper, recurred in the lower peritoneal pouch, possibly another case of pantaloon sac.

Dr. Duncan Eve of Nashville said that the success of all operations for the relief of hernia depended upon obliteration or removal of the sac, and the transformation of the cord to the new bed or canal. Without these two principles, no hernia that was operated upon could be regarded as cured.

Dr. C. W. Allen of New Orleans said that the first important step in hernia was the manner of dealing with the neck of the sac. Formerly surgeons ligated the neck of the sac, frequently transfixing it, but this was unsafe.

Dr. Jere L. Crook of Jackson, Tenn., stated that the reason we did not operate more frequently than we did for hernia was due to the fact that we were perhaps negligent in pointing out to patients the necessity of it. Men wore trusses for years when a simple operation (with a very low mortality) would make them practically perfect men physically. The operation for hernia was one of the most important we should urge upon patients, and if we made it a routine measure, when we had occasion to come across a man who wore a truss in examining him for life insurance, to urge upon him the importance of an operation for the radical cure we would undoubtedly do this operation oftener, and in doing so would add much to the comfort of these patients.

Dr. Robert Caldwell of Nashville thought we were all pretty well agreed as to the treatment of the sac nowadays, and and it was not so much the removal of the sac in toto as it was the treatment of the exudate about the neck of the sac. He said we were going to have recurrences whether we used the Bassini, the Ferguson, or the Macewen method, because we had to deal with different conditions. He did not see why in routine work we should still do the Bassini operation.

Dr. Willis C. Campbell of Memphis said he did not know very much about the technique of the operation, but he had noticed that in all cases at the New York Hospital for Ruptured and Crippled a plaster spica was applied after the operation, which immobilized the parts absolutely and gave opportunity for quicker healing and left practically no dead spaces.

Dr. Charles A. Robertson of Nashville said there was one question in connection with hernia that had been brought to his attention and given him some degree of wonderment, namely, why physicians were not more frequently called upon to operate on hernia. The reason for it lay in the fact that fitting trusses was largely in the hand of instrument dealers and druggists, who made false claims in regard to the permanent or curative value of the truss.

Dr. W. D. Sumpter of Nashville said this subject appealed to him because of his belief that hernia was an operation that could be done under local anesthesia. The operation could be performed under local anesthesia with comparatively little pain. He had done many of these operations under local anesthesia in the last four years.

He thought if local anesthesia were resorted to more frequently more men would be operated on for the relief of this condition who now feared a general anesthetic.

Dr. Paul Dewitt of Nashville agreed with Dr. Sumpter in reference to local anesthesia. There was no doubt but that the operation for the radical cure of hernia could be performed just as completely under local as under general anesthesia. He had operated on several cases under local anesthesia and he had yet to find a case that suffered any amount of pain during the operation.

The Operative Treatment of Fractures of the Long Bones.—Dr. Jere L. Crook of Jackson, Tenn., reported four recent cases of fracture of both tibia and fibula on which he had operated, in all of which he secured good results, and in none of which could he have done so without operation.

Operative Treatment of Fractures.—Dr. C. W. Allen of New Orleans said that a general anesthetic was demanded for the proper reduction of all fractures except the simplest. All fractures after reduction should be subjected to the *x*-ray, and it was often found that what was thought to be a well-reduced fracture proved to be far from satisfactory. In many cases reduction was possible, but could not be maintained owing to the obliquity of the line of fracture. When reduction was impossible operation should unhesitatingly be performed, and one frequently found upon operating on such cases that the interposition of soft material would have made reduction impossible by any other than operative means. The time for operation called for some judgment. In cases seen early, within the first twenty-four hours, when there was not much injury to the soft parts, operation had best be done at once. Where there was extensive injury to the soft parts, or where several days had elapsed before first seeing the case, delay should be advised until the local inflammation subsided, sometimes about the second week, when there would be less danger of infection. He thought far too many limbs were needlessly amputated. With a little hard work and some ingenuity on the part of the surgeon many badly mangled limbs could be saved. As long as the blood supply was sufficient to keep alive the peripheral parts there was a chance. It was better that such patients should spend six months in a hospital and walk out sound and able to make a living than to be discharged after three weeks with the loss of a limb, to spend the rest of their lives as hopeless cripples or helpless charges upon the community.

Dr. W. P. McAdory of Birmingham said that a number of years ago he had a negro patient who was shot through the middle of the femur. He did not know the bullet was lodged between the ends of the bone at the time he put the limb in extension. He kept the limb in extension for five weeks, at the end of which time he took it down to find that he had an ununited fracture. He prepared the patient for operation. He cut down on the seat of the fracture and found the bullet, which was very large, had flattened out, making a piece of metal about the size of a quarter of a dollar interposed between the ends of the bone. He resected both ends of the bone, wired the fragments, and so gave this man a useful limb.

Dr. H. A. Elkourie of Birmingham felt in regard to compound fractures that he would rather cut down upon the bone and fix or wire the fragments together than trust to hypothesis and get bad results.

Dr. A. G. Payne of Greenville, Miss., stated that as far as the treatment of compound fractures was concerned, to his mind there was only one method, and that was to operate at once. The wound should be opened up and the bone thoroughly exposed, and any mechanical device which one might see fit to use to hold the fragments in position would work if one was clean about it.

Dr. Michael Hoke of Atlanta said that as an orthopedic surgeon he was called upon to correct many deformities the result of badly united fractures, and in this connection he desired to say that there was no reliable book written on the mechanics of the joints and on fractures, consequently we could not expect the general practitioner to treat these cases and get good results every time. For instance, if a practitioner put up a fractured elbow joint in the position of flexion and did not incorporate the shoulder, he could not control the upper fragment, the shaft of the humerus.

Dr. John Smyth of New Orleans differed with those gentlemen who wanted to operate on every case. He thought this would be a mistake. He had under treatment the case of a young girl who sustained a fracture of the humerus about an inch and a half above the elbow joint, supracondyloid, where the upper fragment went backward and the lower fragment was tilted forward. These fractures were put up in flexion, with a weight on the elbow joint after the suggestion of Lovett and Stimson. After repeated examinations with the X-ray apposition was very good, and after eleven days the splint was taken off, the arm massaged a little, and a light plaster splint reapplied. The girl will not only have a good functional result, but an excellent cosmetic one.

Dr. Robert Caldwell of Nashville believed that the operative treatment of compound fractures should be the rule, and the nonoperative treatment should be the exception. Of course, much would depend upon the character of fracture the surgeon had to deal with. If he had a transverse fracture, it was known that if it was reduced it was comparatively easy to maintain it in position and one could secure good results by nonoperative treatment, but if one had an oblique fracture, or a spiral fracture, to deal with, although he secured reduction, it was difficult to maintain it; consequently, knowing the comparative rarity of a true transverse fracture, he should say that the operative treatment should be the rule and the nonoperative treatment the exception.

Dr. A. B. Cooke of Nashville said that if under aseptic precautions the open treatment of compound fractures was practiced as a routine measure the question would arise, what possible harm could be done to the patient? This was the main point to decide. If operation could result in no harm to the patient, if properly done, we could not conceive that it would do anything but good for the patient, because it would leave in every individual case upon which this method was practiced an element of certainty which was important to the physician as well as to the individual welfare of the patient.

Dr. Duncan Eve of Nashville stated that until recently surgeons were very well satisfied with firm union. He did not think much about the question of permanent results, but since their ideal had been raised by the *x*-ray the surgeon insisted upon not only a good functional result, but also a cosmetic one. He was afraid the *x*-ray had raised the standard a little too high. While he was not opposed to the operative plan of treatment of compound fractures, he was not modern enough yet to suggest that all closed fractures should be treated by the open method. In compound fractures this method was all right because one had an open wound to deal with. Operation was all right for those fractures one was not able to reduce, or when reduced would not remain in coaptation or apposition, but the time had not arrived when surgeons would generally accept the open method as an every-day plan for the treatment of closed fractures.

Dr. E. Denedre Martin of New Orleans said that when it came to the question of fractures the first and most important thing was to know the character of the fracture, and above all the anatomical structures involved. If one had a simple transverse fracture, he was a poor

surgeon if he could not reduce it and hold it in position. If the surgeon had an oblique fracture, which was due to torsion, he knew he was dealing with contraction of certain muscles and he would have trouble in holding the fragments in apposition and he must overcome the action of the muscles if he would get results.

Gonococcic Vaccine.—Dr. George R. Livermore of Memphis stated that as far as a case of either acute or chronic anterior or posterior gonorrhea was concerned his experience had convinced him that gonococcic vaccine, as a cure, was absolutely worthless. He had used it in all doses and at varying intervals, and in no case did he effect a cure or see other than a modicum of improvement. This statement coincided with statements of prominent genito-urinary men in New York who had also experimented extensively with gonococcic vaccine. On the other hand, some of the complications of both acute and chronic gonorrhea sometimes yielded promptly and satisfactorily to the administration of the vaccine. The complications in which the vaccine had given the best results in his hands were epididymo-orchitis, arthritis, and prostatitis. In the treatment of gonorrhea in women he had several times noted cases that seemed to be benefited by the use of the vaccine. Whether this improvement was a coincidence or not he was unable to say, as other means of treatment were used at the same time, and he did not believe the question would be settled until vaccine therapy was placed on a more rational basis.

Dr. Raymond Wallace of Chattanooga stated that he had had some experience with gonococcic vaccine, and it tallied with that of the author of the paper. He had had the best results in cases of gonorrheal rheumatism. He recalled four cases in which three or four injections effected a cure.

Dr. W. W. Crawford of Hattiesburg, Miss., recalled to mind a woman upon whom he did a hysterectomy. She had old pus tubes, and he thought the organisms were dead. He thought he had a sterile condition to deal with from the length of time she had the inflammatory reaction in the pelvis, but after he had operated he discovered she had a recent infection superimposed on the old gonorrheal infection of some four or five years previously, which occurred at the birth of the child. He confidently believed that if it were not for the use of vaccines in large doses, giving fifty million the first dose, and one hundred million each day for two or three days, this woman would have died: but as an additional reaction was set up by the use of the vaccine she recovered.

End Results of Surgical Operations in Nervous Women.—Dr. S. T. Rucker of Memphis in a paper on this subject drew the following conclusions: 1. Nervous women as a rule did not make good subjects for surgical operations. 2. An operation should not be undertaken unless there was a definite, unmistakable pathological lesion, and that it was the chief cause of the nervous symptoms. 3. A correct estimate of the end results of surgical procedures could not be made, unless the surgeon kept in touch with his patients for months after they returned home. 4. In clearing up diagnosis in obscure conditions, every surgeon should seek the aid of a competent internist, neurologist, and pathologist. 5. Last, but not least, to no one was the golden rule more applicable than to the surgeon. When a patient presented herself she sought relief from suffering. She was not especially anxious to be cut, but to be cured, and the surgeon should always ask himself the question, if this was me or my wife, or my daughter, would I advise an operation?

Dr. A. A. Herold of Shreveport, La., recalled very distinctly a case that occurred in the New Orleans Charity Hospital of a woman whom he had in the gynecological service. She was operated upon four times. First, for a retrodisplacement of the uterus, second, for the removal of one or both ovaries; third, for the removal of the appendix; fourth, for the removal of a kidney. At last, she was transferred to the neurological department, and what became of her after that he did not know.

Dr. George R. Livermore of Memphis said that a man came to him for diagnosis and possible operation for kidney stone. He gave obscure nervous symptoms, with violent pain in the right side. The diagnosis had been previously made of appendicitis by another physician. He was operated on and his appendix removed, but the pain was just as severe as before. Then a diagnosis of gall-stones was made by a surgeon of Cincinnati, who operated for that condition. No gall-stones were found. The gall-bladder was drained, and the pain was just as severe after this operation as before. When he came to him, from the history of the case, he thought his condition was more hysterical or neurasthenic than otherwise. Uranalysis was negative. He had never passed any calculi. *X*-ray examination showed no stone in the kidney, nor shadow anywhere, and so he refused to operate, and advised him to consult a neurologist.

Dr. J. A. Crisler of Memphis recalled the case of a physician who had all the evidences of neurasthenia, including genuine hysteria, and who had the notion he had a bad gall-bladder and a bad appendix. He came to him and he refused to operate on him. He went to every surgeon in Memphis. The man then went out of town to consult another surgeon, who removed his appendix and drained his gall-bladder, and he had since been perfectly well. He said one might cite these cases one after another, and prove on the other hand that surgery was indicated.

Gunshot Wound of the Abdomen.—Dr. F. G. Dubose of Selma, Ala., reported a case of gunshot wound of the abdomen and chest, the bullet penetrating the stomach, the liver and lung.

Foundation of Medicine.—The chairman of the Surgical Section, Dr. E. Denegre Martin of New Orleans, in his address called attention to some of the loose stones in the foundation of medicine, and said methods of teaching were greatly to blame for the awkward work of beginners. The cadaveric courses now given in medical schools went far to better acquaint the student with the anatomical structures involved in the numerous operations, but the technic was at fault, as students only learned the replacement of the structures, but saw nothing of the various modifications which arose in every operation. A mere knowledge of anatomical relations, a theoretical mastery of pathology in the laboratories, was worthless until learned on the living body in relation to other structures. He believed a great advance could yet be made in methods of teaching.

Surgical Treatment of Hepatic Cirrhosis.—Dr. Arthur A. Herold of Shreveport, La., reported three cases, and then drew the following conclusions: "I believe that all well-marked cases of atrophic cirrhosis of the liver should be advised to submit to surgical procedure, informing the patient that it is practically devoid of danger, and that there is a chance of prolonging his life and making him more comfortable thereby; also that he will carry a small hernia with him in the future. I do not consider results obtained on the whole brilliant; but I do not believe that a failure to benefit one of these cases by operation will injure the reputation of either the surgeon or of surgery. As to the anesthetic, if the kidneys show no lesion, ether is preferable, as general anesthesia permits better examination of the liver and more freedom of work. If evidences of nephritis are present, it is safer to use a local anesthetic and do a simple epiplopexy."

Why Ligate the Sac in Hernia?—Dr. H. A. Elkourie of Birmingham said he had done within the last six years twenty-two operations for hernia without removing the

sac, and his results had been very flattering. He had not had a single recurrence and out of the twenty-two eighteen patients were now living within a radius of half a day's drive from his office.

Cancer of the Cervix Uteri and Its Treatment.—Dr. A. G. PAYNE of Greenville, Miss., said that the cervix uteri was affected with cancer more frequently than any other portion of the body. Fully one-third of all women who died of cancer were the victims of uterine cancer, and cancer of the cervix was pre-eminently a disease of the child-bearing period. Panhysterectomy was the only operation by which we could offer a woman with cervical cancer any permanent benefit or result, and then only in case there had been no extension into the bladder, vagina, rectum or glands. As soon as the disease spread beyond the cervix a recurrence was inevitable, and only palliative treatment, operative or otherwise, was indicated.

Coxa Vara.—Dr. WILLIS C. CAMPBELL of Memphis reported a case of this disease, and said the diagnosis was not difficult with care in making the examination. As a rule, no medicinal measures were indicated, but in this case he believed that the thyroid extract deserved a trial. In patients of moderate size a simple stilting abduction brace should be used until the bone was firm, when an osteotomy could be done below the lesser trochanter by any of the various methods and the extremity held in abduction and internal rotation by a plaster spica, including the foot below and extending to the nipple or axilla above. He did not believe that a brace would be satisfactory in a subject with so much adipose tissue, but when further reduced we might be able to use any desirable method. At present the patient was in a plaster spica extending to the nipple line, and the extremity held in as much abduction as possible. The condition had probably been present for one year, and at the expiration of two more years a corrective osteotomy could be done with excellent functional result if there was no further change visible by the *x*-ray, otherwise we should wait until the process was stationary. In the meantime he should apply successive plaster spicas with forcible abduction and internal rotation, which might restore the angle sufficiently to give perfect function.

Purgatives with Pain in the Belly.—Dr. C. N. COWDEN of Nashville said there was no place for the administration of a purgative with pain in the belly unattended by a diarrhea. The point he desired to emphasize as strongly as possible was that the patient's danger lay not in the fact that the bowels did not move, but in the condition that produced the pain and obstruction, and the administration of purgatives of any kind under these circumstances with the idea in mind of attempting to force a bowel movement was not only irrational, but was productive of the greatest harm to the patient. He did not get well because the physician forced his bowels to move but in spite of the effect of the drastic measure. Why not be rational in the treatment of these cases and meet the indications with remedies or measures that were indicated and not by the indiscriminate use of purgatives. Purgatives were valuable remedies and were often indicated in the treatment of disease, but the cases were few and far between, not met with in a lifetime, in which they were indicated in the treatment of acute conditions of the belly, where pain was a prominent symptom.

Surgery of the Ovaries.—Dr. J. A. CRISLER of Memphis said that when a woman came to him with great pain in her ovary, to which no infection could be traced, who suffered before and after her menstruation and in between times, he could not tell, upon exploratory incision which ovary was at fault by any microscopical examination. On the contrary, on many occasions he had found the ovary of which the woman complained and which was tender upon bimanual palpation to be in appearance upon celiotomy entirely normal, while the other ovary might contain a hemorrhagic area half its size. When both ovaries were giving constant pain in a woman who was not necessarily neurasthenic, rendering her practically incapable, when the abdomen was opened and both ovaries appeared as good or better than those noticed in a previous case that were not giving any trouble, he did not know whether to resect a portion of them in the hope of relieving the congestion and retention of large Graafian follicle cysts, or whether to remove them entirely or to merely puncture the cyst and let some better surgeon remove them later or to confess absolute ignorance upon the subject and convict the entire profession of inefficiency, basing the proposition upon the present-day literature upon the subject and of our inability by any known means of differentiating the good from the bad microscopically and not clinically. He did not know when the removal of these ovaries would bring perfect relief to some women who did not seem to miss the so-called internal secretion, while in others a series of the most violent and unpleasant symptoms followed the procedure regardless of the age of the patient. He mentioned these cases to show the broad contrast that could exist and the uncertainty of the effects of the so-called ovarian secretion. A comparison was made of these ovaries that were removed and so far as he could tell, by a careful examination, there was relatively an identical similarity between them. The paranchymatous substance and stroma were normally arranged. The cortical surface presented a normal appearance. The vascularity was identical. There were no varicosities in the ovarian ligament vessels nor in the pampiniform plexus of either side. The corpora lutea were normally situated and distributed. The ovarian tension was not excessive, and the color was good, and no marked prolapse was present, and he did not know what caused the pain and its concomitant chain of symptoms.

Human and Bovine Bacilli Isolated in Cervical Adenitis.—Dr. WILLIAM LITTERER of Nashville stated that eleven cases of primary tuberculous cervical adenitis were studied, which resulted in the isolation of five cultures of *Bacillus tuberculosis* of the human type, and six cultures of the bovine type. The classification of the types was made on the basis of four tests: (1) the morphological characters of the cultures; (2) the dysgenetic or eugenetic characters of the cultures; (3) the relative virulence towards rabbits; and (4) the reaction curve in five per cent. glycerin bouillon. This last test served admirably to distinguish between the two types, provided careful control tests be rigidly adhered to. In gathering up the clinical data of the eleven cases, he was unable to discern a single feature of distinction between those persons who harbored the human type of bacillus and of those who were infected with the bovine type. The only striking difference observed was the result procured from the administration of tuberculin. In order that uniformly satisfactory results be obtained from the therapeutic administration of this agent, he said it was imperative that the nature of the type of infection be determined, so that a corresponding strain of tuberculin may be employed.

Dr. W. M. MCCABE of Nashville reported a case of elephantiasis caused by *Streptococcus erysipelatosus*, which was associated with *Bacillus prodigiosus*.

The Gamete Carriers.—Dr. GRAHAM E. HENSON of Crescent City, Fla., spoke of the rôle of the gamete carriers in the spread of malaria, and said that until such a time as a campaign of enforced screening of all homes and public meeting places had been generally effected it was imperative that, in addition to the proper treatment of cases showing acute clinical manifestations of malaria, some means be devised to corral all chronic gamete carriers who had either frequent recurrences or possibly only

after long periods of time, and that they be kept under treatment long enough to destroy all parasites they might be harboring.

Carbonic-acid Baths in the Treatment of Heart Diseases.—Dr. J. H. HONAN of Bad-Nauheim, Germany, stated that the results of his clinical studies convinced him that carbonic acid baths in most cases reduced high blood pressure, raised low blood pressure, increased the pulse volume, increased elimination, increased pulse amplitude, increased heart energy, increased duration of temperature, reduced peripheral resistance, reduced dilatation, and relieved nervous irritability.

Measles.—Dr. THOMAS WEAVER of Nashville discussed the complications and sequelae of measles, based on a study of 470 cases.

Dr. C. C. BASS of New Orleans described a quick microscopic typhoid agglutination test, and pointed out its application and advantages.

Dr. J. B. MURFREE of Murfreesboro, Tenn., reported a case of aneurysm of the arch of the aorta, and exhibited the specimen. He said the course of thoracic aneurysm tended to death, and satisfactory treatment could only be hoped for when the aneurysm was saccular with a relative small neck to the sac.

Dermatitis Factitia.—Dr. J. M. KIND of Nashville reported six cases illustrating this condition and said that the treatment for them was that of any simple dermatitis The nervous system demanded the greater attention.

Pathology of Anterior Poliomyelitis.—Dr. O. H. WILSON of Nashville said that nearly all fatal cases of this disease terminated by paralysis of respiration, and in these edema of the floor of the fourth ventricle was found, with an extension of the inflammatory process well up the sylvian aqueduct. The destruction of the ganglionic cell was a secondary result of the inflammatory process, and the cell infiltration. The activity of the inflammation, and the resistance of tissue determined the extent of this, which determined the character of the permanent paralysis. When localized destruction of some cells in the anterior horn was found, chiefly in the lumbar enlargement, we had the common type of poliomyelitis; when the pathology was localized and intense at a point involving practically the entire section of the cord, a rare condition, we might have a transverse myelitis. Acute bulbar paralysis might be seen when the intensity of the disease was located in that region, encephalitis when the cord symptoms were insignificant, and polioencephalitis when the symptoms were general.

Dr. CHARLES M. NICE of Birmingham discussed the symptoms and diagnosis of anterior poliomyelitis.

Infant Feeding.—Dr. MARGARET O. DAVIS of Nashville brought out some points regarding the differences in human and cows' milk in infant feeding, the care of feeding utensils, etc. She emphasized the necessity of pure milk, and its preference to the use of drugs in some cases The predisposition to disease of poorly-fed children was touched on. She emphasized the need of certified milk in cities.

Cardiorenal Treatment.—Dr. J. B. GUTHRIE of New Orleans spoke of the use of digitalis in heart diseases. He withheld a salty diet in cases of dropsy, which he said assisted the patients in enduring the thirst, and made easier work for the heart. Measure of the urine was the gauge of treatment, and rest, dry salt-free diet, and purgation gave as striking change as we saw with the addition of digitalis. He recommended purgatives of strong salines or jalap in dropsy cases. In acute dilatation he recommended venesection, as well as the use of opiates to insure rest. He impressed the necessity of treating the heart muscle, even where the kidney or vessels were first affected, that is, to lighten the labor of the heart muscle by depleting measures, purgatives, diuretics, if the kidney was sound, rest in bed where possible, by the use of opiates if there was distress, and by the reduction of drinking fluids. Digitalis might be given to prolong the rest period of the heart beat.

Treatment of Acute Anterior Poliomyelitis.—Dr. A. W. HARRIS of Nashville said that experimental work was still being carried on in this country and abroad, and all the recent knowledge gained as to etiology, pathology, and clinical types should give much encouragement and should lead one to expect that in the near future a more certain means of making an early diagnosis and probably a specific therapeutic agent would be furnished.

Double Perforation in Typhoid Fever.—Dr. E. M. FOLKES of Biloxi, Miss., reported two cases of perforation following typhoid fever. One patient died eleven days after a successful operation for the closure of the perforation. The diagnosis in this case was made early and operation performed promptly. All of the cases of which he had heard had died within twenty-four or thirty-six hours after the operation, which meant that a too early diagnosis could not be made, nor too prompt surgical interference had to save life.

Dr. A. B. COOKE of Nashville presented resolutions which were adopted, endorsing the medical inspection of all school children.

The association by resolution urged upon Congress the necessity of creating a National Department of Health for the protection of the present and future generations and the strict interpretation of the pure food and drugs acts, whereby the public can be shielded from foods drugged with artificial preservatives which seal the inferiority of unfit material, from habit production nostrums, and from dishonest labels, even though in technical conformance with the law.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Isadore Dyer, New Orleans; *Vice-presidents:* For Tennessee, Dr. William Litterer of Nashville; for Florida, Dr. W. W. Adamson of Tampa; for Georgia, Dr. William C. Lyle of Augusta; for Alabama, Dr. T. D. Park of Birmingham; for Louisiana, Dr. J. B. Guthrie of New Orleans; for Mississippi, Dr. A. G. Payne of Greenville; *Secretary-Treasurer,* Dr. Seale Harris of Mobile.

Hattiesburg, Miss., was selected as the place for holding the next meeting.

State Medical Licensing Boards.

SUMMARY OF THE LAWS AND REGULATIONS GOVERNING THE PRACTICE OF MEDICINE IN THE STATES AND TERRITORIES OF THE UNITED STATES.

COMPILED BY DR. JAMES A. EGAN, SECRETARY OF THE ILLINOIS STATE BOARD OF HEALTH, AND PUBLISHED FROM ADVANCE SHEETS OF THE BULLETIN OF THE BOARD THROUGH THE COURTESY OF THE SECRETARY.

THE requirements governing the practice of medicine as set forth below are substantially correct up to the date October 31, 1910. No attempt has been made to furnish a complete digest of the several laws and regulations. It has been the purpose rather to give the leading facts regarding the conditions of medical practice desired by the physician who wishes to locate in a State. Such information as that relating to standards of preliminary education, the fees for examination and license, the time and place of examination, has been purposely omitted. Full information may be obtained of the respective secretaries, whose names and addresses are correctly given. There has been added an abstract of the laws in each State governing osteopaths, midwives, and itinerant vendors of medicine.

Alabama (Laws to 1907).—Graduation not essential. *Examination* required in the following subjects: Chemistry, anatomy, physiology, the etiology, pathology, symptomatology, and diagnosis of diseases, obstetrics, gynecology, major and minor surgery, physical diagnosis, diseases of

the eye, ear, nose, and throat; hygiene and medical jurisprudence. When an applicant states in writing that he does not propose to practise major surgery, he shall be exempt from examination in that branch, and his certificate shall entitle him to treat diseases, provided that he shall not be entitled to perform operations of major surgery. *Credit for years of practice.*—None. The board, however, "gives an applicant who has been in practice five years or longer a less technical examination in anatomy, chemistry, and physiology than is given to recent graduates." *Reciprocity.*—None.

Osteopaths.—No special requirements. Examined, and licensed if they pass the examination above prescribed. Practice not restricted. *Midwives.*—No law. "Midwives are allowed to practise without restriction." *Itinerant vendors.*—Code of Alabama provides for license.

Chairman Board of Censors of the Medical Association of the State of Alabama, Dr. W. H. Sanders, Montgomery.

Alaska (Laws to 1909).—Graduation essential. *Examination* not required. Applications should be made to the clerk of the court of the district in which the applicants desire to practise.

Arizona (Laws to 1903).—Graduation essential from "a regularly incorporated college." *Examination* required in the following subjects: Anatomy, surgery, gynecology, obstetrics, practice, physiology, pathology, chemistry, materia medica and therapeutics. "If the applicant request it, he or she shall have the privilege of being examined in the branches of the science and the practice of medicine other than physiology, anatomy, pathology, chemistry, practice, surgery, obstetrics, and gynecology, by the member or members of the board, if there be any, of the particular school of medicine specified in his or her diploma." *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—Graduation essential, from "a regularly incorporated college." Practice not restricted. *Examination* required, same as for physicians. *Midwives.*—Practice exempted. *Itinerant vendors.*—No special requirements.

Secretary Territorial Board of Medical Examiners, Dr. Ancil Martin, Phoenix.

Arkansas (Laws to 1903).—Graduation essential from a reputable medical school.. *Examination* required in the following subjects: Anatomy, physiology, chemistry, materia medica and therapeutics, theory and practice of medicine, surgery, obstetrics, pathology, bacteriology, gynecology, hygiene. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.**—On licenses issued after an examination only, with the following States: Illinois, Indiana, Kentucky, Louisiana, Maryland, Michigan, Minnesota, Nebraska, Nevada, North Dakota, Ohio, Texas, Vermont, Virginia. On licenses issued on the basis of either a diploma or an examination, with the following States: Indiana, Kentucky, Maryland, Michigan, and Ohio.

*Discrepancies as to the reciprocating States may be noticed, under this heading, in the various States. But the information published under each State is as furnished by the secretary of the State Board of Medical Examiners.

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—Practice exempted. *Itinerant vendors.*—Practice forbidden.

Secretary State Medical Board of the Arkansas Medical Society, Dr. F. T. Murphy, Brinkley; Medical Board of the Arkansas Homeopathic Medical Society, Dr. P. C. Williams, Texarkana; Medical Board of the Arkansas Eclectic Medical Society, Dr. G. A. Hinton, Hot Springs.

California (Laws to 1909).—Graduation essential from a legally chartered medical school, the requirements of which were at the time of graduation in no particular less than those prescribed by the Association of American Medical Colleges for that year. *Examination* required in the following subjects: Anatomy, physiology, bacteriology, pathology, chemistry and toxicology, hygiene obstetrics, histology, gynecology, general diagnosis *Credit for years of practice.*—Five points on a general average for each ten years of reputable practice. *Temporary Licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—Graduation essential from a legally chartered college of osteopathy; course of instruction much inferior to that demanded of medical colleges. Practice not restricted. Two osteopaths on State Board of Medical Examiners. *Examination* required, same as for physicians. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. Charles L. Tisdale, San Francisco.

Colorado (Laws to 1905).—The State Board of Medical Examiners is required to adopt a schedule of minimum educational requirements. "When an applicant for a license offers to the board satisfactory proof that he has complied with such educational requirements as are specified in said schedule, the board shall accept such proof as sufficient evidence of the educational qualification of the applicant to entitle him to a license without examination." Graduation not essential. *Examination* required in the following subjects: Anatomy, physiology, chemistry, symptomatology, toxicology, pathology, surgery, and obstetrics. "The credentials of applicants relating to their general reputation, their preliminary education, and the courses of study they have pursued; the degrees they have received; the number of years they have been engaged in the lawful practice of medicine; their experience in general hospitals, medical departments of the army, navy, and public health and marine hospital service; licenses granted to them by other States and countries; and their experience as teachers of medicine shall be given due consideration by the board in conducting its examination. Upon investigation of an applicant's credentials the board shall, when convinced that an applicant is qualified to practise medicine, grant him a license thereon without further examination." *Credit for years of practice.*—None. *Temporary licenses.*—None granted. *Reciprocity.*—None.

Osteopaths.—Practice exempted by law. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. S. D. Van Meter, Denver.

Connecticut (Laws to 1909).—Graduation essential from some legally incorporated and reputable medical college, approved by the Connecticut Medical Society, the Connecticut Homeopathic Medical Society, or the Connecticut Eclectic Medical Society. *Examination* required in the following subjects: Anatomy, physiology, chemistry, obstetrics, hygiene, surgery, pathology, diagnosis, therapeutics, practice, materia medica. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—State Board of Osteopathic Registration and Examination. *Midwives.*—Examined and licensed. *Itinerant vendors.*—No law.

Secretary Connecticut Medical Examining Board, Dr. Charles A. Tuttle, New Haven. Secretary Connecticut Homeopathic Medical Examining Board, Dr. E. C. M. Hall, New Haven. Secretary Connecticut Eclectic Medical Examining Board, Dr. Thomas S. Hodge, Torrington.

Delaware (Laws to 1907).—Graduation essential from some regularly incorporated medical college in good standing in the opinion of the Medical Council. *Examination* required in the following subjects: Anatomy, physiology, chemistry, pathology, diagnosis, materia medica and therapeutics, practice of medicine, surgery, obstetrics, hygiene. *Credit for years of practice.*—"The General Assembly has provided an examination for elderly physicians who were graduated on a two years' course, but the boards do not extend any privileges or grant a certain per cent. in the examination for previous practice." *Temporary licenses.*—Granted for not less than two weeks nor more than four weeks, but only "to take charge of the practice of a resident or legally qualified physician of this State during the latter's temporary illness or absence from the State." *Reciprocity.*—On licenses granted after an examination only, "with all States having a standard equal to or better than ours."

Osteopaths.—Examination required. Graduation essential from "a legally chartered and regularly conducted school of osteopathy." *Examination* by the Medical Council and some reputable practitioner of osteopathy in the following subjects: Anatomy, physiology, hygiene, chemistry, obstetrics, pathology, diagnosis, histology, gynecology, surgery, urinalysis, and osteopathy. Practice not restricted. *Midwives.*—No. law. *Itinerant vendors.*—Regulated under pharmacy law.

Secretary State Medical Examining Board representing the President and Fellows of the Medical Society of Delaware, Dr. J. H. Wilson, Dover. Secretary State Medical Examining Board representing the Homepathic Medical Society of Delaware, State and Peninsula, Dr. L. A. Kittenger, Wilmington. Examinations are conducted by the Medical Council.

District of Columbia (Laws to 1905).—Graduation essential from a college approved by the Board of Supervisors. *Examination* required in the following subjects: Anatomy, physiology, chemistry, bacteriology, pathology, materia medica, therapeutics, hygiene, histology, practice of medicine, surgery, obstetrics, gynecology, diseases of the eye and ear, medical jurisprudence. *Credit for years of practice.*—None. *Reciprocity* with the following States: Georgia, Indiana, Kentucky, Maryland, Michigan, Minnesota, Nebraska, Ohio, Texas, Vermont, Virginia, West Virginia, Wisconsin.

Osteopaths.—Practice exempted by law. *Itinerant vendors.*—Regulated under pharmacy laws.

All communications relative to licenses to practise medicine in the District of Columbia should be addressed to the Board of Medical Supervisors, Washington, D. C.

Florida (Laws of 1889 and 1905).—Graduation essential from a recognized medical college. *Examination* required in the following subjects: Anatomy, physiology, surgery, gynecology, therapeutics, obstetrics, chemistry. The State Board of Homeopathic Medical Examiners also examines in materia medica. *Credit for years of practice.*—One per cent. for each year of practice after ten years. *Temporary licenses* granted. *Reciprocity.*—None.

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. J. D. Fernandez, Jacksonville. Secretary State Board of Homeopathic Medical Examiners, Dr. C. W. Johnson, Jacksonville. Secretary State Board of Eclectic Medical Examiners, Dr. Hiram J. Hampton, Tampa.

Georgia (Laws to 1904).—Graduation essential from an approved medical college. *Examination* required. The applicant is examined by the board representing the system of practice of the school of which he is a graduate, or by the board which represents the system that he proposes to practise, in the following subjects: Anatomy, physiology, chemistry, therapeutics, practice of medicine, surgery, gynecology, obstetrics, pathology. *Credit for years of practice.*—"Some allowance is made when applicants show proficiency in practical branches." *Temporary licenses* granted. *Reciprocity.*—On licenses issued after examination only with the following States: District of Columbia, Illinois, Iowa, Kansas, Kentucky, Louisiana, Maine, Maryland, Michigan, Nebraska, Nevada, North Carolina, North Dakota, Tennessee, Virginia, and "a few others."

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—No law. Midwives practise without restriction. *Itinerant vendors.*—No law.

Secretary State Board of Regular Examiners, Dr. I. H. Goss, Athens. Secretary State Board of Homeopathic Examiners, Dr. R. E. Hinman, Atlanta. Secretary State Board of Eclectic Examiners, Dr. C. W. Miller, Atlanta.

Hawaii.—Graduation essential from a reputable college of medicine whose curriculum embraces not less than four years of study. *Examination* required.

Secretary Board of Medical Examiners, Dr. Archibald N. Sinclair, Honolulu.

Idaho (Laws to 1909).—Graduation essential from a reputable college of medicine in good standing. *Examination* required in the following subjects: Anatomy, physiology, pathology, diagnosis, hygiene, chemistry, histology, toxicology, and theory and practice of medicine and surgery "as those branches are taught in the reputable, chartered schools of the system of medicine to which the applicant belongs or which he intends to practise." *Credit for years of practice.*—Five per cent. for each ten years of legal practice. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—State Board of Osteopathic Examination and Registration. *Midwives.*—Practice exempted by law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. O. J. Allen, Bellevue.

Illinois (Laws to 1907).—Graduation essential from a medical college in good standing. *Examination* required in the following subjects: Chemistry, etiology and hygiene, physiology, neurology, anatomy, materia medica and therapeutics, pathology and bacteriology, surgery, physical diagnosis, ophthalmology and otology, pediatrics, obstetrics, gynecology, laryngology and rhinology, medical jurisprudence, practice. *Credit for years of practice.*—One per cent. for each year of reputable practice since graduation, up to a total of 30 per cent. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after examination only, with the following States: Arkansas, Georgia, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Jersey, North Dakota, Ohio, Texas, Utah, Vermont, West Virginia, Wisconsin, and Wyoming.

Osteopaths.—Not mentioned in the statutes. Examined and licensed, if found proficient, under section of the medical law providing for examination of those persons "who desire to practise any other system or science of treating human ailments who do not use medicines internally or externally, and who do not practise operative surgery." Practice restricted. *Examination* in the following subjects: Anatomy (same as for physicians), physiology (same as for physicians), chemistry, histology and pathology, hygiene, symptomatology. *Midwives.*—Examined and licensed. Violators of the law prosecuted. *Itinerant vendors.*—Law provides "that any itinerant vendor of any drug, nostrum, ointment, or application of any kind intended for the treatment of diseases or injury who shall, by writing or printing, or any other method, profess to the public to cure or treat disease or deformity by any drug, nostrum, or application shall pay a license of $100 per month into the treasury of the State Board of Health." Violators of the law prosecuted.

Secretary State Board of Health, Dr. James A. Egan, Springfield.

Indiana (Laws to 1909).—Graduation essential from a medical college maintaining a standard acceptable to the State Board of Medical Registration and Examination. *Examination* required in the following subjects: Anatomy, including histology and embryology; general surgery, materia medica and therapeutics, medicine, obstetrics, pathology and bacteriology, chemistry, etiology and hygiene, physiology, neurology, gynecology, laryngology and rhinology, medical jurisprudence, physical diagnosis, ophthalmology and otology, pediatrics. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—On licenses issued, after examination only, with the following States: Arkansas, District of Columbia, Georgia, Illinois, Louisiana, New Hampshire, New York, Texas, Wyoming. On licenses issued on the basis of either an examination or a diploma—if the diploma and license were issued prior to March 11, 1901—with the following States: Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, Ohio, Tennessee, Utah, Vermont, Virginia, West Virginia, Wisconsin.

Osteopaths.—Examined and licensed. Graduation essential from an osteopathic college maintaining a standard acceptable to the State Board of Medical Registration and Examination; course of instruction inferior to that demanded of medical colleges. Osteopath on State Board of Medical Registration and Examination. *Examination* same as for physicians, except that the subjects of medicine and materia medica are omitted. *Midwives.*—Licensed on presentation of approved diploma or on examination. *Itinerant vendors.*—No law.

Secretary State Board of Medical Registration and Examination, Dr. W. T. Gott, Indianapolis.

Iowa (Laws to 1909).—Graduation essential from a medical college in good standing with the State Board of Medical Examiners. *Examination* required in the following subjects: Anatomy, histology, embryology, chemistry, physiology, materia medica and therapeutics, toxicology, obstetrics, gynecology, pathology, bacteriology, etiology, practice, neurology, physical diagnosis, pediatrics, hygiene, surgery, laryngology and rhinology, ophthalmology and otology, medical jurisprudence. *Credit for years of practice.*—One per cent. for each year of reputable practice up to and including fifteen years. *Temporary licenses.*—Granted. *Reciprocity.*—On licenses, issued after examination only, with the following States: Delaware, Illinois, New Hampshire, New Jersey, Texas, Virginia, Wyoming. On licenses issued on the basis of a diploma but without an examination, provided that diploma was issued prior to January 1, 1899, with the following States: Georgia, Indiana, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, New Mexico, North Carolina, Ohio, South Carolina, Utah, West Virginia, Wisconsin.

Osteopaths.—Examined and licensed. Graduation essential from a legally incorporated school of osteopathy recognized as in good standing by the Iowa Osteopathic Association; course of instruction much inferior to that demanded of medical colleges. *Examination* in the following subjects: Anatomy, including practical anatomy; physiology, chemistry, histology, pathology, gynecology, obstetrics, and the theory of osteopathy—the latter excepted "until such time as there may be appointed an osteopathic physician on the State Board of Health and of Medical Examiners." *Midwives.*—No law. *Itinerant vendors.*—Regulated under pharmacy law. Annual fee of $100.

Secretary State Board of Medical Examiners, Dr. Guilford H. Sumner, Des Moines.

Kansas (Laws to 1908).—*Examination* required, but "graduates of legally chartered medical institutions of the United States and of foreign countries, in good standing, as may be determined by the board, may, at the discretion of the board, be granted a license without examination." Graduation not essential. Applicant must present evidence that "he has devoted not less than three periods of six months each, no two within the same twelve months, or after April 1, 1902, four periods of not less than six months each, no two within the same twelve months, to the study of medicine and surgery." *Examination* "shall embrace all those topics and subjects a knowledge of which is generally required by reputable medical

colleges of the United States for the degree of Doctor of Medicine." *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—On licenses issued, after examination only, with the following States: Alabama, Delaware, District of Columbia, Georgia, Illinois, Louisiana, Maine, Maryland, Minnesota, New Jersey, North Carolina, North Dakota, Ohio, South Carolina, Tennessee, Texas, Utah, Virginia, West Virginia, Wyoming. On licenses issued on the basis of either an examination or a diploma with the following States: Indiana, Iowa, Kentucky, Missouri, Nebraska, Wisconsin.

Osteopaths.—Licensed on presentation of a diploma from an approved school of osteopathy. Practice not restricted. *Midwives.*—No law. *Itinerant vendors.*—Annual fee of $50; license to be issued by county clerk.

Secretary State Board of Medical Registration and Examination, Dr. Henry A. Dykes, Lebanon.

Kentucky (Laws to 1904).—Graduation essential from a reputable and legally chartered medical college in the United States. *Examination* required in the following subjects: Anatomy, including histology and embryology, physiology, pathology, chemistry, surgery, obstetrics, gynecology, bacteriology, hygiene, ophthalmology and otology, medical jurisprudence, mental and nervous diseases, etiology, and physical diagnosis. *Credit for years of practice.*—One per cent. for each year of reputable practice. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued, after examination only, with the following States: Delaware, District of Columbia, Illinois, Louisiana, New Hampshire, New Jersey, North Dakota, Texas, Virginia, Wyoming. On licenses issued after an examination or on diploma with the following States: Arkansas, Georgia, Indiana, Iowa, Kansas, Maine, Maryland, Michigan, Minnesota, Missouri, Montana, Nebraska, Nevada, South Carolina, Tennessee, Utah, Vermont, West Virginia, Wisconsin.

Osteopaths.—Examination required. Graduation essential from a reputable college of osteopathy; course of instruction inferior to that demanded of medical colleges. Practice not restricted. Osteopath on State Board of Health. *Examination.*—Same as for physicians. *Midwives.*—Practice exempted. *Itinerant vendors.*—Practice exempted, except that of "any itinerant medical company of two or more persons traveling as a troupe or company."

Secretary State Board of Health, Dr. J. N. McCormack, Bowling Green.

Louisiana (Laws to 1908).—Graduation essential from "a college in good standing of any sect teaching medicine or the healing art." *Examination* required in the following subjects: Anatomy, physiology, chemistry, obstetrics, gynecology, physical diagnosis, surgery, pathology, therapeutics, hygiene, "provided that any person not using internal medication in his practice shall be exempt from examination in therapeutics." *Credit for years of practice.*—None at the present time. It is believed that the Louisiana State Board of Medical Examiners will do so at its next meeting. The allowance, however, will probably not be over 15 per cent. *Temporary licenses* granted. *Reciprocity.*—On licenses issued, after an examination only, with the following States: Arkansas, Georgia, Illinois, Indiana, Kansas, Kentucky, Maryland, Minnesota, Missouri, New Hampshire, Virginia, Wisconsin, provided that applicants "present a diploma from a college rated Class 'A' by this board, *i.e.*, medical colleges rated between 70 per cent. and 100 per cent. by the Council on Medical Education of the American Medical Association."

Osteopaths.—State Board of Osteopathy. *Midwives.*—Law does not apply to midwives in rural districts and plantation practice. *Itinerant vendors.*—Practice prohibited.

Secretary State Board of Medical Examiners, Dr. A. B. Brown, New Orleans.

Maine (Laws to 1901).—Graduation essential from some reputable medical college, or college having the power to confer degrees in medicine, and in good standing with the State Board of Medical Registration and Examination. *Examination* required in the following subjects: Anatomy, physiology, pathology, materia medica and therapeutics, surgery, principles and practice of medicine, obstetrics, chemistry, hygiene, diseases of the eye, ear, nose, and throat, medical jurisprudence. *Credit for years of practice.*—One per cent. for each year of practice, but no credit allowed until after applicant has been in practice for five years. *Temporary licenses.*—Not granted. *Reciprocity.*—With the following States: Arkansas, Delaware, District of Columbia, Georgia, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Jersey, North Dakota, Ohio, South Carolina, Tennessee, Texas, Utah, Vermont, Wisconsin, Wyoming, Virginia, West Virginia. *Osteopaths.*—Practice exempted. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Registration of Medicine, Dr. Frank W. Scarle, Portland.

Maryland (Laws to 1908).—Graduation essential from colleges meeting the requirements of the American Medical College Association or the Intercollegiate Committee of the American Institute of Homeopathy. *Examination* required in the following subjects: Anatomy, physiology, chemistry, surgery, practice of medicine, materia medica, therapeutics, obstetrics, and pathology. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—Maryland is in reciprocal relationship with the following States: Georgia, Illinois, Indiana, Iowa, Kentucky, Maine, Michigan, Minnesota, Nebraska, New Hampshire, North Carolina, Ohio, South Carolina, Tennessee, Texas, Vermont, Virginia, West Virginia, Wisconsin. The recognition of licenses is based on examination only, except the practitioners who were engaged in practice prior to the enactment of the law regulating medical practice are admitted, if properly certified as to professional standing and ability.

Osteopaths.—Practice exempted. *Midwives.*—Practice exempted. *Itinerant vendors.*—No law.

Secretary Board of Examiners representing the Medical and Chirurgical Faculty of the State of Maryland, Dr. J. McP. Scott, Hagerstown. Secretary Board of Medical Examiners of the Maryland State Homeopathic Medical Society, Dr. Joseph S. Garrison, Baltimore.

Massachusetts (Laws to 1909).—Graduation not essential. *Examination* required in the following subjects: Anatomy, surgery, physiology, pathology, obstetrics, gynecology, practice of medicine, hygiene, diagnosis, bacteriology, pediatrics, toxicology. *Credit for years of practice.*—One per cent. of the minimum requirement (75 per cent.) for each year in excess of five years of successful practice. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—No special requirements. Examined and licensed if they pass the examination above prescribed. Practice not restricted. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Registration in Medicine, Dr. Edwin B. Harvey, Boston.

Michigan (Laws to 1907).—Graduation essential from a medical college approved by the State Board of Registration in Medicine. *Examination* required in the following subjects: Anatomy, physiology, chemistry, pathology, materia medica and therapeutics, toxicology, histology, practice of medicine, surgery, obstetrics, gynecology, mental and nervous diseases, diseases of the eye, ear, nose, and throat, bacteriology, hygiene, medical jurisprudence, and public health laws of Michigan. *Credit for years of practice.*—Two per cent. for each year during the first five years of practice and 1 per cent. thereafter up to a total of 25 per cent. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued, after an examination only, with the following States: District of Columbia, Illinois, Louisiana, New Jersey, New York, North Dakota, Texas, Virginia, Wyoming. On licenses issued either on a diploma or an examination with the following States: Arkansas, Georgia, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, Ohio, South Carolina, Utah, Vermont, West Virginia, Wisconsin.

Osteopaths.—State Board of Osteopathic Registration and Examination. *Midwives.*—No law. *Itinerant vendors.*—No law. Secretary State Board of Registration in Medicine, Dr. B. D. Harison, Detroit.

Minnesota (Laws to 1909).—Graduation not essential. Applicant must prove "that he has completed four entire sessions (three prior to 1899) of twenty-six weeks each at a medical school recognized by the State Board of Medical Examiners." *Examination* required in the following subjects: Anatomy, physiology, chemistry, histology, materia medica, therapeutics, preventive medicine, practice of medicine, surgery, obstetrics, diseases of women and children, diseases of the nervous system, diseases of the eye and ear, medical jurisprudence. *Credit for years of practice.*—None. "But length of time in practice is taken into consideration in passing upon an applicant's papers, and the longer an applicant has been in practice the better showing is he required to make in the practical branches, such as the practice of medicine, obstetrics, and surgery." *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued, after examination only, with the following States: Arkansas, Delaware, District of Columbia, Illinois, Louisiana, Maryland, Nevada, New Hampshire, New Jersey, North Carolina, North Dakota, South Carolina, Texas, Vermont, Virginia, Wyoming. On licenses issued, either on a diploma or on an examination, with the fol-

lowing States: Indiana, Iowa, Kansas, Kentucky, Maine, Missouri, Nebraska, Ohio, Tennessee, Utah, Wisconsin. "All applicants for licenses are required to take a practical examination in laboratory work in pathology, histology, bacteriology and urinalysis, and in clinical diagnosis. Applicants for reciprocal registration coming from boards which do not require this examination must take it before this board as a supplementary."

Osteopaths.—State Board of Osteopathic Examiners and Registration. *Midwives.*—Licensed on presentation of approved diploma or on examination. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. W. S. Fullerton, St. Paul.

Mississippi (Law to 1906).—Graduation not essential. *Examination* required in the following subjects: Anatomy, chemistry, obstetrics, materia medica, physiology, pathology, surgery, hygiene. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—None.

Osteopaths.—Graduation not essential. *Examination* required in anatomy, physiology, and hygiene only. *Midwives.*—Permitted to practice without license. *Itinerant vendors.*—No law.

Secretary State Board of Health, Dr. S. H. McLean, Jackson.

Missouri (Laws to 1909).—Graduation essential from a reputable medical college approved by the State Board of Health. *Examination* required in the following subjects: Anatomy, chemistry, physiology, therapeutics, obstetrics, gynecology, surgery, practice of medicine, bacteriology, medical jurisprudence, and such other branches as the State Board of Health may direct. *Credit for years of practice.*—One per cent. for each year of reputable practice. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued, after examination only, with the following States: Illinois, Louisiana, North Dakota, South Carolina, Texas, Virginia. On licenses issued on the basis of a diploma, but without examination, with the following States: Georgia, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Nebraska, Nevada, New Hampshire, West Virginia, Wisconsin.

Osteopaths.—State Board of Osteopathic Registration and Examination. *Midwives.*—Examined and licensed. *Itinerant vendors.*—May be licensed as peddlers; $20 per year.

Secretary State Board of Health, Dr. Frank B. Hiller, Jefferson City.

Montana (Laws to 1907).—Graduation essential from a medical college in good standing. *Examination* required in the following subjects: Anatomy, physiology, materia medica and therapeutics, practice of medicine, surgery, obstetrics, diseases of women and children, diseases of the nervous system, diseases of the eye and ear. *Credit for years of practice.*—Five per cent. for each ten years. *Temporary licenses.*—None. *Reciprocity.*—None.

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. William C. Riddell, Helena.

Nebraska (Laws to 1907).—Graduation essential from a medical school in good standing. *Examination* required in all the branches generally required by reputable medical colleges for the degree of Doctor of Medicine. *Credit for years of practice.*—None; but it is believed that the Nebraska board will adopt the Illinois method at their next meeting. *Temporary licenses* not granted. *Reciprocity.*—On licenses issued, after an examination only, with the following States: Arkansas, Illinois, Louisiana, New Jersey, Tennessee, Texas, Vermont, Virginia. On licenses issued on the basis of either an examination or diploma with the following States: District of Columbia, Georgia, Indiana, Iowa, Kansas, Kentucky, New Hampshire, Ohio, Utah, Maine, Maryland, Michigan, Minnesota, Missouri, Nevada, West Virginia, and Wisconsin.

Osteopaths.—State Board of Osteopathy. *Midwives.*—No law. *Itinerant vendors.*—Practice prohibited.

Secretary State Board of Health, Dr. E. Arthur Carr, Lincoln.

Nevada (Law of 1905).—Graduation essential from a legally recognized college. *Examination* required in the following subjects: Anatomy, physiology, materia medica and therapeutics, chemistry, bacteriology, pathology, toxicology, obstetrics, surgery, general medicine, diseases of the skin, eye, ear, nose, throat, brain, and genitourinary system. *Credit for years of practice.*—One per cent. is allowed for the first five years. After that, 1 per cent. for each additional year. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after examination only with the following States: Arkansas, Illinois, Indiana, Louisiana, Maine, New Hampshire, South Carolina, Texas. On licenses issued on the basis of a diploma, but without examination, with the following States: Georgia, Iowa, Kentucky, Michigan, Minnesota, Missouri, Nebraska, Wisconsin.

Osteopaths.—No law. Osteopaths practice without restriction. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. S. L. Lee, Carson City.

New Hampshire (Laws to 1907).—Graduation essential from a medical college conforming to the requirements of the Regents. *Examination* required in the following subjects: Anatomy, physiology, hygiene, chemistry, surgery, obstetrics, pathology, diagnosis, practice, materia medica, and therapeutics. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after examination only with the following States: Indiana, Iowa, Kentucky, Louisiana, Maryland, Minnesota. On the basis of either an examination or a diploma from a reputable medical college, provided the diploma and license were issued prior to September 1, 1897, with the following States: Michigan, Nebraska, Nevada, Vermont, West Virginia, Wisconsin.

Osteopaths.—Practice of osteopathy exempted by law. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Medical Board representing the New Hampshire Medical Society, Dr. James T. Greeley, Nashua. Secretary State Board representing the Homeopathic Medical Society, Dr. R. V. Sweet, Rochester. Secretary State Board representing the Eclectic State Medical Society, Dr. Walter H. True, Laconia.

New Jersey (Laws to 1910).—Graduation essential from some legally incorporated medical college in good standing with the State Board of Medical Examiners. *Examination* required in the following subjects: Materia medica and therapeutics, obstetrics and gynecology, practice of medicine, including diseases of the skin, nose, and throat; surgery, including surgical anatomy and diseases of the eye, ear, nose, and genitourinary organs; anatomy; physiology; chemistry; histology; pathology; bacteriology; hygiene; medical jurisprudence, and in such other subjects as the board may require. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only with the following States: Delaware, Illinois, Indiana, Kentucky, Maine, Michigan, Minnesota, New Hampshire, Ohio, Vermont, Wisconsin.

Osteopaths.—No law. Osteopaths practise without restriction. *Midwives.*—Examined and licensed. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. H. S. Norton, Trenton.

New Mexico (Laws to 1909).—Any reputable person who is a graduate of a medical college in good standing as defined in the medical law of New Mexico, and who personally appears before the Board of Medical Examiners at its regular meeting, shall be licensed without examination. Examination required of graduates of reputable medical colleges other than those in good standing. *Credit for years of practice.*—Five per cent. for each five years of actual practice. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only with the following States: Iowa and Louisiana. On license issued on the presentation of diploma without examination with the State of Iowa.

Osteopaths.—Territorial Board of Osteopathy. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary Board of Health and Medical Examiners, Dr. J. A. Massie, Santa Fé.

New York (Laws to 1907).—Graduation essential from a medical college registered by the Regents as maintaining a proper medical standard. *Examination* required in the following subjects: Anatomy, physiology, chemistry, hygiene and sanitation, surgery, obstetrics and gynecology, pathology, and bacteriology, diagnosis. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after examination only with the following States: Delaware, Indiana, Michigan, Ohio, Utah, Vermont, Wisconsin.

Osteopaths.—Examination required. Graduation not essential. Applicant must produce evidence that he has studied osteopathy and attended certain courses in a college of osteopathy, maintaining at the time a standard satisfactory to the Regents; course of instruction inferior to that demanded of medical colleges. Osteopath on State Board of Medical Examiners. *Examination.*—Same as for physicians. *Midwives.*—No law. *Itinerant vendors.*—No law.

First Assistant Commissioner of Education, Augustus S.

Downing, M.A., Ph.D., LL.D., Albany. All correspondence relating to the details of examination should be addressed to the Chief of the Examination Division, New York State, Education Department, Albany.

North Carolina (Laws to 1905).—Graduation essential from a medical college in good standing. *Examination* required in the following subjects: Anatomy, physiology, surgery, pathology, hygiene, chemistry, materia medica, therapeutics, gynecology, pediatrics, practice of medicine. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—State Board of Medical Examiners empowered to reciprocate.

Osteopaths.—State Board of Osteopathic Registration and Examination. *Midwives.*—Practice exempted. *Itinerant vendors.*—Licensed by Board of County Commissioners.

Secretary State Board of Medical Examiners, Dr. Benjamin K. Hays, Oxford.

North Dakota (Laws of 1890-1895-1905).—Graduation essential from a reputable medical college recognized by the State Board of Medical Examiners. The State Board of Medical Examiners will not recognize colleges rated by the Council on Medical Education of the American Medical Association below 50 as being in "good standing." *Examination* required in the following subjects: Anatomy, physiology, chemistry, pathology, therapeutics, diseases of women and children, nervous diseases, diseases of the eye and ear, medical jurisprudence, surgery, obstetrics, preventive medicine, histology, and such other subjects as the board may deem advisable. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only, subsequent to June 30, 1905, with the following States: Arkansas, Illinois, Maine, Michigan, Minnesota, Texas, Vermont, West Virginia, Wisconsin.

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. H. M. Wheeler, Grand Fork.

Ohio (Laws to 1910).—Graduation essential from a legally chartered medical institution in good standing, as defined by the State Medical Board. *Examination* required in the following subjects: Anatomy, physiology, pathology, chemistry, materia medica and therapeutics, medicine, diagnosis, surgery, obstetrics, diseases of women and children, and such other subjects as the board requires. *Credit for years of practice.*—Five per cent. for each five years. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only with the following States: Illinois, New Jersey, New York, Texas. On licenses issued on the basis of a diploma but without examination with the following States: Arkansas, District of Columbia, Indiana, Iowa, Kansas, Maine, Maryland, Michigan, Minnesota, Nebraska, Vermont, West Virginia, Wisconsin, Wyoming.

Osteopaths.—Examination required. Graduation essential from a reputable college of osteopathy, as determined by the Osteopathic Examining Committee appointed by the State Medical Board on the recommendation of the Ohio Osteopathic Society; course of instruction inferior to that demanded of medical colleges. *Examination* in the following subjects: Pathology, physiological chemistry, gynecology, minor surgery, osteopathic diagnosis, and the principles and practice of osteopathy. *Midwives.*—Examined and licensed. *Itinerant vendors.*—No law.

Secretary State Medical Board, Dr. George H. Matson, Columbus.

Oklahoma (Laws to 1908).—Graduation essential from "some legally chartered medical institution or college; the requirements of such medical school or college shall have been at the time of granting such diploma in no particular less than those prescribed by the American Association of Medical Colleges or the Southern Association of Medical Colleges in that year in which the said diploma was granted." *Examination* required in the following subjects: Anatomy, bacteriology, physiology, gynecology, obstetrics, toxicology, medical jurisprudence, hygiene, sanitary science, chemistry, physical diagnosis, materia medica, practice, histology, and surgery. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—None.

Osteopaths.—Examination required. Graduation essential from a legally chartered college of osteopathy in good repute; course of instruction much inferior to that demanded of medical colleges. Osteopaths are permitted to administer medicines "in cases of emergency." Osteopath on State Board of Medical Examiners. *Examination.*—Same as for physicians, except that materia medica and therapeutics are omitted, and the applicant "shall be examined in theory and practice by the member of the Board of Examiners who represents the school of practice to which the applicant professes to belong." *Midwives.*—Practice exempted. *Itinerant vendors.*—County licenses required.

Secretary State Board of Medical Examiners, Dr. Frank P. Davis, Enid.

Oregon (Laws to 1907).—Graduation not essential. *Examination* required in the following subjects: Anatomy, surgery, pathology, materia medica and therapeutics, practice of medicine, diseases of the eye and ear, gynecology, diagnosis, obstetrics, nervous diseases, diseases of children, chemistry, medical jurisprudence, histology, and physiology. *Credit for years of practice.*—After ten years of active practice licenses will be granted on a rating of 70 per cent.; after twenty years' practice, 65 per cent. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—Examination required. Graduation essential from "any established school of osteopathy recognized as in good standing by the Oregon Osteopathic Association." Osteopath on State Board of Medical Examiners. *Examination* required in the following subjects: Anatomy, pathology, gynecology, obstetrics, chemistry, histology, physiology, osteopathy. *Midwives.*—No law. *Itinerant vendors.*—Regulated under pharmacy law.

Secretary State Board of Medical Examiners, Dr. E. B. McDaniel, Portland.

Pennsylvania (Law of 1893).—Graduation essential from some approved legally incorporated medical college. *Examination* required in the following subjects: Anatomy, physiology, hygiene, chemistry, surgery, obstetrics, pathology, diagnosis, therapeutics, practice of medicine, materia medica. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—No law. *Itinerant vendors.*—No law.

The Medical Council has supervision of the regulation of the practice of medicine in Pennsylvania. Secretary of Medical Council, Hon. Nathan C. Schaeffer, Harrisburg. There are three separate Boards of Medical Examiners for the State of Pennsylvania: one representing the Medical Society of the State of Pennsylvania; one representing the Homeopathic Medical Society of Pennsylvania; and one representing the Eclectic Medical Society of the State of Pennsylvania.

Philippine Islands.—Graduation not essential. *Examination* required in the following subjects: Anatomy, physiology, chemistry, materia medica, pathology, bacteriology, hygiene, surgery, practice of medicine, obstetrics, diseases of women and children, neurology, diseases of the eye and ear, medical jurisprudence.

Secretary Board of Medical Examiners, Dr. Paul Clements, Manila.

Porto Rico.—Graduation essential from a medical institution in good standing as recognized by the Board of Examiners. *Examination* required in those general subjects and topics a knowledge of which is commonly and generally required of candidates for the degree of medicine by respectable colleges of the United States.

Secretary Board of Examiners, Dr. Quevedo Baez, San Juan.

Rhode Island (Laws to 1908).—Graduation essential from a medical school in good standing. *Examination* required in the following subjects: Anatomy and physiology, materia medica and chemistry, pathology, surgery, theory and practice of medicine, obstetrics and gynecology, medical jurisprudence, and hygiene. *Credit for years of practice.*—None; but a special examination is given to physicians who have been in practice fifteen years or more and who are of good repute in the locality in which they have been practising. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—No specific requirements. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Health, Dr. Gardner T. Swarts, Providence.

South Carolina (Laws of 1904-1905-1908).—Graduation essential from a medical college of established reputation. *Examination* required. The curriculum of the State Board of Medical Examiners is divided into two sections: the Junior and the Senior curriculum. The Junior curriculum comprises the following subjects: Anatomy, physiology, histology, materia medica and medical botany, chemistry, medical physics, bacteriology, and pathology. The Senior curriculum comprises the following subjects: Anatomy, hygiene, sanitary science and State medicine, urinalysis, therapeutics and toxicology, surgery, practice of medicine, diseases of children, obstetrics and gynecology, medical jurisprudence. Applicants holding a diploma from a four-year graded medical college, who have pursued the study of four separate courses, and have obtained marks of not less than 75 per cent. in each individual branch, shall be exempted from examination in the Junior curriculum.

Credit for years of practice.—None. *Temporary licenses.*—Granted. *Reciprocity.*—On licenses issued after an examination only with the following States: Kansas, Maine, Maryland, Michigan, Minnesota, Missouri, Nevada, Utah, Virginia, West Virginia, Wyoming.

Osteopaths.—Examination required. Graduation essential from a duly authorized school of osteopathy. *Examination.*—The same as for physicians, except that materia medica, major surgery and the practice of medicine are omitted. *Midwives.*—Practice exempted. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. A. Earle Boozer, Columbia.

South Dakota (Laws to 1907).—Graduation essential from a legally organized and reputable medical college recognized by the State Board of Medical Examiners. *Examination* required in the following subjects: Anatomy, physiology, chemistry, pathology, therapeutics, practice of medicine, surgery, obstetrics, gynecology, diseases of the eye and ear, bacteriology, medical jurisprudence, and such other branches as the board may deem advisable. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—State Board of Osteopathic Examiners. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. F. W. Freyberg, Mitchell.

Tennessee (Laws to 1907).—Graduation not essential. *Examination* required in the following subjects: Anatomy, physiology, chemistry, pathology, surgery, obstetrics, materia medica, and practice. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—Tennessee has reciprocal relations with the following States: Georgia, Indiana, Kansas, Kentucky, Maine, Minnesota, Nebraska, North Carolina, Utah, West Virginia, Wisconsin. Negotiations are now pending with Maryland and Michigan. Licenses are issued on presentation of diploma without examination to licentiates of Georgia and Kentucky.

Osteopaths.—State Board of Osteopathic Registration and Examination. *Midwives.*—No law. *Itinerant vendors.*—Practice prohibited.

Secretary State Board of Medical Examiners, Dr. C. A. Abernathy, Pulaski.

Texas (Laws to 1907).—Graduation essential from "bona fide, reputable medical colleges, reputable within the meaning of the act." *Examination* required in the following subjects: Anatomy, physiology, chemistry, histology, bacteriology, medical jurisprudence, obstetrics, hygiene, gynecology, pathology, physical diagnosis, surgery. *Credit for years of practice.*—One per cent. for each year of actual practice. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only with the following States: Arkansas, District of Columbia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Jersey, North Dakota, Ohio, Vermont, Virginia, West Virginia, Wisconsin.

Osteopaths.—Examination required. Graduation essential from a recognized school of osteopathy. Practice not restricted. Osteopath on State Board of Medical Examiners. *Examination.*—Same as for physicians. *Midwives.*—No specific law. Examination provided for those who wish to practice obstetrics alone. The act "does not apply to those who do not follow obstetrics as a profession, and who do not advertise themselves as obstetricians or midwives, or hold themselves out to the public as so practising." *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. R. H. McLeod, Palestine.

Utah (Laws to 1907).—Graduation essential from a legally chartered medical school deemed "a recognized school of medicine." *Examination* required in the following subjects: Histology, anatomy, physiology, chemistry, toxicology, urinalysis, materia medica, therapeutics, bacteriology, pathology, theory and practice, surgery, obstetrics, gynecology, pediatrics, dermatology, hygiene, medical jurisprudence, ophthalmology, otology, rhinology, laryngology, and such other branches as the State Board of Medical Examiners may direct. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—Utah reciprocates at present with the following States: Georgia, Kansas, Kentucky, Illinois, Indiana, Iowa, Maine, Minnesota, Missouri, Michigan, Nebraska, New Jersey, New York, South Carolina, Tennessee, Wisconsin, Wyoming. Applicants for reciprocity presenting a license dated subsequent to December 24, 1802, must obtain such license on the basis of an examination. If the license was issued prior to December 24, 1892, Utah reciprocates with any or all of the States named on the basis of a diploma.

Osteopaths.—Examination required. Graduation essential from an osteopathic school recognized by the State Board of Medical Examiners. Osteopath on State Board of Medical Examiners. *Examination.*—The same as for physicians, except materia medica and therapeutics, which are given them by the osteopathic member of the board. *Midwives.*—No specific law. Those desiring to practice obstetrics are examined and licensed, but the law permits practice "in case of emergency," and it exempts "persons practising obstetrics in communities where there are no licensed practitioners." *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. G. F. Harding, Salt Lake City.

Vermont (Laws to 1908).—Graduation essential from a legally chartered medical school recognized by the State Board of Medical Registration. *Examination* required in the following subjects: Anatomy, physiology, chemistry, pathology, bacteriology, hygiene, practice of medicine, surgery, obstetrics, gynecology, materia medica, legal medicine. *Credit for years of practice.*—One per cent. for each year of practice up to ten years. *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only with the following States: Arkansas, District of Columbia, Illinois, Indiana, Kansas, Kentucky, Louisiana, Maine, Maryland, Michigan, Minnesota, Nebraska, New Hampshire, New York, New Jersey, North Dakota, Ohio, Texas, Virginia, West Virginia, Wyoming.

Osteopaths.—State Board of Osteopathic Registration and Examination. *Midwives.*—No law. *Itinerant vendors.*—No law.

Secretary State Board of Medical Registration, Dr. W. Scott Nay, Underhill.

Virginia (Laws to 1910).—Graduation essential from "some medical college or institution teaching the art of healing human diseases." Certain undergraduate students admitted to examination in the subjects of the first two years of the curriculum of an approved medical college. *Examination* required in the following subjects: Anatomy and histology, physiology and embryology, chemistry, pathology and bacteriology, materia medica, therapeutics, and toxicology, hygiene, preventive medicine and jurisprudence, theory and practice of medicine, obstetrics, pediatrics, surgery, and gynecology. *Credit for years of practice.*—None. *Temporary licenses.*—Granted. *Reciprocity.*—On licenses, issued after an examination only, with the following States: Arkansas, Delaware, District of Columbia, Indiana, Georgia, Kentucky, Louisiana, Maryland, Maine, Michigan, Minnesota, Missouri, Nebraska, New Hampshire, North Carolina, South Carolina, Texas, West Virginia, Wisconsin, Wyoming.

Osteopaths.—Examination required. Graduation essential from "some medical college or institution teaching the art of healing human diseases." *Examination.*—The same as for physicians, except that materia medica and therapeutics are omitted. Practice not restricted. *Midwives.*—Practice exempted. *Itinerant vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. R. S. Martin, Stuart.

Washington (Laws to 1909).—Graduation essential from some legally chartered medical school, the requirements of which shall have been at the time of the granting of the diploma in no particular less than that prescribed by the Association of American Medical Colleges for that year. *Examination* required in the following subjects: Anatomy, histology, gynecology, pathology, physiology, bacteriology, chemistry, toxicology, obstetrics, general diagnosis, and hygiene. *Credit for years of practice.*—None. *Temporary licenses.*—Not granted. *Reciprocity.*—None.

Osteopaths.—Examination required. Graduation essential from a legally chartered college of osteopathy in good standing with the State Board of Medical Examiners. Practice not restricted. Two osteopaths on State Board of Medical Examiners. *Midwives.*—No law. *Itinerant vendors.*—Regulated under pharmacy laws.

Secretary State Board of Medical Examiners, Dr. Frank P. Witter, Spokane.

West Virginia (Laws to 1907).—Graduation essential from reputable medical college recognized by the State Board of Health. *Examination* required in the following subjects: Chemistry and medical jurisprudence, materia medica and therapeutics, anatomy and embryology, obstetrics and gynecology, bacteriology and hygiene, physiology and histology, medicine and pediatrics, surgery, diagnosis, laryngology, rhinology, ophthalmology and neurology. *Credit for years of practice.*—None; "but the old practitioner is always taken care of." *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after ex-

amination only with the following States: Illinois, North Dakota, Texas, Vermont, Wyoming. On licenses issued on the basis of a diploma but without an examination with the following States: District of Columbia, Georgia, Indiana, Iowa, Kentucky, Kansas, Maryland, Michigan, Missouri, Nebraska, New Jersey, Ohio, South Carolina, Tennessee, Virginia and Wisconsin—licenses issued prior to May 23, 1895.

Osteopaths.—Examination required. Graduation essential—from a recognized osteopathic college of a standard recognized by the American Osteopathic Association. *Examination.*—In the following subjects: Anatomy and embryology; chemistry and medical jurisprudence; physiology; histology; bacteriology and hygiene; obstetrics and gynecology; surgery; practice of osteopathy, and osteopathic diagnosis. Osteopaths are not permitted to practice medicine or major surgery. *Midwives.*—Practice exempted. *Itinerant Vendors.*—County license required.

Secretary State Board of Health.—Dr. H. A. Barlee, Point Pleasant.

Wisconsin (Laws to 1909).—Graduation essential from a college of medicine and surgery deemed reputable by the State Board of Medical Examiners. *Examination* required in the following subjects: Surgery; hygiene; physical diagnosis; anatomy; pediatrics; obstetrics; gynecology; pathology; bacteriology, histology; materia medica, therapeutics, practice; neurology, dietetics, medical jurisprudence; physiology, laryngology, ophthalmology; chemistry, toxicology, urinalysis. *Credit for Years of Practice.*—Five per cent. for each five years of practice of applicant. *Temporary Licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only, with the following States: Illinois, Louisiana, New Jersey, New York, North Dakota, Texas, Wyoming. On licenses issued on a diploma but without examination, with the following States: District of Columbia, Georgia, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, Ohio, South Carolina, Tennessee, Utah, Vermont, Virginia, West Virginia.

Osteopaths.—Examination required. Graduation essential—from a college of osteopathy deemed reputable by the State Board of Medical Examiners; requirements inferior to those demanded of medical colleges. Osteopath on State Board of Medical Examiners. "Osteopaths, when licensed, shall have the same rights and privileges and be subject to the same laws and regulations as practitioners of medicine and surgery—except in the matter of administration of drugs and the performance of surgical operations." *Examination.*—Same as for physicians, except that materia medica and therapeutics, practice of medicine and surgery are omitted. *Midwives.*—Examined and licensed. *Itinerant Vendors.*—No law.

Secretary State Board of Medical Examiners, Dr. John M. Beffel, Milwaukee.

Wyoming (Laws to 1905).—Graduation essential from a legally chartered college of the system which the person claims to practise. Said college must be recognized by the State Board of Health or the State Board of Medical Examiners of the State in which it is located. *Examination* required in the following subjects: Anatomy, physiology, chemistry, toxicology, pathology, physical diagnosis, gynecology, surgery, obstetrics, hygiene, and bacteriology; also "such branches as are necessary to complete the system of which he is a practitioner. If the applicant is a practitioner of any school or system not represented in the membership of the board, the board shall have authority to call a legally licensed practitioner of that system to assist in the examination." *Credit for years of practice.*—No specific percentage. The State Board of Medical Examiners allows "certain advance in the fundamental branches, e.g., anatomy and chemistry." *Temporary licenses.*—Not granted. *Reciprocity.*—On licenses issued after an examination only, with the following States: District of Columbia, Illinois, Indiana, Iowa, Kansas, Maine, Michigan, Minnesota, Ohio, South Carolina, Tennessee, Utah, Virginia, West Virginia, Wisconsin.

Osteopaths.—Examination required. Graduation essential from "a legally chartered college," recognized by the State Board of Health or the State Board of Medical Examiners of the State in which it is located. *Examination* same as for physicians. Osteopaths not restricted in their practice. *Midwives.*—Examined and licensed. Practice exempted in cases of emergency. *Itinerant Vendors.*—No specific regulations, excepting for those "who shall maintain an office or residence in the State for a period of not more than three months in any one year."

Secretary State Board of Medical Examiners, Dr. S. B. Miller, Laramie.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 10
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 3
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 9
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	Los Angeles

W. Virginia	H. A. Barlee, Point Pleasant	Morgantown	
Wisconsin	J. M. Beffel, Milwaukee	Milwaukee	Jan. 10
Wyoming	S. B. Miller, Laramie	Laramie	Mar. 7

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Louisiana.—At the October examination there were 31 candidates; 11 of these passed. There were 50 questions asked; in the future 100 questions will be set, viz: Ten on each of the following branches: Anatomy, chemistry, gyneology, hygiene, obstetrics, pathology, physical diagnosis, physiology, surgery and therapeutics.

Virginia.—At a recent meeting of the Medical Examining Board it was decided "that applicants for reciprocity from other States shall pay a fee of $25. Those desiring a certificate from this board for the purpose of obtaining reciprocity from another State shall pay a fee of $10."

California.—At the August examination out of 111 regulars 95 passed, 16 failed; 31 osteopaths, 22 passed, 9 failed; six homeopathists, 3 passed, 3 failed; 3 eclectics, 1 passed, 2 failed.

Washington.—In the July examination 109 doctors appeared before the board; 78 of these obtained a license to practice.

Tennessee.—Out of 284 applications for license before the State Board of Medical Examiners, 280 received licenses.

North Carolina.—At the examination this year there were 95 applicants; 79 of these were granted licenses.

Pituitary Extract in Postpartum Hemorrhage.—A. Foges and R. Hofstätter confirm the observation already made by Bell, namely, that pituitary extract increases the contractile power of the uterus. This action begins within five minutes after an intramuscular injection of 1 to 2 c.c. of pituitrin. It is therefore a potent factor in combating postpartum hemorrhage, and has the advantage over ergotin in not causing pain and infiltration at the site of injection. Administration by mouth, however, is of no avail.—*Zentralblatt für Gynäkologie.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of December 10, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	549	154
Diphtheria	281	26
Measles	131	4
Scarlet Fever	251	7
Smallpox	—	—
Varicella	149	—
Typhoid Fever	49	16
Whooping Cough	49	4
Cerebrospinal Meningitis	6	8
Malarial Fever	—	—
Totals	1,465	219

Experience with Serum Sickness.—G. C. Schiffen observed in 200 cases of this condition that 20.1 per cent. had an exanthem, while one-half of the cases began with fever. The incubation period was commonly seven to eleven days. Seldom was there albuminuria or pain in the joints, which pain was chiefly present in the cervical and upper dorsal portions of the spine.—*Mitteilungen aus dem Wilhelmina-Krankenhause in Amsterdam.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended December 9, 1910.

NEUROLOGY IN ZURICH*.

V. MONAKOW'S NEW THEORY OF BRAIN LOCALIZATION; JUNG'S PSYCHANALYSIS AND INTERPRETATION OF DREAMS.

By E. W. SCRIPTURE, Ph.D. (Leipzig), M.D. (Munich).

NEW YORK.

ASSOCIATE IN PSYCHIATRY AT COLUMBIA UNIVERSITY.

I.

VON MONAKOW'S work on aphasia[1] has led him to a new theory of brain function and brain localization. According to the prevailing theories the various sensory and motor activities of the brain are located in different regions. Thus the occipital lobe is the region for the sensations of sight, the middle portion of the two central gyri is the arm-center, Broca's convolution or the rear end of the inferior frontal gyrus with its operculum and the operculum of the prefrontal gyrus form the speech center, etc.

We can distinguish several grades of reasoning concerning these centers. "Localization" has come to mean for most persons that the sensations of sight are manufactured in the occipital lobe, the motor images of words in Broca's convolution, etc. A little less extended is the view that, although the sensations and images may not be manufactured in the center, yet this center is indissolubly connected with certain mental experiences; when it goes out of activity that portion of mental life ceases; thus, extirpation of Broca's convolution must abolish speech.

In the first place we must distinguish between the fact of the localization of the results of an injury and the hypothesis of the localization of a function. For example, if an injury to Broca's convolution produces aphasia we have the fact which we express by calling this part of the brain the "center of aphasia," that is, the injury to a certain point produces a loss of speech. It is pure hypothesis to say that it is the "center of speech," by which we mean that the mechanism of speech lies in that part of the brain. The two things, center of aphasia and center of speech, are not identical; the former means the place at which an injury produces a certain speech trouble; the latter means the place in which those nerve activities take place that result in speech. The center of motor aphasia may lie in Broca's convolution; the center of speech may be there or somewhere else.

Extending the distinction to brain localization in general, we must distinguish between the localization (or origin) of the symptoms of a disease and the localization of the function itself.

Having drawn this distinction between center of aphasia and center of speech we have first to ask, Does the center of aphasia lie in Broca's convolution? After that we may ask, Where is the speech center?

Does the center of aphasia lie in Broca's convolution?

There are numerous cases of motor aphasia. v. Monakow has collected forty-three well-observed ones in which lesions in and around the Broca convolution were found.

Among these cases v. Monakow reports fourteen where there was complete motor aphasia but a nearly complete return of speech after months or years, and yet at the autopsy a large lesion was found in Broca's region. v. Monakow reports the case of a druggist who had three aphasic attacks, from each of which he recovered in a week or so. Years later he died. The brain sections showed that Broca's convolution was entirely gone.

To explain such cases the principle of substitution has been proposed whereby a different part of the brain takes on the activities of the part destroyed. Of this theory v. Monakow remarks that no one would assert it who is familiar with anatomy. A substitution would require the presence of embryonal cells in the other part of the brain which would have to go through the entire development. The extremely complicated mental activities required for speech—memory, association, sense of rhythm, etc.—took many years for their development. Shall we assume that a hitherto untrained part of the brain can acquire all this training in the few weeks or days in which some patients recover? If another part took on the function we must expect the recovery of speech to proceed at least as slowly as the learning of speech in childhood or of a foreign language; yet some patients recover suddenly.

There are, however, many other cases in which complete or partial motor aphasia existed for a long time with no injury of Broca's convolution found at the autopsy. In some of these cases there were severe lesions in other regions sometimes far distant; in other cases no coarse lesions could be found.

If we assume that the center of motor aphasia lies in Broca's convolution we have at most only twenty-nine cases that agree with the assumption, and at least twenty-eight that contradict it. We must conclude that there is probably something wrong with the assumption itself. Let us, says v. Monakow, go over the facts carefully again with attention to certain features hitherto not brought into prominent consideration.

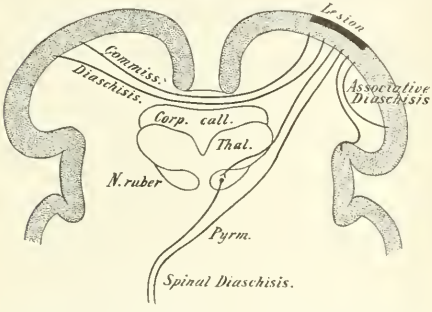
The localization of the symptoms of a cortical lesion means the reaction of the central nervous system to the localized injury. This reaction may arise from secondary factors such as edema, compression, filling of ventricles, toxines, etc.; these have no bearing on the present problem, and we will omit them for further discussion. The reaction rises

*Address before the New York Academy of Medicine, Section of Neurology and Psychiatry, Oct. 10, 1910.

mainly from two important factors. One is the direct anatomical result from injury whereby a certain portion of the brain is put out of activity; thus when a hemorrhage destroys Broca's convolution the reaction will show such changes as depend directly on that portion of the cortex.

The other important factor is the dynamic one. An injury to a point in cortex is followed not only by symptoms arising from anatomical lesion at that point, but also by symptoms arising from irritations transmitted to many parts of the brain. The condition may be termed "irritative shock." According to Goltz, Hitzig, and Charcot, the irritative shock consists of positive irritation of the various parts of the brain by nerve currents sent from the seat of the lesion. According to v. Monakow it consists simply of the effects on these distant points arising from the communication being cut off. This last factor would be what v. Monakow calls the "diaschisis factor."

An analogy to a hemorrhage in Broca's convolution may be found in the burning of a telephone central. If the Bryant central were put out of activity there would be not only the trouble at that central



Scheme to illustrate Diaschisis. A lesion of the cerebral cortex is followed by symptoms resulting not only from the loss of function at the seat of lesion, but also by those resulting from the interrupted connections with other parts of the cortex. The former are the "residual" symptoms, the latter the "diaschisis" ones. The symptoms of motor aphasia, for example, result from disturbed action of many parts of the cortex; only a very few of the symptoms can be "localized" in Broca's convolution.

and among the subscribers with that central, but also trouble all over the city wherever a message had to go along a wire belonging to Bryant. The trouble at the Bryant central would correspond to the anatomical factor; the trouble resulting to the subscribers and centrals who are thereby cut off would be the diaschisis factor. Affairs might gradually recover from the upset condition due to the diaschisis factor. Those symptoms from which the city does not and cannot recover from the loss of the Bryant central are the residual or direct lesion symptoms. All the others are diaschisis symptoms.

Under "diaschisis," then, we understand an interruption of functions of portions of the brain outside the region of the original lesion, but anatomically connected with it. The diaschisis usually arises from an acute local lesion; it resembles shock in its nature.

The cells affected by the lesion are thus of two kinds: (*a*) the directly injured nerve cells at the region of the lesion, (*b*) the indirectly disturbed cells at distant points.

If the directly injured cells do not recover and the indirectly disturbed cells find a way to readjust their activities completely, then the only symptoms remaining will be those directly depending on the lesion—the "direct lesion symptoms."

Cases of motor aphasia where the patient recovers his speech and where the autopsy shows destruction of Broca's convolution show that the phenomena of motor aphasia are mainly diaschisis effects, and only those symptoms—namely, hesitation, slight perseveration, difficult construction of sentences, slight word-amnesia—which never disappear, are direct effects of the lesion.

Cases where the aphasia is prolonged indicate that the diaschisis effects do not disappear so rapidly. Cases where the motor aphasia is permanent indicate that the diaschisis effects simply remain permanently ("protracted diaschisis" of v. Monakow). Why the diaschisis effects disappear partly or wholly in some cases and not in others depends on the conditions of health in those parts of the brain.

The system of diaschisis connections in the brain can be studied by following the course of fibers that undergo secondary degeneration and of the changes in the cells put out of function in the distant parts of the brain. In the Ladame—v. Monakow case, which I had the opportunity to study last summer, several definite regions of degeneration could be found.

If we accept the views thus explained, we can answer the first question proposed a while ago, "Does the center of motor aphasia lie in Broca's convolution?" No, because motor aphasia occurs without any injury to that region. Broca's convolution is the region where injury is most often followed by motor aphasia; it is especially connected with some of the finer mechanisms of speech. To produce motor aphasia there must be disturbance over widely separated areas of the brain; just what areas we do not yet know. The very phrase "center of aphasia" is meaningless if by "center" we understand a definitely marked off area of the cortex. We might well use the term to include all the portions of the brain involved in aphasia, no matter how widely distributed; the components of the center then remain to be determined.

To the next question, "Where is the speech center?" we must reply that in the old sense of the word "center" no such thing exists. In the newer meaning I have proposed, the center of speech includes all the widely separated parts of the brain that are involved in producing the spoken word.

This doctrine of diaschisis has brought about greater precision of thought in regard to brain localization. It does away with the possibility of apportioning the higher mental activities to special parts of the brain. According to v. Monakow, only the elementary components of action may be localized as brain reflexes. All mental activities, even of the simplest kind, require widely separate portions of the cortex for their existence. This means that mental functions cannot be localized in the usual way as islands of the cortex, there can be no center of speech, or center of hearing, or center of association, etc.

You remember the two stages which every new thought must go through: I. It is not true. II. It is not new.

Many writers who have discussed v. Monakow's views have rejected them; all of those I have seen have failed to even faintly grasp what they are. This is not entirely their fault; v. Monakow seems to have a difficulty in stating his theory clearly. But the diaschitis theory fits so well with the clinical

phenomena of aphasia that it cannot fail of immediate acceptance as soon as it is clearly understood.

It is very easy to make the other criticism, namely, that the theory is not new. As v. Monakow points out, he has adopted the Goltz theory of irritative shock with the modification that the effects of the shock of the distant parts are only those of interrupted function and not of irritation. His diaschisis theory is closely related to the views of the earliest and greatest workers in brain localization. In addition to the investigators mentioned by v. Monakow, I know that Ludwig, the great physiologist of the last century, held a similar view. He used to compare the deduction of the location of the speech center from the tumor and hemorrhage cases to an experiment of shooting a pistol at a clock. The clock stops. Autopsy shows that a certain wheel was broken by the bullet; would you call this wheel the "center" of the movement of the clock? The movement of the clock involved all the wheels, although a lesion of one of them stopped the clock.

II.

The work of Dr. Jung[2] in psychanalysis is based on the remarkable discoveries of Freud[4] of Vienna; it contains, however, several new features.

There are three methods of getting at the facts of mental life.

The first is that of simple observation; we interpret the patient's condition by what he tells us and by what we can observe. This leads to treatment by the usual medical and hygienic methods and by therapeutic talks. A patient, for example, complains of having no will power and no steadiness of purpose. This we understand directly from analogy with our own weakness and proceed to a regular education of will. The most widely known representative of this line at the present moment is Dubois of Bern.

The second method is that of experimental psychology; its aim is a most careful and accurate analysis of the patient's mental condition by experimental tests and records. The brilliant work of Kraepelin and his pupils at Heidelberg and Munich has been done exclusively on the insane.

The third method is that of psychanalysis. Suppose a patient presents himself with a paresis of the right arm which began years ago. There is not the slightest symptom of anything organically wrong. It is evidently a hysterical paralysis. Or suppose a man appears complaining that he is tormented beyond endurance with the fear that he cannot urinate. He never has the slightest difficulty, and he knows the fear to be foolish. Yet this fear is so constant and overpowering that he has been obliged to give up work. Again a patient comes to the office saying that for years he has been tormented with the fear of touching filth; he washes his hands a hundred times a day, he avoids shaking hands with me because he fears I may have filth on mine. He does not take the chair I offer him, but selects another for a similar reason.

Such cases are quite beyond the method of observation. In our own mental life there is nothing like these conditions; they are so far beyond our understanding that they seem weird or unbelievable. The patient with the fear of filth told me that he knew this fear to be utterly nonsensical, and that he spent hours discussing it with himelf. It is one of the greatest achievements of the method of psychanalysis that it has found the mental mechanism of such cases. In fact, some of them are so typical that probably some of those who hear me now can tell at once in outline what was the matter in each case. The first is one of Dr. Jung's, which I will give in detail as an illustration. The second is one of Dr. Stekel's[4]; the third is my own. Of these last two I shall say nothing further.

To analyze the first case Dr. Jung used his association method. In this method a word is spoken and the patient is required to say at once what he first thought of. The time he takes is measured with a stop-watch. After a hundred such associations he is required to tell again what he thought in each case. The following is an example from one of Dr. Jung's records:

Word spoken.	Associa'n.	Time.	Memory.	Sensitive topic or complex.
head	hair	1.4	x	
green	meadow	1.6	x	
water	deep	5.0	swim	!
stick	knife	1.6	x	
long	table	1.2	x	
ship	sink	3.4	steamer	!
ask	answer	1.6	x	
wool	knit	1.6	x	
obstinate	friendly	1.4	x	
lake	water	4.0	blue	!
sick	well	1.8	x	
ink	black	1.2	x	
swim	can	3.8	water	!

Whenever the time of association is unusually long, when there is evidence of forgetfulness, when the patient does not respond at all to the word called out, when his association is superficial—in short, whenever the association is of unusual character—the word called out touched upon some topic on which the person was highly sensitive. The sensitive topic indicated by the record above was an experience on the water.

Applied to the man with the paretic arm, the association tests showed that the words in the list where the most disturbance occurred (long time, forgetfulness) were "proud," "pure," "arm," "bird," "death," "sin." The words he thought of as associations most frequently were "love, like," 8 times; "not," 6; "I," 4; "marriage," 3; "arm," 3; "lake," 3. Now just try to put these words together as a picture of his mental condition. "I am (or was) proud that I am (or was) pure. I have sinned. I would prefer death. I do not love my wife (marriage)." The words "arm," "bird," "lake," remain unexplained.

His own story is that he was always proud of his immaculate life. One day he notices that he is impotent with his wife. He is much worried and decides to consult a prostitute, with the result that he finds he is not impotent. But this immoral act utterly disgusts him as a man of high principles; he would rather die than do it again. He has a dream of a sturdy farmer who stretches out his arm; a bird flies down upon it and sings. This dream contains four typical elements that recur over and over in dreams. The stretched-out arm appears in dreams always as one of the symbols for the stiff male member. In matters relating to women the right side always refers to the lawful wife; the left to the illegitimate connection. Again the chief person in the dream always represents the dreamer. Finally, a dream always represents the fulfillment of an unfulfilled wish. The patient thus realizes

in his dream the relation to his wife that he cannot realize in reality. In his dream, moreover, he reveals that his paralyzed arm is a symbol for his trouble. In fact, a person familiar with the results of psychanalysis could have deduced at once the essential point in his case from the symptom of the hysterically paretic arm. As soon as the patient understood the mechanism of his case the paresis disappeared.

Another case of Dr. Jung's was that of a happily married woman subject to explosions of jealousy with outbreaks of violence and running away from the house. These outbreaks she carefully kept secret from the rest of the family; she wreaked her temper on her husband, who was a model man. In the association tests the strongest disturbances occurred with the words "happiness," "anxiety," "religion," "choose," "marry," "part," "death," "die." In her associations she uses "like" 13 times; "man," 10; "child," 7; "necessary," 7; "beautiful," 6; "I," 4.

It was possible to guess the story from these results alone, but it was easier to confront her with the record and show her that she had revealed conclusively that something is the matter with her happiness, that she is anxious about something, that religious questions are troubling her, etc. The patient owned up that she is not happy with her husband, that she is anxious about the future and does not know what to do, that she married outside of her religion a man whom she chose against the wishes of her parents, and that she is debating if she shall part from him or die. She also says that she likes men, that a child is necessary for a happy marriage, that she (I) is still beautiful enough to attract men.

Further conversation showed that she had fitted herself to her husband, but she is not satisfied with him and from time to time the feeling of resistance breaks through. She would like to be loved by some other man; she had even telephoned to a young man to meet her in her husband's absence. She would be happy in any case if she had a child. The outbreaks of jealousy are projections of her own wishes; she would like to do the things with men which she accuses him of doing with women.

Another method of psychanalysis is that of running associations; this was introduced by Freud. The patient is told to let his mind wander with perfect freedom and to tell his thoughts as they arise. The method is useful in the most varied ways. It must first be made clear to the patient that his cure depends upon telling the truth; no matter how private may be the thought that arises, he must tell it frankly to the physician.

This method I will illustrate by the case reported by a clergyman of Zurich[5]. He noticed in a composition written by one of his pupils, a boy of eleven years, indications of strained relations among the members of the family. Knowing that he could not possibly get the facts otherwise, he applied a combination of the association experiment with running associations. For example, the word "water" aroused the association "corpse" after four seconds. Thereafter the boy associated "ship," a "drowned person," "I saw how a drowned person was taken into a boat. "Now tell all the words that occur to you," said the clergyman. "Bathe, swimming, bathhouse, bottom, seaweed, shark, earth, stone, springboard, air, chain, beam, submarine boat, crew, no air, drowned." "What occurs to you now?" asked the clergyman. "I saw some moving pictures with two divers that found gold. One cut the air tube of the other, took the gold, and went up." The word "diver" brought up the association of "the dead diver in the moving pictures. We could see his pale face. We once got a wax mask representing a dying king with eyes turned up. Arno (his brother) put on the mask and wrapped a shroud around him. He looked like a ghost. I was frightened. The dying diver reminds me of this wax figure (meaning his brother in the mask)." Over and over again the boy produces series of associations ending up in some representations of his brother as dead, as in prison, as tortured, as murdered by himself, as crucified, etc. It was very evident that he hated his brother from the bottom of his soul. This he did not realize in the least himself. The information and the treatment came through this method of psychanalysis.

The method of running associations is based on certain laws of the association of ideas. One of these we may state as follows: The oftener an idea or an element of an idea has been in mind the more frequently it will appear in associations. The brother Arno was constantly in little Max's mind; no matter what he started to think about, the thought of Arno would sooner or later appear. Another law is that the intenser an idea is or the more emotion it arouses the more often it recurs. A person will remember the time he made a fool of himself, no matter how much he wishes to forget it. Start any one on memory associations, and he will inevitably land over and over again on the chief topics in his mind and will involuntarily deliver his secrets over to you.

The more the running association is freed from the control the better the information concerning the person's mind. Seat yourself in quiet and let your mind wander in associations. You will notice that at each step a dozen new things crowd in together. Instinctively you pick out one and proceed. For example, with the word "lamp" there appear at once to my mind in half-formed condition a certain gas flame, a certain electric light, a certain proverb, etc.; one of these I have to catch because I cannot think clearly of all of them at the same time. I catch the certain electric lamp. It is in a certain room; this leads my thoughts in that direction. If I had caught the gas flame, my thoughts would have gone otherwise.

From childhood up we have been trained to control our thoughts, to proceed in an orderly fashion, to speak only in a modest way, even to think in a modest way, etc. This control becomes automatic. When we let the thoughts wander, we automatically catch only those thoughts that fit with our training. In the presence of another person we are trained to speak only in a discreet manner; even to think otherwise is not proper. Automatically we catch only the discreet thoughts and suppress the others. In the doctor's office the conversation is freer, but even here it usually requires some training before the patient will let himself think freely.

Another method is that of assigning a topic concerning which all impromptu thoughts are to be noted down. For example, the physician tells the patient to note down on the spot each thought that arises impromptu concerning himself (the physician). For example, a patient reports that in an entirely impromptu manner the thought occurred to him that the doctor was getting bald; on another occasion he said he thought the doctor was getting rather stout, and so on. An entire group of these

observations revolved around the signs of advancing age; this was, in fact, one of the great troubles of the patient, namely, that he was getting old. Another patient reports that the thought had occurred to him that the doctor was extremely considerate of the feelings of his patients, that he was really rather bashful, and so on. This simply reflected the patient's condition of bashfulness and overanxiety about how people felt toward him. Still another patient thought that the doctor must make a great deal of money out of his practice, that he dressed in expensive clothes, etc. Of course, the inference was at once clear, namely, that the patient's thoughts centered around money. I have never had an experience quite like one that Dr. Jung related to me. One of his patients, a clergyman, told him that the thought had occurred that Dr. Jung was not strictly truthful, that he was not quite honorable in dealing with his patients, that he did not believe that he led a strictly moral life, etc. Before knowing the facts of the case Dr. Jung replied, "It is *you* who are the liar, *you* have not acted honorably with your parishioners; *you* are doing something immoral." The thoughts that arise impromptu like this are always reflections of the patient's own personality.

Another fundamental method of psychanalysis is the study of dreams. During the daytime the associations of ideas and emotions that occur to us are constantly regulated by the impressions from our surroundings. In the factory our thoughts will be driven in business channels, and it is quite unlikely that thoughts of what the children are doing at school bother us. When we get home the reverse will be the case. As we fall asleep this regulation by the surroundings falls off; our mind wanders according to its own instincts and our dreams are pictures of our inner selves.

The dreams of children are very simple because their minds have not received much regulation. A child dreams she is in a boat on the water. The day before she had not been allowed to go in the boat. Freud's 19-months-old child had been obliged to fast for a day. That night she was heard to say in her sleep: "Anna Feud Erbeer Hochbeer Eierpeis Papp." Evidently she was dreaming that she, Anna Freud, had strawberries, blueberries, egg food, and pap to eat.

These and countless other dreams of children make clear two fundamental laws: 1. The content of the dream, i. e., the things used in the dream are derived from the preceding day or from a very recent time. 2. Every dream represents the fulfillment of a wish that has remained unfulfilled. To these laws there is never any exception.

As we grow up from childhood we are taught to guide our thoughts in certain channels; there are topics that we must not even think about or even dream about. The habit of control becomes automatic. The result is that when the unfulfilled wishes push themselves through this control they do so in more or less disguised form. This "symbolism" must be interpreted in order to get at the real meaning of the dream. The more highly cultured the person the more complicated is the symbolism; persons of simple lives have franker dreams; children use little or no symbolism.

A patient relates the following dream: He is on the Philadelphia train. The conductor comes for his ticket. He has lost it. The conductor makes him pay his fare. He is annoyed at the occurrence. He also finds that he has lost a sheet of paper which the doctor had given him to write his dreams on.

When asked if anything relating to a ticket on a railway journey had occurred lately, he replied that it had been previously arranged that he should go on a business journey to Chicago at the expense of the firm. The business had just been settled by mail and he had thus "lost his ticket." He had decided, however, to go at his own expense ("pay his fare") in order to see his mother (the unfulfilled wish) whom he always visits when business takes him to Chicago. The sheet of paper beside his bed for recording his dreams is a constant worry to him. The dream realizes the unconscious wish that it would get lost just like the ticket.

There was nothing in the dream that differed much from ordinary life; the symbolism is very transparent. "Lost his ticket" is symbolic for "lost his journey," "paying again" for "going again." Yet the patient had not the slightest idea of the meaning of the dream.

In the following dream the symbolism is more elaborate:

"1. How I like some form of literary activity more than medicine.

"2. Driving an automobile, black car with red wheels; putting on speed down hills, finally seeing a fence, a sort of square hole through which I tried to pass in the car very quickly, as there was no other way to avoid hitting the fence, but the car caught on a bottom post and smashed up. Don't know who people in car were. They were strangers. There was a lady in car whom I know; she was pretty well shaken up, and I remember going to a house nearby to ask for her. Quite a crowd there, and they treated me to sarsaparilla. Later I recall looking down from a high bank on the Hudson with the same lady and watching an express train go by."

The patient says the dream has no meaning for him. The fence, as he describes it, seems to be a wall with a low passage through it. He distinctly states that he has seen nothing like it. No association rises in his mind concerning it. I am at once reminded of the Biblical phrase, "Sooner shall a camel pass through the eye of a needle than a rich man enter the kingdom of Heaven." I also recall a picture of a wall with a low opening and a camel in front of it too large to pass through.

On the preceding evening the patient had told me that he is thinking of giving up medicine. I asked him if he needed to work for a living. He said no; he had enough for himself, but not enough to get married on. I told him that if he were a poor man, the question of giving up medicine would never have entered his mind, and that being well-to-do deprived him of a motive and thus hindered his progress in the study of medicine. We also discussed taking up something else and I urged him not to break things up so.

The first dream badly states this as an unfulfilled wishes concerning medicine and literature.

In discussing the dream, I asked him what class of people own automobiles. He answered: The well-to-do and the rich. The dream pictures him as a rich man in an automobile coming to a fence. He wants to go through, but finds the passage too small and experiences a smash-up. This is a symbolic statement of just what we had been discussing concerning the study of medicine and what the first dream seems to have announced as a topic for further dreaming. The dream here represents his wish to give up medicine, which he has not yet done.

"Putting on speed down hills" seems to refer to frequent discussions I had had with him concern-

ing how hasty and recklessly he had been working on the stimulation of coffee and at the expense of his nerves. He is now restraining himself with difficulty; the old instincts and wishes break through in the dream.

"A lady in the car" was a friend whom he had met at the railroad station on the preceding day. While crossing the Hudson on a ferry he had discussed with her his desire to give up medicine. In the afternoon she went for a ride with his brother in an automobile. In answering my question regarding his financial condition he had added quite gratuitously: "But not enough to marry on;" this admits that he would like a companion. In his dream his wish is fulfilled by the lady in the car; he wishes he were rich enough (automobile).

"The crowd in the house near by" consisted of girls dressed in white. He thinks it looks like a festive occasion. Many years ago he was in love with a girl and paid no heed to any other woman; when she became engaged to somebody else he felt relieved, although for several years he had determined to marry her. "Festive occasion with the girls in white" seems to represent a wedding to which he was going with a lady. When he arrived he found that she was not there. She had been lost and instead of a festive occasion the bride's maids gave him nothing more than a sarsaparilla. This also seems to indicate a wish on his part to keep out of such an entanglement as marriage, to lose the lady even by a smash-up, and to put up with a soft drink rather than to be tied down by marriage.

The strangers in the car and the style of the car were not explained.

The last part of the dream refers to a walk he had taken. He says himself that he would wish to have a house situated on the Hudson. He would evidently like to have the lady in it. The association with the Hudson and the railway seems to have been prepared by the incident of meeting her at the railway station and crossing the Hudson with her.

The following dream is more elaborately symbolical.

"I bought a ticket to some place, a single ticket, because I was not coming back. At a certain station on the way I get off. I go to the manager's office, where I find two men at work over papers. I stand at attention, heels together in the German fashion. The man has an American military cap of dark blue. I say to myself, 'Shall I give a military salute or take off my hat?' When the manager turns around I ask for the return of my money, because I have found a patient on the train. The manager, who has now become a younger man, says yes, but it will be dear; it will cost one fare plus a hemorrhage, plus an infarct. I reply, Never mind, the expense is nothing to me. The assistant reckons out what I am to get and says it will be about 50 per cent."

The patient had originally been in doubt whether he should stop for treatment in this town or go to one much farther off. Stopping at the nearer place, he had a few days before seen the doctor and his assistant (manager and clerk) at a scientific meeting. The doctor had told him he could not begin treatment till next week (he stands at attention waiting). The patient holds the doctor in great respect (the dream clothes him in a military costume and makes him manager of the station). At the same time the doctor is a personal friend; the two feelings are present at the same time and the patient doesn't quite know how to act ("Shall I give a formal military salute or take off my hat in a friendly manner?"). The patient naturally expects the doctor to do him enough good to compensate him for what he loses by not going to the other place ("I ask for the return of my money for the part of the journey not taken").

It is characteristic of dreams that the personalities are often changed. The patient now represents himself as a doctor who had found a patient on the train. Instead of remaining the inferior (the patient) he for a moment gratifies himself that he is the superior (the doctor), who is about to treat a patient.

The dream now notes the fact that the doctor is younger than the patient (manager is now younger). The patient had been somewhat worried over the probable expense and feared what the dream declares ("it will cost you dear"). On the previous evening the patient had discussed the matter with a friend and remarked that the journey was not entirely for the sake of the treatment (one fare), but also to learn the method; he had also complained that the treatment cost him part of the time he wished to give to some anatomical work ("hemorrhage plus infarct"). These two topics had occurred to him during his anatomical work on the preceding day. He had finally concluded that he was ready to pay any price if he could be cured ("never mind, the expense is nothing to me"). The 50 per cent. seems to refer to the fact that the treatment was taking about half the time from some other work.

The further interpretation could be made only in connection with the rest of the treatment. A vitally important defect of the patient's character was an inability to properly and promptly understand his relations to other persons; the uncertainty as to how he should approach another person expressed itself in the dream as the doubt concerning how he should greet the doctor; this hesitancy in greeting had actually given him very great mental distress for many years. Another defect was a constant conflict between a naturally spendthrift nature and an acquired but annoying and ill-judged penuriousness; the whole dream consists of questions of expense. This dream, as well as many others, expressed the patient's thoroughly egocentric view of the events of life.

The same symbols are used over and over again in dreams to such an extent that they become typical. Around the Lake of Constance the Zeppelin airship is the symbol, not only in dreams, but also in jocular conversation, for the erected male member, as is quite natural from its shape. The following incident occurred in this region. One doctor, a disbeliever in psychanalysis, said to another: "You have asserted that every dream gives the fulfillment of an unfulfilled wish. Last night I dreamed that I was piloting a Zeppelin airship; that I came to a mountain which I couldn't get over; that I was much afraid that the airship would sink to the ground crushed up, but that I finally got over the mountain. I certainly have not wished for an airship; if I had one, I would not wish to climb mountains with it and I would not wish to smash it." It required very little skill for the other doctor to reply: "Last night you attempted a certain act; you were not successful at the Mons Veneris, and your ship collapsed. You did not finally succeed. Your dream makes you succeed where you failed in reality." The interpretation agreed exactly with the facts.

Of what use is psychanalysis? In the first place, it gives us a method for investigating the subcon-

scious. Our mental life shows itself to us as a series of conscious thoughts; what we know directly of ourselves we say is consciously known. But the direction of our conscious thoughts is largely determined by our entire past history stored up somewhere outside of consciousness. The sum of these outside influences we term the "subconscious." For example, if I pronounce the word "hate" each of you thinks of something different. The entire sum of forces involved outside of the word I pronounced and outside of the present scene belonged to the subconscious. Some slight attempts have been made to get at these subconscious processes by the accurate methods of experimental psychology, but the laboratory men have not yet become interested in the work. Freud has found a set of methods that for the first time reveal clearly the fact and laws of the subconscious. The results show a remarkable fixity and uniformity; over and over again one patient after another reveals the same typical condition till finally you can guess most of his story by the time he has begun it.

In the second place, psychanalysis enables us to cure a large number of persons that cannot be cured by other methods. Many cases of hysteria may be cured by hypnotic suggestion, but this proceeds by curing a symptom without understanding the disease. The better way, and in many cases the only way, consists in finding the cause of the disease. The cause lies always in some suppressed emotional experience in the past; it can be found only by psychanalysis. Exactly the same statements are true concerning the various psychasthenias and anxiety neuroses. As the patient learns his own mental mechanism by analysis, he finally recognizes the emotionalized idea that causes his trouble. The disease arises from the suppression of this idea. As soon as it is dragged forth the trouble disappears. The psychanalysis is therefore the method of cure.

In the third place, the method is of immense value in correcting unprofitable mental attitudes. Children often grow up with distorted ideas of their surroundings; in many cases they never succeed in making a proper readjustment. By psychanalysis such weak spots in one's mental adjustment become clear, and a readjustment gradually follows. The revelation to the egocentric patient referred to above (dream of the station-master) was followed by a marked change in character. The method is applicable in every case of defect of character, such as in bashfulness, timidity, obstinacy, temper, greed, etc.

IMMUNITY REACTIONS AS PRODUCTS OF NATURAL SELECTION.

By R. G. ECCLES, M.D.,

BROOKLYN, N. Y.

No subject has proven of more intense interest to progressive physicians during the last quarter of a century than has that of immunity to disease. No other is likely to be of greater interest for at least a century to come. Metchnikoff's revelations concerning phagocytosis, followed by the successive discoveries in serum immunity, have constituted one continuous series of stimulating surprises to the medical profession. But one unpleasant feature mars the final result and that is the heritage of memory-racking, useless synonyms that remain as a reminder of the international wrangles which occurred over various disputed points. Students who are unable to sweep these aside are very apt to fare badly in endeavoring to secure a comprehensive conception of the subject as a whole. It rarely occurs to them that they are but dealing with a special phase of the physiology of digestion or that to understand it properly they must first know the chief facts of the chemistry of digestion. "Constantly in striving to comprehend the processes which are concerned in the destruction of bacteria and their products, the neutralization of cell products, and development of immunity," says Adami, "we find ourselves brought back to the fundamental fact that these constitute but special cases of the dissociation of food stuffs, of assimilation, and digestion. The processes which occur when a cell destroys an ingested microbe must be identical with those which occur when it digests any other foreign matter, and bacteriolysis in the body fluids must be brought about by procedures of the same order as occur when fibrin is digested in the gastric juice."[1] It is evident that Metchnikoff takes the same view of the subject when he asserts that "the destruction of microorganisms in the animal is an act similar to true digestion."[2] Ehrlich, too, expresses this view when he tells us that "we shall probably not err if we regard the addiment (complement) as having the character of a digestive ferment."[3] The discoverer of opsonins, in agreement with the others, tells us that "it would seem probable that the bacteriolytic, bactericidal, and bacteriopsonic effects exerted by the blood fluids are each in their degree manifestations of a digestive power exerted by the blood-fluids and bacteria brought into contact with them."[4] According to these and other investigators the active agents concerned are enzymes —digestive ferments. Of late years our physiologists have been discovering that enzyme action is probably as universal as is life, and that all sorts of living things carry on their life functions by the aid of enzymes. Chittenden declares that "we are practically justified in the assumption that the great ma-

jority of the intra- and extracellular chemical changes taking place in living organisms are the result of enzyme action." Again he tells us that "in that more or less hidden world of microorganisms, so potent for good and evil, tangible enzymes are likewise responsible for many, if not all, of the chemical reactions by which the life and activity of the organism are manifested."[5]

Granting that evolution through selection is true, and it follows as a consequence that digestion in us is but a specialized form of the intracellular digestion of unicellular protozoans. As Andrewes has recently expressed it, "intracellular digestion is the primordial form of that function; seen to perfection in the ameba, it is still carried out by the mesoblastic cells of animals higher in the scale. Such, I take it, must have been the germ from which the battle of infective disease originally sprang. The primitive means of bodily defense must almost inevitably have been phagocytic. It must have included the two factors of ingestion and of digestion by whatever enzymes the cell possessed for its normal nutritional processes."[6] The sea anemones that lie between us and the unicellular organisms still continue to digest their food and to dispose of infecting parasites in the old way, notwithstanding the fact that they possess a food cavity or sort of stomach. Metchnikoff tells us that "when the actinian is hungry it protrudes its tentacles in order to seize marine animals, which it conducts to its mouth. The lips and the esophagus are used to estimate the quality of the capture, and if it is found unsuitable the anemone rejects it, first surrounding it with a layer of mucus. If, however, the food is found to be suitable, the actinian retains it in its large cavity and throws around it a multitude of its mesenterial filaments. These penetrate it in all directions, and as their epithelial cells are capable of sending out ameboid processes they seize and ingest the particles, which immediately enter the protoplasmic contents. * * * The nutritive parts of their prey pass into the ameboid epithelial cells and there undergo a purely intracellular digestion."[7] Lankester says that "the lowest multicellular animals provided with a digestive sac or gut, such as the polyps, have the sac lined by digestive cells which have the same ameboid character as 'phagocytes' and actually digest to a large extent by swallowing or taking into their individual protoplasm raw particles of food."[8] The earliest demonstrations of phagocytosis were made with transparent water fleas (Daphne), but now "the phagocytic action of the corpuscles on bacteria can be watched by placing a drop of blood on a slide and adding a loopful of culture of bacteria in broth diluted with sea water. The corpuscles can be seen to send out pseudopodia in the direction of the bacteria and engulf them."[9] Describing a slide containing blood and micrococci as watched under a microscope, Dickson says: "Many of the polymorphs showed the included cocci in all stages of disappearance, the cells apparently continuing to englobe fresh organisms, as those previously taken up were digested."[10] That phagocytosis in the higher forms is not confined to the blood cells is now known, and Wells tells us that "not only leucocytes but tissue cells are capable of moving and performing phagocytosis when properly stimulated, and apparently all or nearly all fixed cells may act as phagocytes under some conditions."[11] Abderhalden calls attention to the fact that the leucocytes "are present in the intestines in large numbers during digestion,"[12] seemingly indicating that they take some part in that function. While the polynuclear leucocytes appear to look after bacteria, the protozoa are apparently looked after by the mononuclear, as trypanosomes can be seen "while still living," surrounded by and being "digested by the mononuclear leucocytes."[13] Hiss has suggested that "phagocytic cells may depend naturally on other cells and bacteria as a part of their regular food supply,"[14] so that the hunting within the intestines and blood for dead cells, bacteria, and protozoa may be pursued by our cells with the same object in view as that of an ameba when it hunts for and ingests the bacteria of a pond. In this hunt either may englobe an organism that is more than a match for their digestive abilities and "overcharged with microbes" they may perish, for where these are endowed with unusual virulence "no struggle is possible."[15]

In the evolution of intestinal digestion from the primitive intracellular form it seems as if this did not exhaust the possibilities of such readaptations. The microbe-invaded cœloma and circulation seem to have followed along a similar path and acquired proteolytic powers. If we "take a guinea-pig that by successive inoculations has been rendered highly immune to virulent cholera spirilla and introduce into its peritoneal cavity five to ten times the ordinary fatal dose of an agar culture of the cholera spirillum, or inject into the normal guinea-pig a like dose of spirillum mixed with an excess of cholera immune serum from another guinea-pig, * * * by removing with a pipette some of the peritoneal fluid from time to time, it is seen that the injected bacteria undergo destruction, and this apart from any phagocytosis. * * * They become motionless, swell, become rounded like micrococci; * * * become progressively smaller, their substance undergoing solution."[16] This pen picture of what occurs during bacteriolysis, or digestion of bacteria, is quite like what happens to a mass of egg albumin when submitted to the action of the gastric juice. The same results have been secured in a test tube by adding immune sera of cholera to cholera germs or immune sera of typhoid to typhoid germs. The microbes gradually fade away and disappear as would a piece of sugar in a cup of tea. The inoculations of the animals that supply these immune sera causes them to secrete digestive enzymes adapted to the kind of germ inoculated. Each species of germ having a structure somewhat different from other species requires different enzymes and in different proportions in order to accomplish their solution. In ordinary digestion our various kinds of food require quite different enzymes to accomplish their solution. Carbohydrates like starch cannot be digested by the same enzymes as digest protein—the albumin of former days. A close fitting covering of either upon the other, placed in an enzyme solution ready to digest the interior one but not the exterior, would result in no digestion. The way the stomach would manage such a case would be to supply both the required kinds in the order in which required. The way it seems able to adjust these makes Abderhalden declare that it would "almost lead one to assume that the digestive glands are furnished with intelligence."[17] Chittenden tells us that "a diet of bread, for example, leads to the secretion of a smaller volume of gastric juice than a corresponding weight of meat produces, but the juice secreted under the influence of bread is richer in pepsin and acid, *i.e.* it has a greater digestive

action than the juice produced by meat." Concerning duodenal digestion he tells us that "on a diet composed mainly of meat, the proteid digesting enzyme is especially conspicuous, while on a bread diet, with its large content of starch, the starch digesting enzyme is increased in amount."[18] Of gastric digestion Abderhalden says: "The total acidity likewise varies according to the nature of the food. It is greatest with meat and least with bread. It is interesting, also, to note that the duration of the secretion is also regulated according to the nature of the food; and in fact during the course of secretion, from hour to hour, the composition adjusts itself qualitatively to the conditions."[19] These facts have been repeatedly verified by Pavlov and his pupils. In bacteriolysis a serum that will digest a comma bacilli promptly is one in which the enzymes are adjusted to its structure. Any other kinds of bacilli having different structures, containing substances indigestible by the enzymes of the serum that digests the comma bacilli, could not digest them completely. If the differences happened to be due to differences in their respective envelopes there might be no digestion of any except the one used in producing the serum. If our cells are unable to produce needed enzymes for some kinds of envelopes there will be no bacteriolysis. For some such reason as this "human serum exerts absolutely no bacteriocidal action on the *Staphylococcus pyogenes,* the *micrococcus melitensis,* and the plague bacillus."[20] As our stomachs cannot digest hair or feathers while the stomachs of moths can, so our serum is powerless as against these germs, but our phagocytes are able to dispose of them properly. Here we get a clear understanding of why it is that certain kinds of diseases do not have antitoxic serums in the blood by which to overcome them. The germs have, during their ages of past experiences, been permitted to survive through various kinds of adaptations. Not one but many paths have been followed by the different species. Because of this not one but various routes must be followed by us in our searches after means for overcoming their baneful influences.

The important part that a belief in natural selection, through parasitism, indicates may be played by the products of digestion in the mechanism of immunity demands some consideration of the nature of these products in order to understand what that part may be. The research work of the last quarter of a century has taught us that these products are entirely unlike what they had been imagined to be. Even the work done by the enzymes is different from that which they were supposed to do. Pepsin, once believed to be the chief digestive agent, is now relegated to an inferior position in the work of preparing food for bodily use. It is totally unable to digest some kinds, and while it can start the digestion of a beefsteak or an egg it cannot complete the task. It is only able to break up the large protein molecules into smaller ones known as proteoses and peptones, but these are relatively large as compared with the final products. Trypsin attacks and tears down the fragments produced by the pepsin into still smaller pieces, but it requires erepsin to finish the job. But erepsin could not begin the work of disrupting the proteins of eggs or meat. These must first be attacked by pepsin. The final fragments—the molecules out of which the body builds its tissues—are known to chemists as amino acids. One very important fact about these smallest fragments is that the process of digestion only cleaves them apart and does not produce them. As morphine preexists in its sulphate so these preexist in the protein molecule, whether that molecule comes from a plant or an animal. It is accepted as a fact that "on chemical grounds there is no more reason for dividing the proteins into two groups of animal and vegetable proteins than there is for making a similar distinction between the carbohydrates."[21] Lusk assures us that "all forms of proteid decomposition follow, therefore, the pathway of cleavage into amino acids."[22] Abderhalden asserts that "the amino acids which split off from albumin by the action of alkalis and acids are already formed in the albumin molecule and are not formed by a secondary process."[23] Plimmer tells us that "the hydrolysis of polypeptids by enzymes shows most conclusively that the protein molecule is built up of amino acids."[24] Long says: "It matters little how the decomposition is effected, the products of protein destruction are essentially the same. * * * The conclusion follows, therefore, almost of necessity, that these are true nucleus groups."[25] No wonder, then, that Curtis could forcibly assert that "the thing of legs and locomotion, of spine and speech, can build his organic walls only ont of organic bricks ruthlessly ripped from existing walls of other animals and plants."[26] A rather suggestive fact in relation to the philosophy of evolution is that these acids, that constitute the building material of all living things, are crystallizable and are thus a sort of connecting link between ourselves and the mineral world with its mimicry of life in the inorganic crystals. The work of separating the amino acids in a pure form from various proteins has been a tremendous task, but its importance is so great for future biology that it will well repay the effort. The honor of having done a very large part of it belongs to Professor Osborne and his associates of the Connecticut Agricultural Experiment Station. It is laying a foundation for a scientific system of dietetics that is bound before long to rid the world of the crude guesswork and faddish notions that to-day fill our textbooks on this subject. When medical men generally come to realize that what the arrangement of the bricks and stones of a building is to the beauty and permanence of that building so the arrangement of these amino acids—the plasm builders of our cells—is to our bodies, there will be a change made in a large part of what to-day masquerades as medical science. The facts already in our possession seem to indicate that as these acids are arranged within our structures so is the grade of our being on the tree of organic evolution. As regards their arrangement in the proteins of the vegetable world, Osborne tells us that "no two seeds are alike in respect to their protein constituents. Similar proteins are found only in seeds that are botanically closely related. * * * The leguminous seeds are similar in the general character of their proteins, but marked differences exist between the proteins of the various groups. * * * Although the data for generalizations are as yet few, those that are available plainly indicate a close connection between the chemical constitution of the seed proteins and the biological relations of the plants producing them. That similar differences exist between homologous proteins of different species of animals is becoming evident from the facts which are gradually accumulating, and these strongly suggest a chemical basis for the multitude of diverse forms of animal and vegetable life."[27] Let me ask the reader to concentrate his attention for a minute on the world of meaning that can be easily read into the last few lines of this quotation—

what it says by implication. When a man who has spent the best part of his life on work of this kind offers us such a conclusion as the summing up to date of that work it deserves, and should receive, from biologists, the most profound attention. To learn from him that amino acid distribution in our tissues is not haphazard—not meaningless—but orderly and significant and that it indicates the existence of a correspondence between the morphological characteristics of living things and their chemical makeup is certainly important. The distribution of these amino acids in proteins, if due to natural selection—and what else can an evolutionist imagine it to be due to?—should be such as would supply to the tissues the greatest possible resistance to the enzymes of parasites. Since various proteins are known to have various resisting powers toward bacteria and protozoa what is more reasonable than to suppose that these differences may be due in part, or in whole, to the kinds, proportions, and arrangements of the amino acids in their structures? There is a large amount of experimental evidence supporting the view that digestibility and indigestibility are due to these factors. This will have to be considered in another connection.

The following amino acids are known at present and most of them have had their constitutional structures investigated. Mann tells us that "the constitution of all the amino acids except diamino-trioxy-dodecanic acid is thus known, and with the exception of histidin they have all been synthesized."[28]

MONOAMINO ACIDS.
1. Glycocoll.
2. Alanin.
3. Valin.
4. Leucin.
5. Serin.
6. Amino - 4 - oxy - caproic acid.
7. Aspartic acid.
8. Glutamic acid.
9. Amino-hydroxy-succinic acid.
10. Amino-hydroxy-suberic acid.

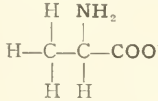
DIAMINO ACIDS.
11. Diamino-propionic acid.
12. Lysin.
13. Arginin.
14. Histidin.

DIAMINO ACIDS (Continued).
15. Diamino - 3 - oxy - dodeconic acid.
16. Diaminoglutaric acid.
17. Diamino-adipic acid.
18. Diamino-dihydroxy-suberic acid.
19. Diamino - oxy - sebasic acid.
20. Caseanic acid.
21. Caseinic acid.

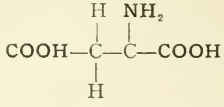
RING AMINO ACIDS.
22. Prolin.
23. Hydroxy-prolin.
24. Phenylalanin.
25. Tyrosin.
26. Tryptophane.

THIOAMINO ACID.
27. Cystin.

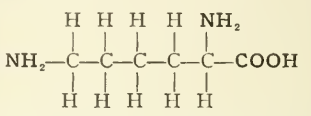
Concerning these amino acids Wells tells us "that there is one important point that they all have in common; each one is an acid which has an NH_2 group substituted for a hydrogen atom on the carbon nearest the acid radical. * * * Through this arrangement every one of the constituents of the proteid molecule is provided with a group with a strong basic character and a group with a strong acid character."[30] The following graphic formula of alanin, giving the basic and acid groups in prominent type, may help make clear Professor Wells' meaning to readers unfamiliar with chemistry.



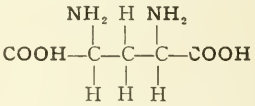
When an acid unites with alanin it links itself to the molecule through removing one of the H atoms of the NH_2 group. When an alkali unites with alanin it links itself to the molecule by removing the terminal OH of the COOH group. Vinegar is sour and has acid characters because it has a COOH group. In the absence of this group no organic molecule has been found with acid characters. The NH_2 group in organic molecules makes them more or less basic or alkaline. In the case of aspartic acid we have two COOH groups which make it much more acid than alanin and make it able to link itself to two alkaline molecules instead of one. Its formula is:



It is customary in writing the above formula to reverse the left-hand COOH and write it HOOC, but in order not to confuse readers but little familiar with chemistry both groups have here been made to face the same way. In the case of lysin and other diamino acids there are two NH_2 groups, thus:



These two NH_2 groups make lysin able to take up and unite with two acid groups. In diaminoglutaric acid we have still a different arrangement. The following is its formula:



Here we have two alkaline groups and two acid ones. It has therefore four points for union with other molecules. Let readers unfamiliar with chemistry try and work out how many combinations of horseshoe magnets they could make if they should unite them pole to pole—a single pole marked N to a single pole marked S. If both poles of one were united with both of the other that would end the combinations. If only one pole of each should be united there would always be two poles left uncombined, no matter how many magnets were used. As they were added the size of the combined magnets would increase, but there would always be two free poles. Now let the same readers imagine they have an indefinite number of magnets with their curved ends fused together forming a four-pointed magnet. The ordinary magnet would be like alanin. The four-pointed double magnet would be like diaminoglutaric acid. Now endeavor to conceive of the number of combinations possible with this if only one pole of each was united to one pole of another. Then think of the complex ways in which they would come together. In aspartic acid and lysin we have two three-armed magnets, but one has two positive poles and the other two negative ones. Bring magnets of these kinds into the combination and the complexity of forms possible would be inconceivably large. Note, however, the fact that the more aspartic acid molecules we link together by single bonds of each the more free COOH there is in the combination. It becomes more and more intensely acid. The reverse is true when we link lysin molecules together. The more of them there are thus linked the more and more alkaline the newly formed molecule becomes. If

linked so as to close up all bonds the resulting molecule would be neutral. The fact that proteins are both basic and acid proves that they are linked so as to leave many COOH and NH_2 groups free. Mann declares that "Egg albumin must be at least a thirty-five acid base, *i. e.* have thirty-five COOH groups unsaturated within a single molecule. He also tells us that "albumins must also be pluribasic acids."[31] To this we owe the great chemical plasticity of the protein molecules in living things, so that it would be difficult to overestimate its importance. Its selective value in every form of life is so great that it is inconceivable that anything other than natural selection could have produced it.

The study of the basicity and acidity of proteins has shown us that those found in germ and sperm plasm are predominatingly alkaline in character, while those found in somatic (bodily) structures tend toward acidity or are decidedly acid. In other words *animal vitality leans toward alkalinity* and animal protection toward acidity. Abderhalden says that "if we compare the relative amounts of the various amino acids occurring in the individual proteins we notice appreciable differences. This is especially striking if we compare the individual groups. In the first place we notice the varying proportions of the mono and diamino acids that go to make up the individual proteins. The latter are very strongly represented in the protamines (alkaline proteins) and least so among the albuminoids. Between these two extremes we find the common albumins and the histones. Very noticeable is the predominance of special monoamino acids, *e. g.* glutamic acid and leucin in the albumins present in the seeds of plants."[32] Chittenden also draws attention to this fact when he tells us that "the basic character of protamines with their large content of diamino acids is much more marked than that of ordinary proteins, such as are found in somatic nucleoproteins."[33] Mann tells us that the albumins proper are neutral or slightly alkaline, while the mucins are acid.[34] "The globulins," says Abderhalden, "are like acids and turn blue litmus red."[35] Is there any significance to these acid and alkaline relations of the tissue proteins? Are they survivals in the struggle with parasites, as the theory of natural selection would seem to demand? We have found that the mucins are not easily digested by bacteria and that they are a "means of steadily removing bacteria from mucous surfaces."[36] We have learned that these acid globulins may likewise be antibacterial, for "the antibodies are usually found in the globulin fraction of the native proteins,"[37] the precipitins may be bound up with them,[38] the agglutinins are precipitated with them, the antitoxins are related to them, and the amboceptors are associated with them, while they are actually found in snake venom constituting part of its composition.[39] Plant seeds require protection from bacterial destruction when exposed in the ground from season to season in dampness and changing temperatures and the "globulins form much the greater part of the reserve portion of all seeds except those of cereals."[40] Even the cereals have acid proteins.[41] Laurent in his studies of potato rot found that the *Bacillus coli communis* "produces a soluble ferment which has the power of digesting the cellulose membrane in the tuber of the potato and at the same time secretes an alkaline juice without which this digestion cannot go on. * * * The alkaline secretions of the bacillus studied by Laurent may be neutralized by the acid juice of the potato, and when certain races of tubers prove immune from decay it is, according to this observer, because of the production of sufficiently acid cell juice. Moreover, he actually succeeded in communicating an artificial immunity to varieties of the potato which were more susceptible to decay by immersing them for several hours in solutions of certain organic acids. On the other hand, when he treated varieties endowed with a well marked natural immunity with alkaline solutions the tubers became very susceptible to the decay set up by the bacillus. The struggle between the potato and the *Bacillus coli* reduced itself, then, to the chemical reaction between the alkaline cell secretions of the microorganism and the acid secretions of the potato."[42] Place this alongside the fact that "the greater number of important bacteria and all the pathogenic species thrive best in media containing albuminoid substances and of a slightly alkaline reaction to litmus."[43] "Only a few varieties," says the same author, "require an acid medium and none of these belong to the parasitic bacteria." In the face of facts of this kind what other conclusion can we possibly reach than that the protection of our most vital parts—the alkaline parts—requires acid tissues to beat back our bacterial enemies? If pathogenic bacteria are unable to live on acid tissues until they have neutralized them then the struggle between ourselves and these bacteria must have been in large part such another struggle as that between the colon bacteria and the potato. In the survival of the fit our somatic cells should have tended acidward during the milleniums of the past. Since they would themselves perish in an acid medium the acidity had to be available acidity while the circulation maintained its neutrality. The tissues had to be able at all times to present to the bacteria more acid than the bacteria had alkali, otherwise the latter would have been able to digest and thus destroy the former. That protein molecules are capable of becoming intensely acid we have already seen. The fact that they can form hydrochloric acid from salt to supply the gastric juice is evidence of the high point to which this power has been elevated. But the tissues of metazoa have found it necessary in this matter to avoid Charybdis in trying to steer clear of Scylla. The parasitic protozoa live a different life from that of the bacteria. They, like ourselves, begin their digesting with an acid medium. Tissues that the bacteria cannot digest the protozoa are able to attack. Proteins that are digestible only in an acid medium bacteria could do nothing with. Such proteins, however, would constitute a flaw in our armor when trypanosomes or malarial parasites had to be routed. They would have to be protected by different forms of indigestibility and it does not require a long hunt to find these. Substances containing large amounts of glucosamin, of glycocoll, etc., and that are represented by mucins, chitins, elastins, and the like, resist, in varying degrees, both tryptic and peptic digestion. These are found in the parts of the body most exposed to parasitic danger. But besides these, two very distinct types of phagocytes—distinct in this matter of digestive ability—are found in the circulation. One of these kinds does its digesting in an acid and the other in an alkaline medium.[44] It is thus evident that the cells as well as the tissues have been compelled to match these opposite kinds of danger by varying in methods of digestion. The fact is that the sole weapons of offence and defence, in both microbes and cells, up to the time Tennyson's "Nature red in tooth and claw with ravine"

came into being, were concerned with digestion. The struggle for existence was a struggle against the digestive powers of foes and a struggle to intensify the individual's digestive power against its foes. Only such variations as could hinder the digestion of the enemy and heighten the ability to digest of the individual against that enemy had any selective value. Every tissue that failed to erect barriers against digestion had to perish as unfit. There is no other conceivable way in which we can put reason into this problem, as they had only digestive mechanisms with which to fight. For long ages of time it has been "nip and tuck" between the cells of the higher forms of life and the parasites. Every tissue has been forced out of existence that failed to convert itself into a biological *chevaux-de-frise* in this hungry battle. Check had to oppose counter check again and again through countless generations, until each attacked tissue became deadly to the tissue that dared to attempt its absorption as food, *i. e.* by poisoning it. As a result "all foreign proteids when introduced into the circulation of animals are more or less toxic."[45] Why?

When completely digested meat, egg, or other protein passes the intestinal wall it reaches the cells as perfectly assimilable amino acids. The COOH and NH_2 groups in these acids constitute their points of chemical affinity with the cell receptors. When undigested meat, egg, or other protein is injected directly into the circulation of an animal they appear not to be assimilated until torn down into amino acid fragments. Notwithstanding the fact that they possess the same points of affinity for the receptors as do the amino acids, they are rejected as foods by the cells until decomposed. The differences in the arrangements of the different amino acids in different proteins shows that the order in which the COOH and NH_2 groups occur on the surfaces of the various kinds of protein molecules cannot be the same. In proteins from the same species of animals, *i. e.* in homologous proteins, the arrangement is probably the same. In proteins from different species of animals, *i. e.* in heterologous proteins, the arrangement must be quite different. Basic and acid affinities bristle all over the surfaces of all protein molecules, but in those from the same kind of animal they are arranged alike toward each other —they are amphoteric, through evenly neutralizing each other. Such molecules cannot rend each other by contact through hydrolytic cleavage. In heterologous proteins the groupings render them attractive to each other, but with an attractiveness that is probably destructive. Acid faces base with acidity sufficient to activate the ferments present in the cell and digest that part of the cell which its affinity has seized. The more unlike two species happen to be the more they have in their phylogenetic histories drifted asunder in the structures of their proteins because of their wars with parasites and readjustments to match the dangers from such parasites. The wider the differences in the acid and basic affinities of their respective proteins, in respect to the ways they are distributed in a molecule, the more able they will be to neutralize each other's effects and hinder each other's digestive ability. In the past struggles for existence digestion having played the chief and, probably, the only part, what other sort of fitness could aid survival better than a fitness that could destroy the enemy through its own attempts at digesting the fit individual? Why should we wonder at all proteins being toxic when we see that their salvation has, probably, depended upon this very quality? The severity of the tuberculin and mallein reactions in tuberculosis and glanders should not surprise us when we have discovered that in a parasitic natural selection the destructive agent is the activated enzyme and that the tissue proteins do the activating. Why should we deem it out of the ordinary "that anaphylaxis can be induced by bacertial proteins, and notably with those of the *B. coli* group?"[46] We are astonished at the exceedingly minute amounts of pure egg albumin that can kill an animal sensitized by a previous injection of the same albumin a couple of weeks before, and yet it is exactly what might be expected, *a priori,* if selection has worked through parasitic destruction of higher animals. "The sensitizing and intoxicating effects have been produced with such extremely minute quantities of protein," says Wells, "that it seems not unwarranted to maintain that these experiments settle this point conclusively. As repeatedly recrystallized egg albumin, giving every evidence of chemical purity, is capable of causing sensitization in doses of one twenty-millionth of a gram, and of killing sensitized pigs in doses of one twentieth of a milligram, it is evident that if either of these effects were due to something other than the egg albumin itself this contaminating substance must have a potency beyond the bounds of imagination." In the same article Wells tells us that "tryptic digestion of serum furnishes further evidence of the protein nature of the substances concerned in the anaphylaxis reaction. Both sensitizing and intoxicating principles are attacked and slowly decrease in strength as the coagulable protein disappears."[47] The fact that "the phenomenon of anaphylaxis with bacterial cultures corresponds exactly with the anaphylaxis to non-poisonous proteids, such as serum and eggwhite,[48] and that "with zein there was no difficulty in securing effective sensitization and fatal intoxication with all the characteristic symptoms[49] shows how universal it must be. The vegetable, the animal, and the protistan worlds all show this mark of continuous and general parasitism. It is evidently as widespread an internal adaptation against pathogenic organisms as is the external one of excessive indigestibility which is characteristic of the exposed surfaces of every thing that lives. The external protection against parasitic digestion is so ubiquitous that, like atmospheric pressure, few are ever conscious of its existence. Every kind of organized being is encased in what is well-nigh digestion-proof armor. The capsules of bacteria, the spore covers of sporozoa, the suberose and cellulose barks of trees and herbs, the chitinous encasements of insects and crustaceans, the mineral coverings of shellfish, the scales of swimming fish, the tough hides of amphibians and beasts, the feathers of birds, and even the delicate cuticle of man, all attest the antiquity of enzyme warfare on the part of parasites. They are all reflection images of the digestive ability of disease-producing microorganisms. In a similar way anaphylaxis appears to be an internal reflection-image of the same struggle for existence and survival against intracellular digestion. Both, however, are fitnesses that are as available for parasite against host as for host against parasite. Guns and armored cruisers, fortifications and mines are the monopoly of no nation and the defences against disease become in turn the offensive weapons of disease. When the proteins of dead and dying bacteria make us ill by their poisonous effects our proteins are taking revenge upon them by poisoning and digest-

ing them. If there is any place in nature where the struggle for existence and survival of the fit can be better seen than in a microbe-invaded body this writer does not know where it is. As soon as a fight begins the least resisting microbes perish first and the most resisting last, the least immune phagocytes die first and the most immune last. Both sides appear boldly at the commencement of the fray, but it is not long before one side or the other takes to flight, leaving victorious microbe or victorious phagocyte master of the battlefield. Soon there is a rally in which reinforcements appear and the fight begins anew. The victor may now become the vanquished and be compelled to fly or perish utterly. The flight of the phagocytes is technically known as leucopenia. In anaphylaxis they seem to lose their valor early in the fray and rush to the lungs as if gasping for breath. "I have," says Andrewes, "examined the lungs and other organs of seven rabbits killed while in the leucopenic condition—mostly about a quarter of an hour after the bacterial injection. Where the leucopenia has been pronounced the number of polynuclears in the lung is very much increased. Thus in a rabbit immunized against *Streptococcus fæcalis* and killed a quarter of an hour after a large dose of the living organism I found 51,000 polynuclears per cubic millimeter of lung tissue. In a coli-immune animal dying two hours after a moderate injection of vaccine, with a circulating polynuclear count of only 205 per cubic millimeter, there were 60,000 polynuclears per cubic millimeter of lung."[50] The same author says: "I am inclined, indeed, to think that initial leucopenia is a more delicate test of the occurrence of the reaction between antigen (antibody generator protein) and antibody in the circulation than the clinical symptom of anaphylactic shock. I have never seen shock without some degree of leucopenia, but I have seen a marked leucopenia without any symptoms of constitutional disturbance."[51] That there is real danger to the phagocytes in the condition of anaphylaxis has been made evident. "Experiments where guinea pigs were inoculated with tuberculosis bacilli," says Miss Reed, "show that the neutrophil first reacts by a rapid increase in the number of lobes. * * * Observations in the hospital, together with these experiments, seem to prove that the neutrophils first react to the presence of bacilli or a toxin by some metabolic change, which is shown by increase in the number of lobes in the nucleus; these reacted cells then break down or are used up in the blood."[52] Their lobes are first damaged and then they die. Since "the nucleus seems to act as the main (though possibly not the only) oxidizing agency of the cell,"[53] and, as Lillie working with "the cells of the blood, the liver, and the kidneys of frogs" found that "the oxidations were most rapid in those organs and those regions of organs where the nuclei were densest"[54] we have here what appears to be an adequate explanation of why the chief symptom of anaphylaxis is checked respiration. Breathing being but an expression of total cell oxidations, damage to cell nuclei should arrest it *pari passu* with the amount of such damage. The behavior of the phagocytes in leucopenia seems to admit of no other conceivable explanation than this.

The exceedingly great poisonousness of egg, meat, vegetable protein, and bacterial tissues, when they can reach the interiors of living cells in an undigested or partly digested condition, raises the question as to what constitutes poisonousness. Proteins are evidently not far short in their deadliness toward some animals from our most deadly toxins and it is possible that they may cast some light upon how the latter happen to be so terribly destructive. A preparation of botulinus poison has been made of which "one part of toxin to five hundred million parts of body weight suffices to cause death,"[55] and "a tetanus toxin has been prepared of which 0.00005 milligram killed a mouse weighing fifteen grams; a man weighing seventy kilograms, with the same susceptibility, would be killed by 0.23 milligram. This would make the poison 300 times more potent than strychnine."[56] Notwithstanding this great potency we are told by our textbooks that trypsin, pepsin, and papain destroy tetanus and diphtheria toxins[57] and that these enzymes do not merely neutralize the toxin but actually digest it.[58] By mouth, toxins, like foods, lose their poisonousness, "a fasting rabbit bearing a whole gram of typhoid toxin introduced into its stomach by means of a tube, without apparent effect"[59] and "one gram of the gastric juice of a dog will neutralize fifty fatal doses of diphtheria toxin, or 10,000 of tetanus toxin, using the guinea pig as the test animal."[60] Roux and Yersin prepared a very destructive diphtheria toxin and while it "acted with such extraordinary virulence when injected subcutaneously into guinea pigs and pigeons, it could be swallowed without danger."[61] With such an array of facts concerning the digestibility of these toxins and considering their relationship to the organisms that produce them, should we not be inclined to conclude with Adami that "it is most satisfactory to regard the toxins and particularly the bacterial exotoxins as cleavage products of protein metabolism and as approximating in their nature the primary nonpolymerized protein molecule?"[62] This would make them really foodstuffs. As gradually produced results of successive natural selections favoring the bacteria they could not possibly be conceived of in any other light. They must have evolved from our so-called non-poisonous protein. Our knowledge of anaphylaxis casts light upon just how such an evolution could occur. The toxin proteins have only to be in possession of the proper arrangement of COOH and NH_2 groups to be able to act upon the obstructing barriers the victims have thrown up, thus activating the enzymes of the cells and causing the digestion of these cells. By being arranged in a way that makes them specific for and chemotactic to the neurons of the central nervous system their deadly digesting character becomes assured. Varying in this direction would steadily keep removing them from the ordinary food proteins that are usually adapted in their affinities for many kinds of tissues. Nor was it necessary for such variations to be selected because they increased the deadliness of the toxin. It was enough that with smaller and still smaller amounts the parasite was enabled to check the digesting power of the host upon themselves. Prompt arrest of digestion could save them and let the host live. It is well known that under toxin intoxication hunger disappears. There is no cry of the cells for food. The microbes' lives would be saved more effectually the more promptly they became able to check the appetite of the host and this they apparently do by making hunger dangerous to the host. For the cells of the host to be absorbing food in the presence of toxin would mean the absorbing of the toxin as well. To stop feeding is to close the open gate of destruction. To have the nucleoplasm of the cell digested with its own

enzymes is a happy adaptation—happy for the disease germs but not for us. Natural selection is thus responsible for our undoing as well as our upbuilding and protection. To natural law the microbe is as great as is the man and, apparently, of as much importance. The poisonousness seems, thus, to be the digestibility of the vital part. Pfeffer rightly says: "It is the nature of the protoplasm which determines whether a substance shall act as a poison or not."[63] There are no such things as poisons *per se*. A poison is poisonous because we have not adapted ourselves to it in any considerable amounts. There is no line of demarcation between the most deadly poison and the food that nourishes our bodies. They merge into each other exactly as the deadly fire merges into the absolutely necessary normal temperature. Stahl trained *Æthelium septicum* until a 2 per cent. solution of grape sugar was deadly to one specimen and the food supply of another.[64] Pere trained *Thyrotrix tenuis* so that it fed and throve upon deadly formaldehyde.[65] Park declares that substances like carbolic acid "can, when in sufficient dilution, provide the necessary carbon and even act as stimulants to the growth" of bacteria.[66] Chittenden tells us that "the amount of hydrochloric acid secreted during twenty-four hours by the normal individual, under ordinary conditions of diet, amounts to what would constitute a fatal dose of acid if taken at one time in a concentrated form."[67] The relativity of poisonousness is one of the best established facts of modern science. The antidoting of poisons by the body is one of the most interesting of all the studies in biology. The production of antitoxins and other antibodies by the body seems almost miraculous and its mechanism will be taken up by the writer in a future article.

That cell nuclei are not left exposed to constant danger from bacterial products goes without saying. Every cell is a little organism—a machine—with many distinct parts having various protective functions. The nucleus, being, probably, the most vulnerable part, has, by natural selection, been, like our viscera, shielded by various devices. Among these is a surface film or membrane which has to be pierced before the nucleus is seriously open to danger. The same is true of microbes, and these frequently increase the thickness of this outer covering, sometimes adding two, three, or more layers, like the different coverings of an onion.[68] Being almost digestion-proof, they are of decided selective value. In the case of our cells such thick coverings would be injurious. In them the envelope is thin so as to permit of the free passage of such soluble materials as are required for active nutrition, for respiration, etc. Substances that stimulate the cell protoplasm must do so through this membrane. Lillie tells us that "stimulation in irritable or contractile tissues depends primarily on a temporary and readily reversible increase in the permeability of the surface films or plasma membranes of the constituent cells" and that "marked increase of permeability, if prolonged for more than a short time, is highly injurious to cells."[69] The exact chemical composition of these membranes is not known. We know that they contain lecithins, cholesterin, and proteins. If there are many kinds of cholesterin, as some chemists hold, it is possible that no two cells from different species contain the same kind of lecithin, cholesterin, or protein. Cells of all kinds —vegetable as well as animal—contain these. The vegetable cells have cellulose also as a protection, the bacteria, and, probably likewise, the protozoan parasites have chitin as a substitute for cellulose and many—possibly all—metozoa have such glycoproteids as mucin and mucoid as adhesive substances of a large number of cells. There is thus a chemical kinship of carbohydrate connecting all sorts of cells throughout the world of living things. Such a combination or blending is, or can be, of such baffling complexity from the viewpoint of digestion that it would seem to require all manner of enzymes and of activators to unravel and dissolve it. The lipoids require lipase, the carbohydrates probably various amylases, the acid proteins alkaline proteases, the alkaline proteins acid proteases, and the cholesterins a variety of oxidases. As soaps and oils can pierce erythrocytes it seems probable that the lipoids are, for animal cells, very important constituents. Their removal destroys the semi-permeability, laying the cytoplasm open to proteolytic digestion. Other kinds of cells seem less liable to such cytolysis. In sensitizing an animal with foreign proteins a period of about ten days is needed before a second injection will produce anaphylactic shock. It would seem from our knowledge of the cell membranes, the cytoplasm, and the nucleus that so slow is the digestive process in these that this period is consumed in increasing the permeability to an injurious amount. This we should expect, judging from the nature of the tissue to be tunneled. In bringing the chitin of bacteria into solution by digestion the first result we should expect would be the releasing of glucosamine and the further breaking of this down into glucose and acetic acid in accordance with the following equation:

$$2C_{15}H_{26}N_2O_{10} + 6H_2O = 4C_6H_{12}NO_5 + 2C_2H_4O_2$$

These products of digestion are positively chemotactic for phagocytes and softened chitin we should expect to be sticky in character. Cholesterin being related to the terpenes,[70] we might expect its oxidation products to resemble resins in stickiness and in chemotactic quality. The coincidence of these qualities being associated with the first point of attack in bacteriolysis should put us on the alert for a possibile connection of these with opsonins and agglutinius—the first responses in bacteriolysis. The specific character of both accords well with the digestion complexity of the membrane structure. Each species would require a different combination of enzymes and activators to dissolve it readily. J. Loeb thinks that the "agglutination of sea urchins, bacteria, etc., can be explained by a softening of the surface of the floating material and subsequent cohesion."[71] This sticking together of the bacteria on being acted upon by a serum made specific to that particular kind of bacteria is the basis of Widal's reaction in typhoid fever. The surface of the typhoid germs is, in this case, apparently being acted upon by a proper combination of enzymes to dissolve slightly the membrane. Before such dissolving has proceeded far traces of the membrane material would have diffused into the blood stream, reached the phagocytes, and through its positively chemotactic nature attracted them in the direction from which it was coming. The nearer the phagocytes approached the bacteria that the serum was thus acting upon the greater would become the proportion in the blood and the greater the attraction. Phagocytes have no mysterious way of finding bacteria that have reached the circulation in dangerous numbers. How else can we conceive of their crowding into the regions where not too virulent bacteria are found? That they fly from very virulent bacteria in leucopenia we have seen, and seen the prob-

able reason why. There must have been an incessant destruction of phagocytes, through all past time, that failed to be attracted to disease-producing bacteria and failed to be repelled from dangerous amounts of bacterial poisons. When the poisons became diffused to non-poisonous amounts and the opsonins increased to attractive amounts the conditions for their destructive work were favorable and disease was brought under control. There could, however, be neither negative nor positive chemotax is without real substances being dissolved into the blood-stream and acting as such. Phagocytes are indifferent until the opsonins reach them and stimulate them into activity. In every disease there is a local center of weakness—of vulnerability—where disease germs are able to multiply and live at the expense of the cells. In pneumonia it is the lungs. In typhoid fever it may be Peyer's glands. In meningitis it is the meninges. In rheumatism it is the joints. In every individual there are parts that are practically immune to any one particular kind of germ. Is there any way by which these immune parts can be compelled to help the vulnerable parts in the uneven struggle of active disease? In human warfare the stay-at-home people, who live remote from the national points of vulnerability that an enemy has attacked, are compelled to supply money and the munitions of war to maintain the armies. Does the body contain no medium of exchange that can be increased by stimulating invulnerable cells? We have seen how bacteriolytic enzymes can be forced to accumulate in the peritoneum and there to kill and destroy bacteria in a specific way. If the attacked cells and phagocytes of the body in pneumonia have not enough specific enzymes to dissolve the invading pneumococci why cannot we compel the uninvaded regions to produce enough enzymes and activators to hurry up the destruction of the foe? These idle, unattacked parts have a superabundance of such enzymes that are only awaiting a strong enough stimulation to cause them to be poured into the blood stream. Why not inject weakened or dead bacteria vaccines of the kind that is making the attack into the tissues that are invulnerable to their attack and thus hurry up the supply of destructive agents that the blood-stream can carry to the battlefield? The vaccines thus injected will be quickly digested, the circulation will carry the bacteriolytic serum to where it is most needed, the living bacteria of the dangerously diseased part will have their surfaces dissolved, the attractive substances they thus give up will reach phagocytes in the most remote parts of the body, these will be stimulated into hurrying to the seat of battle and the active leucocytosis thus started will mean victory for the patient over his disease. In the active field of battle the bacteria present deflect the enzyme (complement) to themselves, and there not being enough to reach them all many of them are left uninjured. To stir up the secretion of specific enzymes in immune parts is to get a sufficient supply to the vulnerable parts in time to be of service. This appears to be the secret of opsonic action, of bacteriolysis, and of the self-limitation of not-too-violent diseases. It is an expression of nature's primitive mode of warfare and of the decree of the ages that living things must digest or be digested in the fierce struggle for existence.

THE PROBABLE DURATION OF LIFE.

By A. H. STEWART, M.D.,

LAWTON, OKLA.

The growing realization that the old belief in the extraordinary strength, size, and longevity of the early inhabitants of the earth was founded chiefly on fiction. That all living things have a tendency, through the inherent property of protoplasm, to grow old from the very beginning of life, appears to have rather increased than decreased the tremendous interest that has always been associated with the question of the probable duration of life.

This is not surprising since the new biological conception of life and the recent discoveries in sanitary science place the chief responsibility of prolonging life, with certain limitations, upon the individual and the community.

Through the aid of the microscope we have learned that the several building materials—muscle, bone, nerve, etc., of which bodies are made up are not composed of homogeneous masses of these respective tissues, but are themselves built up of myriads of minute cells, which, with certain limitations, are themselves living organisms; for it is through them that the distinctive feature of living matter, assimilation, nutrition takes place. It is through these tiny cells that the constant stream of dead matter that is taken into the system is rearranged into living matter and the equally continuous outflow of dead matter that has once been in the living form is removed from the economy. This power of living matter to convert dead food into living substance like itself is one of the great physicochemical mysteries of life and is that which distinguishes living from dead matter. For all practical purposes these cells, with their cytoplasm and nucleus, are the smallest subdivisions into which the body need be divided. Commencing with the two parent cells, which possess the inherent property of mutiplication and growth by division and redivision and differentiation, the body is ultimately built up. But aside from this vital capital with which the young organism is endowed by the parent cells, how it grows, and the degree of perfection and vital resistance which it attains depend wholly upon the nutrition which it receives and assimilates. Since, then, all growth begins in the cells it is evident that the growth of the body is the sum of the growth of the tissues and the growth of the tissues is the sum of the growth of the cells of which the tissues are composed. The rate of growth is most rapid when the tissues are at their least density and decrease gradually as the density of the tissues takes place until the body reaches the average limit of the race. The slight variation in the normal rate of growth, a few days after birth, is not well understood but is believed to be due to the establishment of respiration and the extra expenditure of energy necessary to maintain body warmth, as during gestation this is furnished by the mother. It goes without saying that growth is accelerated by favorable and retarded by unfavorable conditions; that it is more rapid in the country than in the city, during vacation than while at school, is favored more by outdoor than indoor occupation, and is greater in summer than in winter. The rates of vertical and of horizontal growth, or of height and weight, appear to be inversely to each other. So is the rate of growth of organ and function. Aside from the well recognized period of accelerated growth at puberty, preceded and followed by a slightly retarded growth, there are numerous individual unclassified variations and rhythms. Although there appears to be a partial compensatory acceleration of growth after temporary retardation from sickness or deficient nutrition, it is questionable whether such rapidly accumulated tissue possesses the same power of resistance as in the case of uninterrupted growth. Nothing is more certain than that the rapid increase of weight that often follows recovery from protracted illness from the infectious diseases is often merely an accumulation of nonvital tissue due to a perversion of nutrition. Investigation among a large number of school children in large cities has shown that growth decreases with each lower stratum of society, indicating that continued denutrition leads to permanent physical deterioration somewhat proportionate to the extent of such denutrition. Notwithstanding the fact that the absolute height and weight increase gradually, the rate of increase gradually decreases. This is not only true of absolute height and weight, but of the relative weight per unit of body weight. This is strikingly shown in the following analysis of Quetelet's somewhat faulty tables of growth. According to these tables, a child that weighs six and one-half pounds at birth, if well nourished, will gain twelve pounds the first year but only four pounds the second year. Here the absolute gain the second year is only one-third that of the first year, but as the weight of the child is two-thirds greater at the beginning of the second than at the beginning of the first year, the rate of decrease per unit of body weight is much greater. In height, the gain the first year is 148 mm., the second year 93 mm., the third year 72 mm., while from the twentieth to the twenty-fifth years the average is 12 mm., and from the twenty-fifth to the thirtieth it is only 0.8 mm.

As variation in growth is less later in life than in early childhood, it is probable that the possible final achievement of the body, like a spent ball, is more easily affected adversely by deficient nutrition late than early in life. Contrary to the popular opinion that there is a period of development followed at maturity by a period of decline of the vital forces, there appears to be a continuous decline from the beginning to the end of life. This continuous decline of the vital forces of living matter has been roughly compared to a clock, the mainspring of which suffers gradual loss of elasticity from molecular changes until winding will no longer make it run. The renewed energy given to the clock by winding is supposed to represent the renewed energy that comes to the body through the food we eat and the air we breathe, while the loss of elasticity in the spring through molecular changes is supposed to represent the loss of vital force through molecular changes in the body. Again, the growth and decline of the body has been compared to a man building a wall. It is said that a man builds a wall which keeps on growing, but as the man becomes tired it will increase more slowly and finally ceases to grow altogether when he is worn out. So the vital forces build the body which develops, but all the while the forces are losing their power. The cessation of growth, then, is not due to the body

reaching maturity, but is merely a final term in a series of losses.

"As soon as we bee begunne, we did beginne to be undone."

In the illustration just given the time required for the man to become tired and finally worn out depends upon at least three factors: the stock of vital energy with which he commenced work, the amount and character of nutrition received and assimilated, and finally how he conserves his energies. There is nothing fatalistic about this. Admitting that through the inherent tendency of living matter to grow old there will come a time when he must lay aside his implements and rest under the shade, the time, within certain limits, when this shall be depends materially upon the conditions just mentioned. Although no law has been or probably can be formulated on the subject, a wide range of observations appears to indicate that the sooner an organism reaches maturity the shorter will be its duration and that in many animals the whole duration of life is some five or six times the period required for complete development. Thus as man is from twenty to twenty-five years in reaching maturity, he should live from one hundred to one hundred and twenty or thirty years. That even the greatest of these possibilities have been exceeded by both man and woman in many instances the records of centenarians abundantly prove. The fact that this is the exception rather than the rule does not prove that through new discoveries relating to life's processes and the conservation of energy the rule and the exception may be reversed. In its final analysis the question is how long may an adjustment be maintained between internal relations and external relations. If the vital force that comes with genetic continuity is of the highest intensity and external relations are favorable it should not only be possible but highly probable that instead of a very small minority, a very large majority of lives could be extended far beyond the century mark. The term vital force is here used in its modern sense as an expression of the physicochemical energy resident in living matter and not as a supposed mystic power independent of thermic electric or chemical energy. Thus the vital force inherent in the germ plan and the force added through nutrition is the initial and acquired capital or forces out of which our bodies are made up. Although the architectural plan of this structure is in a measure predetermined by the determinants in the germ plasm, how it will conform to the pattern depends materially upon the character of the initial and acquired capital and the conservation of energies. If these can stand the highest test there is no physiological reason, says Dr. W. A. Hammond, why mankind should not drive old Father Time down the highway of life beyond the one hundred-year mark. The so-called law that fixes man's time on earth at three score and ten years has no divine authority. We may as well live one hundred years as fifty years.

Prof. Fisher of Yale University in a recent address (Feb. 5, 1909) at New York said: "It has long been known that there is no iron law of mortality but that mortality depends upon the hygienic state of the community. Bains, in a recent paper in the *Journal* of the Royal Statistical Society, has calculated that the average duration of life in India is only twenty-three years for males and twenty-four years for females, or less than one-half the life space of the advanced countries of Europe. The estimates of Finkelburg show that in Europe human life has probably doubled in the last three hundred and fifty years. More recent and more reliable figures show that life is lengthening more rapidly to-day than ever. If we take life for different periods for England, France, Prussia, Denmark, Sweden, and Massachusetts, we find that human life lengthened during the seventeenth and eighteenth centuries at the rate of four years per century; that during the first three-quarters of the eighteenth century it increased at the rate of nine years per century; that at present it is lengthening in Europe generally at the rate of seventeen years per century, and in Prussia (which is perhaps the home of preventive medicine) at the rate of twenty-seven years per century." For this country the rate can only be judged by the statistics of Massachusetts, which show that life is lengthening by about fourteen years per century, or approximately one-half the Prussian rate. If the achievements in preventive medicine and sanitary science increase in the future as they have in the recent past the present average duration of life of about thirty-four years in this and most European countries ought to be materially lengthened before the end of the present century. There are constantly about 3,000,000 people seriously ill in the United States, one-half of whom suffer from preventible diseases. More than 500,000 persons are constantly ill of tuberculosis, one-third of whom die annually. Notwithstanding the effort at rigid exclusion, deaths from tuberculosis cost the insurance companies of this country nearly $50,000,000 annually. An eminent American physician said recently that the causes of nearly all the infectious diseases were so well understood and their prevention so easily accomplished that according to all the rules of liability for criminal negligence, for every man who died of typhoid fever some one ought to be shot. Again, an eminent English surgeon, Frederick Treves, said: "The time will come when it will be as anomalous for persons to die of scarlet fever, typhoid, cholera, or diphtheria as for a man to die of a wolf's bite in England." And it was Sir James Crichton Browne who said, "Every man is entitled to his century."

Fortunately we do not have to depend upon mythical characters of olden times nor even upon comparatively modern celebrities like John Parr, Thomas Jenkins, or St. Mungo, who are reputed to have lived 152, 160, and 185 years, respectively, for proof that the century mile post has been passed in many instances. Our own John Leonard Roeder, Sarah McDonald, and Noah Raby, who lived 109, 131, and 131 years, respectively, and William Macabee, Elizabeth Wonderly, and José Quirterrez, who are still hale and healthy at 107, 108, and 120, respectively, furnish incontestible proof of this fact. James Click of Prestonburg, Kentucky, with whom the writer was well acquainted, had family records to prove his claim of 104 years when I last saw him. He then appeared to be about seventy and asked rather seriously if I could not find him a nice young wife in my travels. He lived some years after this but just how long I have not been able to learn. The United States census for 1900 shows that there were 3,981 centenarians in this country at that time. The latest available statistics on the subject show the number of centenarians in each of the following countries at the time of such enumeration as follows: England, 146; France, 213; German Empire, 78; Spain, 410; Servia, Bulgaria, and Roumania, 5,540.

FURTHER NOTES ON THE TREATMENT OF PARALYSIS AGITANS WITH PARATHYROID GLAND.

By WILLIAM N. BERKELEY, A.B., B.Ph., M.D.,

NEW YORK.

By way of introduction for those unfamiliar with the literature of this subject, some preliminary comment will perhaps not be unwelcome. It may be therefore briefly stated that when the parathyroid glands are removed from a dog or other suitable animal, a curious and characteristic train of symptoms follows,—hurried respiration, tachycardia, profuse salivation, twitching and shivering of the voluntary muscles, rigidity, intermittent convulsions, rapid wasting, and death. There is now an enormous literature on the subject. A fairly complete bibliography may be compiled from the writings of Jeandelise[1], Pool[2], Erdheim[3], Berkeley and Beebe[4], and Ochsner and Thompson[5].

MacCallum[6] in a further interesting and important contribution to the subject has shown that a suitable dose of a soluble calcium salt, injected into the veins of a dog that has been successfully operated upon in this way, will arrest the spasms and for a few hours restore the animal to a normal condition. He concludes that the parathyroid glands therefore preside in some way over the calcium metabolism of the body, and that the symptoms in question are caused by a deficiency of calcium. S. P. Beebe and I[4] have successfully repeated this experiment, which is one of the most striking phenomena in the physiological laboratory; from a series of additional experiments, however, we have been disposed to conclude that in such cases the calcium has a "drug effect," and that the parathyroid glands more likely furnish enzymes of prime importance in the intermediary metabolism of nitrogen. The subject is a difficult one and awaits further research.

Whatever the ultimate solution of the physiological problem may be, such remarkable and characteristic symptoms strongly suggest some causal relation between a defective secretion of these glands and one or more of the known convulsive diseases; and medical men have not been backward in guesses of various kinds. Exophthalmic goiter was long ago proposed by Gley[7] and afterward given over. Vassale proposed puerperal eclampsia[8]. Epilepsy was first suggested by MacCallum (acknowledgedly in a tentative way[9]), but further independent researches by this author[10] brought him to the conclusion (reached about the same time by Pineles[11] and Erdheim (*l.c.*) and rather vaguely suggested by Jeandelise (*l.c.*) in 1902, four years previously) that *tetany* is the final answer to this long-standing question.

Without going further into the extensive literature of this part of my topic, it will be enough to say that tetany—whether associated with surgical damage to the parathyroid glands in thyroidectomy, with infantile rickets, with pregnancy, or with dilation of the stomach—is unquestionably *one* of the answers. But a further inquiry remains whether this be the *only disease* having any relation to these glands; and it is now some years since the Swedish neurologist, Lundborg[12], and I[13], working along different lines, and each independently of the other, conceived the idea that *paralysis agitans* is possibly due to some chronic disorder or disease of the parathyroid glands.

In support of this hypothesis I have offered (*l.c.*) the following considerations: Paralysis agitans has all the marks of a chronic toxemia; the symptoms following parathyroidectomy are remarkably like those of paralysis agitans; in cases of myxedema and exophthalmic goiter paralysis agitans has not infrequently occurred as a complication or sequela; of fourteen reported autopsies on paralysis agitans, two by Erdheim (*l.c.*) and nine by R. L. Thompson[14], showed negative parathyroid glands, but two by C. D. Camp[15] and one by myself[16] showed distinct pathological changes; and lastly a remarkable percentage of cases of paralysis agitans treated with properly identified fresh gland, or a properly made extract, have been greatly benefited.

This statement brings me finally to the special object of this paper, which is to report some further improvements in the preparation of a glandular extract which will be suitable for the treatment of this disease.

My first cases were treated with commercial parathyroid gland. This worked well in a few cases, but was found so variable and uncertain in its action that it had to be given up. I next tried a preparation of properly identified gland rubbed up in the crude fresh state to a dry powder with milk sugar. This was distinctly better, but still seemed to be variable and unstable. Later on I tried a nucleoproteid solution of the parathyroid made up by Beebe's method[4] and preserved with a few drops of chloroform in the bottom of each bottle. This has still further raised the percentage and degree of improvement, but it precipitates rapidly, and is very susceptible to damage from temperatures above 5° C., therefore hardly admitting of transportation to any great distance.

My latest process, devised some months ago, and giving great satisfaction to five or six of my patients who had not done well on other preparations, is this: The nucleoproteid extraction process (Beebe's method, *l.c.*) is adhered to generally, but all the preliminary steps are hurried, and the precipitated nucleoproteid is not redissolved, but quickly dried in a draught of cold air; so that within eight or ten hours after the warm glands leave the bullock a minute amount of smooth yellow powder is obtained which stands physiological tests admirably, is stable, easily handled, and does not require a freezing temperature for its preservation (though for safety's sake it is recommended to keep it on ice).

The powder is rubbed up with milk sugar as a menstruum and is dispensed in sealed and dated bottles of sixty capsules (an average month's supply). Each capsule contains one-fiftieth of a grain of parathyroid nucleoproteid. The average dose is two per day—sometimes less than this where the patient is sensitive to the action of the remedy. The bottles are now to be had in several pharmacies in New York. This preparation is the best I have so far tried. It will give satisfaction not only in Parkinson's disease, but also in almost any form of tetany where the stomach can retain food. Otherwise a sterile hypodermic preparation of the nucleoproteid must be used.

In paralysis agitans there are no special contraindications, though some patients complain of "nervousness," inability to sit still, and an aggravation of their habitual constipation after a few days' dosage. Nothing is necessary in these cases except to diminish the dose and increase again more slowly. Little benefit can be expected of a satisfactory character except from small doses continued over a long period of time—three months to a year.

In looking over the notes of my own cases and of those treated in consultation (now upward of sixty in all) I find that between 60 and 65 per cent. of those who have given the remedy a fair trial have spoken favorably of it and have continued the treatment. More than a dozen, who began three or four years ago, have greatly improved and are now only uncomfortable when they are without the medicine.

With such a percentage of benefited cases as this there seems no longer any reasonable doubt of the etiological relation between the disease and the remedy. One or two cases in the hands of medical friends or correspondents appear to be almost cured, though of such a disease in a patient of advancing years a "cure" is always to be spoken of with reserve.

The hope seems justifiable that by further study of the complicated chemical problems involved it will be finally possible to cure paralysis agitans with parathyroid gland as surely as cretinic idiocy is cured with thyroid.

ANOTHER CASE OF PYLORIC OBSTRUCTION.

By ALEXANDER GOLDMAN, Ph.G., M.D.,

NEW YORK CITY.

ASSISTANT, VANDERBILT CLINIC.

In studying a certain line of cases and observing that the same thing occurs every time under the same circumstances, one concludes that such is the law in these cases. In the Medical Record, February 19, 1910, I wrote an article on pyloric obstruction. It was the result of a study of a large number of cases at the Vanderbilt Clinic. I had selected a series of four cases to prove my contention that as soon as there is retention of food, as evidenced by the presence of food remains in a fasting stomach, in a patient showing any serious symptoms of digestive disturbance, it always meant pyloric obstruction, and that a laparotomy should be performed. We had a case recently in which, not to be considered too narrow, we had not applied this strict rule, and, as a result, the patient died of pyloric obstruction.

Mr. V., an Irishman by birth, grocery clerk, 50 years old, came to the clinic August 23, 1907. He did not remember any diseases of childhood; had always been well, had pneumonia at 41, smoked, did not drink, and denied all venereal diseases. One year previous (1906) he began to have sharp pains in the epigastrium, knife-like in character, almost continuous, and aggravated by eating meat, the attack lasting four weeks. Three weeks previous to the time he came to the clinic the symptoms returned, with belching and regurgitation of waterbrash, and vomiting which reduced the pains, the vomitus consisting of acid-tasting substance. He thought he had lost weight and strength. Physical examination: Physique well built, tongue dry, pulse regular and of good quality, heart overactive, second aortic slightly accentuated, lungs negative; abdomen; no pain or tenderness anywhere, stomach percusses 1½ inches above navel; weight, 158½ lbs. A test breakfast was given and removed one hour later; quantity extracted, 420 c.c.; quantity remaining, 56 c.c.; food, well broken up; mucus, normal; total acidity, 76; free HCl, 62. On the 29th his fasting stomach was pumped; quantity extracted, 60 c.c.; mucus, normal; no food remains; total acidity, 60; free HCl, 50. The patient felt well; alkaline treatment was given. He returned October 5, saying that he felt well until two days previous. During these two days he vomited sour material. His fasting stomach was pumped; quantity extracted 100 c.c.; no food remains; total acidity, 94; free HCl, 82. He was given bismuth, one drachm per dose, and came back to the clinic five days later, saying that during the intervening time he had had his stomach washed at the Hudson Street Hospital, and that blood had been obtained. He weighed now 151¾ lbs. He was ordered to rest in bed and apply an ice-bag to abdomen. He returned November 9, felt very good and weighed 155 lbs. The fasting stomach was pumped; quantity extracted, 70 c.c.; acidity, 74; HCl, 54. He continued to visit the clinic occasionally, calling for bismuth. He kept on gaining steadily in weight until, on October 3, 1908, he reached 185 lbs. He felt the same until July, 1909, when the stomach was pumped again; quantity extracted, 150 c.c., consisting of mucus, flakes, and shreds, but no visible food; acidity, 84; HCl, 64. He again had excruciating pains in the epigastrium, day and night, was constipated and weighed 146 lbs. Sigmoidoscopic examination was negative. The stomach when inflated percussed 1½ inches above navel, showing that it was not enlarged. He felt better until Jan. 11, 1910, when his fasting stomach was again pumped; quantity extracted, 200 c.c. of a greenish substance containing flakes and some shreds, but no solid food; acidity, 104; HCl, 80. On January 18 his fasting stomach was again pumped, and some mucus and bismuth taken at 10 o'clock the night previously was obtained. The fasting stomach was washed out and a substance obtained having a strong odor of fermentation, and small particles of meat, rice, and raisins. On January 30 the fasting stomach was washed, and much food and seeds eaten two days previously, farina, and other cereals were obtained. February 3 the fasting stomach was pumped, and meat, rice, raisins, and free blood were obtained. The patient weighed 153 pounds, and felt better again until June 9, when he

returned feeling badly, weak, vomiting, and weighing 136 pounds. The fasting stomach was pumped and a substance obtained consisting of finely broken up meat eaten 48 hours previously, and rice eaten 84 hours previously. He was then sent to the hospital, where he received the Lenhartz treatment. He returned to the clinic saying that he had been in the hospital four weeks under this treatment. He felt weak, had no pain, ate quite well, and vomited occasionally. July 22 he went to the country, started again to vomit everything he ate, and was getting worse and worse. August 11 he felt very badly, vomited great quantities of food and blood, and died.

This man came to the clinic at the very beginning of his illness, at a time when a diagnosis of ulcer alone could have been made. Step by step his condition was aggravated, and with every new attack he came nearer and nearer to the fatal stage. His first test breakfast showed 450 c.c., far above the amount obtained in a normally working stomach of normal size. The fasting stomach contained amounts of 60 to 100 c.c., quantities very large and very highly acid. All this pointed towards an abnormal stagnation of food in the stomach, which was not dilated, a condition very favorable to the man, showing that the obstruction was only recent and slight. January, 1910, his fasting stomach contained 200 c.c, with shreds and acidity, 104-80, a condition which should have pointed sufficiently towards an early diagnosis of pyloric obstruction. January 18 the first actual solid material was obtained from a fasting stomach, bismuth subnitrate, and then remains of meat, rice, raisins, etc. January 30 the fasting stomach gave up seeds and cereals eaten two days previously. February 3 the same condition obtained. On another occasion food eaten eighty-four hours previously was obtained, but the fact that a diagnosis of simple retardation had been previously made, the fact that the patient kept on getting better and worse, and that he kept on losing and regaining weight alternately compelled us to send him to the medical side of the hospital, where, it seems, the three years of study and treatment of the patient in the clinic were not taken into consideration. He was given the Lenhartz treatment, though he himself asked for an operation, having been told at the clinic that in the hospital he would probably be operated upon, as it had been considered that the case had gone too far for the palliative treatment. Of course the patient became very much worse under this treatment, and when he left the hospital he felt much worse than he was willing to admit to his friends.

There is no doubt in my mind that if a laparotomy had been performed at this early stage the man would have been alive to-day, as exemplified by the case operated on by Dr. G. E. Brewer in August, 1908, a case far worse and one much further advanced, which is doing well to-day.

This case indicates to the author's mind three points of greatest value: (1) The conservative procedure in serious gastric conditions that do not improve after a reasonable trial of medical treatment is to operate. (2) In all cases of retention of foodstuffs accompanied by serious symptoms the specter of pyloric obstruction asserts itself too strongly to permit fanciful diagnosis. (3) If hospitals were informed of what had already been done for the patients in dispensaries, much valuable time would be saved and many lives spared.

1789 Fulton Avenue.

A SIMPLE CLINICAL METHOD FOR MEASURING THE DIAMETER OF THE PUPIL.

By TOM A. WILLIAMS, M.B., C.M. (EDIN.),
WASHINGTON, D. C.
CORRESPONDING MEMBER PARIS NEUROLOGICAL SOCIETY, ETC.

The method utilizes that generally used, which was first employed by A. Fick.[1] It depends upon the principle that a small aperture in a card placed a short distance from the eye appears as a circle, the diameter of which equals that of the pupil. If two holes are used it is evident that if the circumferences of the two circles appear exactly to touch the distance between the apparent centers will equal the diameter of either, as it consists of half the diameter of each. That is to say, it will equal the diameter of the pupil. Now, it is found experimentally that when the two holes are separated by a distance equal to the diameter of the pupil then the apparent images just touch. So that it is very easy to measure the pupil by placing before the eye a series of holes at varying distances from one another.

Accordingly a scale is constructed consisting of perforations in a card placed apart respectively one, two, three, four, five, six, seven, and eight millimeters. The diameter of the patient's pupil is then easily ascertained by the distance between the two holes of which the apparent images most nearly touch when he looks through them at a distant object.

Showing the distance in millimeters of the perforations in the test card. The pupil is normally not larger than the distance between the dots in the space marked 4. Inequality between the two pupils may be ascertained by making two holes at a distance exactly corresponding to the diameter of one pupil and then ascertaining whether the circles exactly touch when the holes are placed before the other pupil.

But this well-known method gives only the temporary pupil diameter, which is very variable in different persons. For purposes of absolute comparison, it is necessary to combine it with a standard state of pupillary adaptation. Now, it is known that although it requires two hours in the dark for maximal dilatation to occur, yet a convenient, practical, very extensive adaptation to dark occurs at the end of two minutes and is almost maximal in twenty. Upon reexposure to light the pupil contracts in proportion to the logarithm of intensity of the light to which it is exposed.

But Schirmer[2] has found that there is practically no variation in the amount of contraction within the very wide range of one hundred and eleven hundred millimeter-candles, and that in normal individuals the pupil measures between three and four millimeters after maximal adaptation to dark. Charpentier[3] found increased sensitiveness even greater than did Aubert after pupillary adaptation to darkness; but the clinical importance of the facts does not warrant their discussion in this place.

Hence if the patient to be examined is placed in the dark room for two minutes, and then placed so that his eye is exposed to a light between one hundred and eleven hundred candle-power, a standard stimulus is attained uniform enough for the practical purposes of the clinic, and accurate enough for statistical comparison.

New York, December 24, 1910.

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE report of the Surgeon-General of the Navy has just been issued. A satisfactory feature of the report is that the health of the navy, as a whole, shows decided improvement. The death rate of 5 per thousand is lower than has ever been previously recorded. The total damage for disease alone in percentage of sick was 3,952, which when compared with Medical Inspector Gatewood's ten-year tables is found to be lower than for any year since the Spanish-American War. The grand total damage in percentage of sick for 1909 was 4.619 as compared with 5.218, the average computed in the above-mentioned ten-year tables. There has been a shortage of officers for the medical corps, due, it is said, to the failure of Congress to enact any one of the four measures which provided for equalizing the compensation of acting assistant and assistant surgeons and which has made it imperative for the bureau to recommend the direct appointment of assistant surgeons from civil life and the elimination of the prescribed probationary period, which was authorized by the department on August 19 last. The lack of officers has pressed somewhat heavily on those in service and little leave of absence has been granted.

Conditions in the Hospital Corps as regards numbers and effectiveness are practically the same as reported last year, but the recruiting of women nurses has been very slow on account of the efforts to obtain only those best qualified. Emphasis is laid in the report on the need of legislation providing for the appointment of dental surgeons for the navy. Attention is also called to the benefits which would ensue from the formation of a medical reserve corps for the navy. Possibly, the most important part of the report is that in which General Stokes recommends alterations in the methods of physical training of the personnel of the navy. The manner in which such physical training is now carried out is stigmatized as being too much of the *laissez aller* character, consisting of walking or riding a prescribed number of miles within a time limit, and the report states that after the first year of the physical test the consensus of opinion of medical officers seems to be that it has utterly failed to accomplish the design to encourage regular daily exercise; very few have observed any real benefits, considerable tangible harm has resulted, and many officers justly question the expediency of placing what amounts to a severe strain upon the heart when adequate preparation is not made mandatory. The recommendation is put forward that more recreative and continuous exercises be substituted, while for the younger personnel the adoption is urged of the Swedish system of physical training as followed in the British service.

It is contended that taking into consideration the English, German, and American military statistics and experiences pointing to the protective properties of typhoid vaccination it should be adopted on such navy stations as are shown by annual experience to suffer from the disease habitually. As in the army so in the navy, venereal diseases cause an immense amount of sickness and disability. According to the report a fairly consistent estimate might now be ventured that the true incidence of primary venereal infections in the navy is not far from 200 per 1,000. The Asiatic stations showed an increase of 60 per cent. admission rate for 1909 over 1908. The first quarter of 1910 has exhibited an appreciable reduction of the admission rate for venereal diseases, so that it may be hoped that the turning point has come. The admission rate for pulmonary tuberculosis has continued to fall and the rate for all forms declined in the navy from 6.26 for 1908 to 5.60 per thousand last year. The admission rate for malarial affections declined from 29.8 for 1908 to 18.85 for 1909. It is also very encouraging to note that the admission rate for alcoholism has been lower for the past three years than for many years. Among the conclusions reached by General Stokes and which have not been referred to above are that medical officers of extensive practical experience should be assigned to duty under the "Aid for Inspections," one for hospitals and shore stations and one for the service afloat, that adequate sanitary facilities for the personnel of ships in dry docks should be provided, and that Congress should be urged to appropriate a sufficient sum for the building of two suitable hospital ships.

The report of the navy for the past year is satisfactory and affords evidence that not only is more careful attention being paid to the health of the sailor, but that in many respects, for instance, with regard to drinking, the sailor himself leads a more healthful life.

DORSAL PERCUSSION OF THE THORAX AND OF THE STOMACH.

IN the century and a half that have elapsed since Auenbrugger first showed the diagnostic value of percussion, its field of usefulness has gradually widened until to-day its applications are of the utmost complexity and precision. Among the other pioneers in this fertile domain were men whose names stand out in the history of internal medicine—Corvisart, the translator and commentator of Auenbrugger's work; Laennec, who with his method of mediate auscultation increased the clinical value of percussion; and finally Piorry, who

invented the method of mediate percussion and of pleximetric percussion, and who by means of these originated the new method of organic plexigraphy or organography. In spite of the valuable results of which the use of the pleximeter gave early promise, this instrument was for a long time all but abandoned, together with the practice of dorsal plexigraphic percussion.

The extensive clinical sphere of dorsal percussion has for many years been the subject of untiring investigation by Willam Ewart, who has already contributed amply the results of his work on the organic plexigraphy of the thorax. In his latest communication in the Proceedings of the Royal Society of Medicine, July, 1910, he has revised the delineation of the dorsal topography of the thorax, has contributed a new method of post-gastric percussion and has described a new clinical sign termed "the dorsal gastric nucleus of resonance." Among his practical conclusions it is noted that organ-plexigraphy, long restricted to the precordium and epigastrium, still calls for greater accuracy and completeness than have yet been given to it in these regions, and should no longer be restricted to them, but should be used in any situation, and whenever it may serve a useful purpose. Dorsal plexigraphy, although too long neglected by clinicians in spite of Piorry's writings and of more recent work, affords the larger field for normal organography, particularly in the abdomen, as from the front, apart from the lungs, percussion is still taught to be limited to an incomplete delineation of four organs only—the heart, the liver, the stomach, and the spleen. The list of its normal findings in the back includes the heart and its left auricle, the liver, the spleen, an indication of the mediastinal structures, the kidneys, the pancreas, and an indication of other mesenteric structures, besides the pelvic district. Moreover, it possesses a separate field and a method both exclusively its own in vertebral or spinous-process percussion. The total range of the dorsal examination exceeds anything to be obtained from the front, including the entire contents of the trunk.

For clinical diagnosis more pathology is revealed by percussion in the back than in front, and a large field for surgical diagnosis is opened up by this procedure. Spinal percussion is not limited to mere scoliosis and kyphosis, but includes the earlier diagnosis of vertebral and intervertebral disease, of rheumatoid ankylosis and deformity as distinct from merely functional rigidity, and of spinal neoplasms. New fields for diagnosis by the surgeon and by the physician alike are opened up by dorsal percussion in three most important regions inaccessible from the front, namely, the posterior mediastinum, with its glandular, inflammatory, aneurysmal, tracheal, esophageal, and other affections; the mesenteric region, no less vital and no less remote in connection with the varied affections of the central abdominal organs, and the iliac region, which is of special importance in these days of pandemic appendicitis. The value of Grocco's triangular dullness for the diagnosis of empyema *versus* serous effusion, of supradiaphragmatic *versus* infradiaphragmatic fluid collections, is still imperfectly understood, but is of growing practical importance.

In the field of stomach diagnosis a fresh departure is contained in the demonstration that normally the stomach is distantly accessible to examination in the back. Ewart describes a hitherto unrecognized "dorsal gastric nucleus of resonance," a circular area from two to two and a half inches in diameter, situated immediately below the inferior angle of the left scapula. Over this area the percussion note is one of increased resonance and of tympanitic quality, the result of the deep-seated resonance of the stomach, the constancy of position and the circular shape being determined by sound-refraction, the liver acting as a lens for the resonant waves. The clinical value of this sign is concerned chiefly with the diagnosis of the various forms of dilatation of the stomach. The loss of a perfectly circular outline is the first step towards the disappearance of the gastric nucleus, which may be the starting point of progressive encroachments outward of an enlarging area of dorsal gastric resonance. This occurs in the dorsal or backward type of upward dilatation of the stomach, first definitely described by Ewart, who conceives this as the cause of one of the most severe and dangerous forms of heart distress of mechanical gastric origin.

Open-Air Schools.

The experience of European countries has shown the value of open-air schools in the treatment of early tuberculosis, or the pretuberculous state, a fact which is also beginning to be well recognized in America. A very interesting account of the school at Vernay, which is maintained by the city of Lyons, is given by Paul Vigne in *Annales de Médecine et de Chirurgie Infantiles* for July 1 and 15, 1910. It was in 1906 that Grancher pointed out that to cure tuberculosis in children the malady must be diagnosed in its earliest stage and that it is not sufficient to rely on the addition to the general work of the ordinary school of merely an additional meal, but that a more serious and prolonged effort must be made by the municipality because the poverty of the parents makes it impossible for them to procure sufficiently nourishing food for their children. He advocated taking these children from their parents and placing them in the best possible hygienic surroundings, while allowing them to continue their studies. He said that the amount of fresh air and of nourishing food must be doubled and the number of school hours halved. In pursuance of this idea the city of Lyons established a school on the lines suggested by Grancher. It is in a large, well appointed building situated in the midst of a park. It has a hall for play, to be used in bad weather, paved with tiles so that it can be washed and disinfected. There are a spacious dining room, large dormitories, which can be entirely opened to the air at night, a medical director, and all necessary appliances for treatment. It has been open for three seasons and has accommodated about two hundred boys in all. It is open from May to the end of September. The children stay for about two months at a time. In general they are children of tuberculous parents, and in

43 per cent. there were decided signs that the tuberculous process had begun. The day consists of thirteen hours, of which only two and a half are spent in the out-of-door school. Two hours are spent in gardening and several more in recreation. There are five plentiful meals of the best quality and milk warm from the cows owned by the school. All the children show a gain in weight and in many cases physical signs in the lungs recede or disappear. The benefits have been found to justify the expense. The open-air schools in Germany and England for the most part are only day schools, the pupils going home each night. The children received are in the pretuberculous stage only. These day schools are of the greatest benefit to pretuberculous children by way of prophylaxis, but if really tuberculous patients, those with the fully developed disease, were taken it would be necessary to resort to the Vernay system in order to get a permanent cure.

Decline of Vaccination in London.

Statistics relating to hospitals and vaccination in London and to other kindred matters have been published recently. According to the London *Times* of October 15 figures respecting London hospitals show that the total expenditure of these institutions during the year 1908 amounted to rather over $5,000,000; that their total incomes were in excess of this expenditure by nearly $500,000; that they received 118,867 in-patients and had a daily average of 8,759 in residence and that they treated more than one million and a half out-patients. The hospitals of the Metropolitan Asylums Board received 35,967 patients during the year, all of them, of course, suffering from some form of infectious disease. The vaccination statistics of London are most discouraging and afford ample evidence that in the metropolis of Great Britain vaccination is steadily falling into disrepute. The vaccination figures for London are not available for the year 1908, but are given for 1906 and 1907. From a study of these it is obvious that the materials for a severe epidemic of smallpox are being accumulated. Out of 126,475 children born in 1906 only 68.1 per cent. and out of 122,831 children born in 1907 only 65.9 per cent. are known to have been successfully vaccinated; while the "conscientious objections" which amounted to 1.5 per cent. of the births in the former year rose to 3.1 per cent. in the latter. "Moreover," remarks the writer in the *Times*, "these do not nearly account for all the children born, and there must be a large unvaccinated residue, and it is needless to state that such a residue among careless parents is a constant source of danger to the rest of the population. It might be useful to obtain the figures regarding vaccination in New York and compare them with those of London. Now that by universal vaccination in civilized countries smallpox has been robbed of all its terrors disbelief in its efficacy has developed among the unthinking. However, the proofs of the value of vaccination are so abundant even at the present time that an intelligent perusal of the history of what has been accomplished in this line in Porto Rico and the Philippines should convince the most skeptical. Unfortunately, the anti-vaccinationist is not endowed by nature with the ability to study any medical records of vaccination intelligently.

News of the Week.

To Investigate Typhoid Fever at Annapolis.—A board of inspection, consisting of Medical Inspector John M. Edgar, Surgeon Edward G. Parker, Surgeon Charles St. J. Butler, and Passed Assistant Surgeon Owen J. Mink, was appointed by the Secretary of the Navy on December 12 to investigate the epidemic of typhoid fever which occurred recently at the Naval Academy at Annapolis. The department is said to be concerned over the cause of the disease more than over its prevalence at present, as it is believed that no new cases are likely to develop.

Civil Service Examination.—The New York State Civil Service Commission announces examinations, to be held on January 28, 1911, for the purpose of filling vacancies in the positions of Medical Superintendent, Erie County Home and Hospital, at a salary of $2,000, and laboratory assistant in the State Cancer Laboratory, Buffalo, at a salary of $720 to $1,000. The first examination is open only to men who are residents of Erie County. Details, circulars, and application blank may be obtained from the State Civil Service Commission, Albany, N. Y.

Aged Negro Woman.—Dinah Hicks, a negro woman born in slavery, died at her home in New Rochelle, N. Y., on December 12, at the reputed age of 110 years.

Charitable Bequests.—A number of Brooklyn, N. Y., institutions received bequests under the will of the late Mr. George L. Fox of that city, who died on December 5. Among them are the Jewish Hospital, $25,000; Industrial Home for the Blind, $15,000; Brooklyn Home for Consumptives, $10,000; St. Catherine's Hospital, $25,000; the Brooklyn Hospital, $20,000; the Eastern District Hospital, $100,000; St. Mary's Hospital, $25,000; the German Hospital, $25,000; Brooklyn Eastern Hospital Dispensary, 5,000. In addition to these the New York Ophthalmic and Aural Institute receives $10,000, and St. John's Hospital, Long Island City, $20,000.

The will of Morris J. Bluen of New York bequeaths $2,000 each to the National Jewish Hospital for Consumptives at Denver, the Montefiore Home, and the Hospital for Deformities and Joint Diseases, New York.

Tuberculosis Hospitals.—The Boards of Supervisors in the various counties in New York are rapidly establishing hospitals for sufferers from tuberculosis. Fourteen counties already have fairly adequate provision. Ontario County will open its institution for phthisis patients in a few days, while Ulster, Monroe, and Schenectady counties are caring for such patients in temporary hospitals until permanent buildings are completed. Dutchess County cooperates with the city of Poughkeepsie, Albany County sends its patients to the City Hospital Pavilion, and Chemung to the Elmira Hospital. Three counties in addition recently voted to establish hospitals, and in twenty the matter is under consideration.

Hospital for the Bronx.—The Tremont section of the Bronx, New York, is soon to have a new hospital of from 50 to 100 beds. A certificate of incorporation was recently issued to the organizers, a number of New York physicians, who form the Board of Directors. Among them are Drs. Abraham Jacobi, Willy Meyer, Samuel W. Lambert,

H. H. M. Lyle, Wolff Freudenthal, and George W. Jacoby.

American Hospital in India.—Cable dispatches announce the dedication on December 8 of the Ellen Thoburn Cowen Memorial Hospital at Kolar, South India. The hospital, which has been erected and equipped at a cost of about $12,000 by the Woman's Foreign Missionary Society of the Methodist Episcopal Church, is in charge of Dr. Margaret D. Lewis of Chicago.

Damages for Autopsy.—An unusual case, said to be the first of its kind in New York State, was heard before the Supreme Court of Queens County, New York, on December 12, the defendants, two physicians, who are accused of having performed an unauthorized autopsy on the body of a woman who died at St. Joseph's Hospital, Far Rockaway, last February, and of having removed portions of the body after the autopsy. The action was brought by the children of the dead woman, and the jury returned a verdict awarding them damages in the amount of $8,000.

Dr. Edwin B. Cragin has resigned from the position of Consulting Obstetrician to the Sydenham Hospital of this city.

Dr. Louis Plumer Posey has been appointed by Governor Stuart to membership in the Pennsylvania State Board of Medical Examiners in succession to Dr. C. S. Middleton, resigned.

A Memorial Hospital.—Preparations are being made by the residents of Lakewood, N. J., for the erection of a hospital as a memorial to the late Dr. Paul T. Kimball, who died there last month.

Barnard Skin and Cancer Hospital.—The Board of Directors of the Barnard Free Skin and Cancer Hospital (St. Louis Skin and Cancer Hospital, announces the completion of the new hospital building, which was opened for inspection, prior to its occupancy, on December 20.

Cholera in Italy.—That the cholera situation in Italy has not yet been fully controlled is shown by the report from Rome on December 12 of six new cases and three deaths, and again on December 16 of five new cases.

The Gaynor Fund.—The money received in response to the appeal for a Thanksgiving Fund to be presented to St. Mary's Hospital, Hoboken, amounting to $15,184.73, was given to the sisters in charge on December 18. A part of this will be used for the endowment of a bed to be known as the "Gaynor Bed."

Measles in Newburgh.—Two hundred cases of measles in the city are reported by the Health Officer of Newburgh, N. Y. The teachers of both public and private schools have been asked to have all classrooms thoroughly cleaned and fumigated so as to eradicate all possible sources of contagion. The cases are said to be of a particularly mild character.

The American Dermatological Association will hold a brief winter session at the invitation of its New York members on Thursday afternoon, December 29, at the Academy of Medicine in this city. The meeting will be devoted entirely to the exhibition of rare and interesting cases. Before the meeting the New York members will entertain the visiting members at a luncheon at the Yale Club. In the evening many of the visitors will attend and take part in a symposium on leprosy at a stated meeting of the Academy, arranged under the auspices of the Section on Dermatology. The local committee is Dr. S. Pollitzer, Chairman; Dr. John A. Fordyce, and Dr. Howard Fox.

The National Confederation of State Medical Examining and Licensing Boards will hold its twenty-first annual meeting in Chicago, Ill., on Tuesday, February 28, 1911, at the Congress Hotel. The subjects to be taken up at this meeting will be a consideration of the State Control of Medical Colleges; a report by a special committee on Clinical Instruction; a report on a proposed Materia Medica List by a special committee; the report on a paper presented at the St. Louis meeting by Mr. Abraham Flexner of the Carnegie Foundation for the Advancement of Teaching, and some special papers on such subjects as the Regulation of Medical Colleges, Necessity for Establishing a Rational Curriculum for the Medical Degree, and others, by men eminently qualified to prepare papers upon such subjects. The symposium will be composed of ten papers presented from the viewpoints of the State, the law, medical colleges, State medical examining and licensing boards, and the medical profession. The chief object of the symposium is to determine, as far as possible, the feasibility of placing medical colleges under State control. An invitation to this meeting is extended to all members of State Medical Examining and Licensing Boards, teachers in medical schools, colleges, and universities, and all others interested in securing the best results in medical education. The officers of the confederation are: *President*, Dr. J. C. Guernsey, Philadelphia, Pa.; *Secretary-Treasurer*, Dr. George H. Matson, State House, Columbus, Ohio.

Bibb County (Ala.) Medical Society.—At the annual meeting held at Centerville on December 9 the following officers were elected: *President*, Dr. W. B. Buntin; *Vice-President*, Dr. W. J. Nicholson; *Secretary and Treasurer*, Dr. M. B. Williams; *Censor*, Dr. W. M. Peters; *County Health Officer*, Dr. L. E. Peacock; *County Physician*, Dr. S. C. Meigs.

Jefferson County (Ala.) Medical Society.—The annual meeting was held in Birmingham on December 5. Officers were elected as follows: *President*, Dr. James McLester; *Vice-President*, Dr. Mann of Ensley; *Secretary and Treasurer*, Dr. C. E. Dowman; *County Health Officer*, Dr. H. N. Rosser; *County Physician*, Dr. R. H. Hamrick; *Assistant County Physician*, Dr. George Stubbins; *Censar for five years*, Dr. Frank Lupton, reelected.

Morgan County (Ala.) Medical Society.—Election of officers at the annual meeting on December 2 resulted as follows: *President*, Dr. F. B. Hunter, Falkville; *Vice-President*, Dr. M. W. Murray, New Decatur; *Secretary*, Dr. J. L. Gunter; *Censar*, Dr. T. J. Russell, Woodland Mills.

Monterey County (Cal.) Medical Society.—Officers were elected at the annual meeting on December 3, as follows: *President*, Dr. T. C. Edwards; *Vice-President*, Dr. A. M. Ritchie; *Secretary*, Dr. H. T. Crabtree; *Treasurer*, Dr. John Parker.

Bibb County (Ga.) Medical Society.—The following officers were elected at the annual meeting in Macon on December 7: *President*, Dr. G. T. Miller; *Vice-President*, Dr. A. P. Kemp; *Secretary and Treasurer*, Dr. Carl Anderson; *Censors*, Dr. J. W. Duquid and Dr. G. P. Gostin.

Clarke County (Ga.) Medical Society.—At the annual meeting on December 4 the following officers were elected for the ensuing year: *President*,

Dr. D. H. DuPree; *Vice-President,* Dr. S. S. Smith; *Secretary and Treasurer,* Dr. John Gerdine; *Censor for three-year term,* Dr. M. M. Mathews; *Censor for the one-year term,* Dr. A. C. Holliday; *Delegate to the Georgia Medical Association,* which will meet in Rome next year, Dr. H. M. Fullilove; *Alternate,* Dr. J. C. McKinney.

Madison County (Ill.) Medical Society.—Officers were elected at the annual meeting on December 2, as follows: *President,* Dr. W. H. C. Smith, Godfrey; *Vice-President,* Dr. E. C. Ferguson, Edwardsville; *Secretary and Treasurer,* Dr. E. W. Fiegenbaum; *Delegate to Illinois Medical Society,* Dr. J. M. Pfeiffenberger.

Johnson County (Ia.) Medical Society.—At the annual meeting at Iowa City on December 7 the following officers were elected: *President,* Dr. F. L. Love; *Vice-President,* Dr. Jessie Hudson; *Secretary and Treasurer,* Dr. J. J. Lambert.

Shawnee County (Kan.) Medical Society.—The following officers were elected at the annual meeting on December 4 in Topeka: *President,* Dr. M. C. Porter; *Vice-President,* Dr. S. A. Johnson; *Secretary,* Dr. H. M. Connor; *Treasurer,* Dr. J. N. Beasley.

Shreveport (La.) Medical Society.—At the annual meeting on December 6 the following officers were elected: *President,* Dr. Milton F. Smith; *Vice-President,* Dr. J. E. Knighton; *Treasurer,* Dr. J. A. Hendricks; *Secretary,* Dr. A. A. Herold.

Minnesota Valley Medical Society.—The following officers were elected at the annual meeting held on December 6 at Mankato: *President,* Dr. L. A. Fritchie, New Ulm; *Vice-Presidents,* Dr. H. B. Aitken, Le Sueur Center, and Dr. J. J. O'Hara, Janesville; *Secretary,* Dr. A. G. Liedloff, Mankato; *Treasurer,* Dr. G. F. Merritt, St. Peter.

Jackson County (Mo.) Medical Society.—At the annual meeting held in Kansas City on December 6 officers were elected as follows: *President,* Dr. J. D. Griffith; *Vice-President,* Dr. J. Q. Chambers; *Secretary,* Dr. E. L. Stewart; *Treasurer,* Dr. W. F. Kuhn.

Platte County (Mo.) Medical Society.—At the annual meeting held on December 7 at Platte City, the following officers were elected: *President,* Dr. E. R. Hull, Camden Point; *Vice-President,* Dr. J. W. Shultz, Weston; *Secretary,* Dr. A. S. J. Smith, Dearborn; *Treasurer,* Dr. Frank Shafer, Edgerton; *Delegate to State Convention,* Dr. J. J. Carter, Weston.

St. Joseph-Buchanan County (Mo.) Medical Society.—At a meeting held in St. Joseph on December 7 officers for the ensuing year were elected as follows: *President,* Dr. S. F. Kessler; *Vice-Presidents,* Dr. J. I. Byrne and Dr. J. F. Owens; *Treasurer,* Dr. J. M. Bell; *Secretary,* Dr. Herbert Lee; *Delegate to State Convention,* Dr. C. O. Jeffries.

St. Louis (Mo.) Medical Society.—Officers were elected at the meeting on November 25, as follows: *President,* Dr. Robert E. Schleuter; *Secretary,* Dr. Fred C. E. Kuhlmann.

Lancaster County (Neb.) Medical Society.—At the annual meeting at Lincoln on December 3 the following officers were elected: *President,* Dr. J. M. Mayhew; *Vice-President,* Dr. W. M. Cowgill; *Secretary,* Dr. R. R. Adams.

The Seaboard Medical Association of Virginia and North Carolina held its annual convention in Kinston, N. C., on December 7 and 8, officers being elected for the ensuing year as follows: *President,* Dr. Clarence Porter, Newport News, Va.; *Vice-Presidents,* Dr. N. M. Gibbs, New Bern, N. C.; Dr. J. H. Hiden, Pungoteaque, Va.; Dr. H. M. Carson, Edenton, N. C., and Dr. James H. Culpepper, Norfolk, Va.; *Secretary,* Dr. J. R. Parker, Goldsboro, N. C. The next annual meeting of the society will be held at Newport News, Va.

The Late Dr. Brothers.—At a meeting of the New York Obstetrical Society, held December 13, the following resolutions were adopted:

WHEREAS, The New York Obstetrical Society has learned with deep sorrow of the untimely death of our esteemed Fellow, Dr. Abraham Brothers, and, *Whereas,* For many years he has been an earnest and able worker in this Society, giving freely of his best efforts to its scientific interests throughout his fellowship, and, *Whereas,* It is greatly to be regretted that his life work should have been cut off in the fullness of his manhood and at the height of his powers, it is therefore

Resolved, That the New York Obstetrical Society recognizes with profound regret and sorrow the loss of a greatly esteemed fellow, and that the Society begs to extend its sincere sympathy to the sorrowing family in their affliction, and be it further *Resolved,* That these resolutions shall be spread upon the minutes of the Society, and that copies of the same shall be transmitted to his widow and the medical press as a token of our respect and as a reverence to his memory.

Signed: GEORGE GRAY WARD, JR., Chairman; HERMAN J. BOLDT, JAMES N. WEST, *Committee.*

Obituary Notes.—Dr. CARL H. KROEBER of Yonkers, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1896, visiting physician to St. Joseph's Hospital, Yonkers, and a member of the Jenkins Medical Association, died at the Loomis Sanatorium in Liberty, on December 12, aged 41 years.

Dr. CLARENCE W. ERWIN of Erwinton, S. C., a member of the Medical College of the State of South Carolina, Charleston, in 1880, died at his home on November 24, after a long illness, aged 53 years.

Dr. O. A. HARRISON of Meridian, Miss., a graduate of the University of Louisville, Medical Department, in 1882, a member of the Mississippi State and Lauderdale County Medical Societies, died at his home, on December 3, aged 65 years.

Dr. MONTREVILLE MCHENRY of Benton, Pa., a graduate of the University of Vermont College of Medicine in 1878, died of paralysis following injuries received in an accident several weeks before, on December 3, aged 74 years.

Dr. JOHN S. SHRAWDER of Collegeville, Pa., a graduate of the Jefferson Medical College in 1865, died at his home, on December 7, aged 71 years.

Dr. JERE M. MAIN of Laredo, Tex., a graduate of the Medical Department of New York University in 1859, died at his home, on December 9, of senile debility, aged 94 years. Dr. Main was attached to the flagship *Constitution* at the time when Commodore Perry, commanding the American fleet, first visited Japan.

Dr. JULIEN E. HEQUEMBOURG of Chicago, Ill., a graduate of the Rush Medical College, Chicago, in 1882, attending gynecologist to St. Joseph's Hospital, Chicago, and a member of the American Medical Association, the Illinois State and Cook County Medical societies, the Medico-Legal Society of Chi-

cago, the Chicago Society of Internal Medicine, and the Physicians' Club of Chicago, died at St. Joseph's Hospital of an attack of heart disease immediately after performing an operation, on December 10, aged 54 years.

Dr. Richard L. Cook of Sturgeon Bay, Wis., a graduate of the Medical School of Maine, Portland, in 1860, and a veteran of the Civil War, died suddenly of heart disease on December 2, aged 77 years.

Dr. Walter J. Wait of St. Louis, Mo., a graduate of the Medical Department of Washington University in 1880, died at his home on December 6, aged 70 years.

Dr. Martin J. Thompson of Meridian, Miss., a graduate of the Medical College of Alabama, Mobile, in 1873, and of the Medical Department of the Tulane University of Louisiana in 1889, formerly vice-president of the Mississippi Medical Association and president of the Lauderdale County Medical Association, died at his home on December 5, aged 65 years.

Dr. James F. Dick of Dongola, Ill., a graduate of the Medical Department of the University of Tennessee, Nashville, in 1878, died at his home on December 2, aged 63 years.

Correspondence.

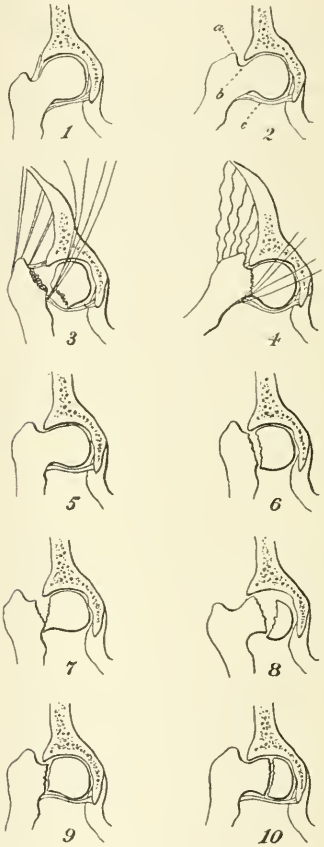
THE ABDUCTION TREATMENT FOR FRACTURE OF THE NECK OF THE FEMUR,

AND ITS INTERPRETATION, IN A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS.

To the Editor of the Medical Record:

Sir:—In the Medical Record of March 19, 1904, the Abduction Method, which had been tested for a number of years, was formally presented as a routine treatment for Fracture of the Neck of the Femur. The method is a mechanical adaptation to the anatomy of the joint that enables one to correct deformity and to fix the fragments securely; viz., the normal inclination of the neck of the femur (130 degrees) (Fig. 1) permits a range of abduction at the hip of from 40 to 60 degrees, a movement that is definitely checked by contact of the upper border of the neck with the projecting rim of the acetabulum. During the movement of abduction the head of the femur glides downward until its lower third emerges from the acetabulum and distends the lower part of the capsule. At the limit of normal abduction under anesthesia the base of the neck is in contact with the rim of the acetabulum, the tissues covering the trochanter are apposed to the tissues covering the pelvis and the capsule is tense (Fig. 2).

In complete fracture of the neck of the femur the limb is usually shortened, somewhat flexed, rotated outward and often slightly adducted. Thus the outer fragment is turned forward, displaced upward and usually lies on a lower plane than the head (Fig. 3). As one has no control over the inner fragment, contact can be assured only by adjusting the outer fragment to it. This is accomplished as follows: The patient having been anesthetized is lifted to a sacral support, the shoulders resting on a box of equal height, while the extended limbs are supported by two assistants. The assistant holding the uninjured limb then abducts it to the anatomical limit, to illustrate the normal range, which varies in different individuals, and incidentally to fix the pelvis by direct bony contact. The operator first flexes the thigh to disengage the fragments. The assistant then extends the limb and by manual traction overcomes the shortening, as demonstrated by the relation of the trochanter to Nélaton's line, and by measurement. He then under traction abducts it to the normal limit, the operator meanwhile lifting the thigh from beneath. Inspection should now show absolute correspondence between the extended limbs, as to abduction, rotation, length, and position of the trochanters. In this attitude the injured part is securely fixed by a plaster spica extending from the nipples to the toes.



Diagrams to Illustrate the Text.—1. The normal hip joint. 2. The anatomical checks to abduction: *a*. Impact of the trochanter with the ileum; *b*. Contact of the upper border of the neck and the rim of the acetabulum; *c*. Tension of the capsule. 3. The deformity of complete fracture, showing the influence of the muscles. 4. Reposition by traction and abduction, showing the relaxation and change in direction of the muscles and the security of the position. 5. Coxa vara deformity, showing the direct limitation of abduction by the deformity. 6, 7 and 8. (Epiphyseal fracture.) Varieties of fracture usually classed as impacted. 9 and 10. Correction of deformity by the abduction method.

The advantages of the abduction treatment should be obvious if one understands the mechanism of the joint. (1) In abduction the outer fragment is turned downward and inward toward the inner fragment; (2) in full abduction, under traction, the capsule is made tense, and being attached about each fragment this tension should align them; (3) at the limit of abduction the trochanter is brought into contact with the tissues covering the pelvis, or if the fracture is near the head, the

outer fragment is engaged beneath the rim of the acetabulum, thus providing a direct check against displacement; (4) in full abduction the direction of the muscles is so changed that their contraction can no longer displace the fragments; (5) finally, the attitude of abduction, which is directly opposed to that indicative of deformity and symptomatic of weakness, is the attitude most favorable to restoration of function when the support is removed (Fig. 4).

The Abduction Method of Correcting the Deformity of Impacted Fracture.—The essential deformity of incomplete fracture is a depression of the femoral neck (coxa vara) (Fig. 5), and unless this is corrected disability is inevitable. In most instances the fracture is complete with but slight displacement, and in such cases it may be corrected by the manipulation already described. If, however, it is incomplete, a form most often seen in early life (Fig. 7), it may be easily and safely corrected by the aid of slight leverage, as follows: As normal abduction depends upon the upward inclination of the neck, it must be limited in direct proportion to the lessened or lost angle. Thus, the range of abduction under anesthesia is checked by contact of the neck with the upper border of the acetabulum, a contact that fixes it. Now under steady traction, aided by downward pressure on the projecting trochanter, the limb is still further abducted with the aim of overcoming or lessening the deformity. In other words, the deformed neck lies in a plane representing normal abduction while the shaft is in the median line. The shaft is therefore abducted until the normal relation is restored, at least to the degree that is practicable. When this is accomplished, the outward rotation having been reduced, a plaster spica is immediately applied. This method, in which the only movements permitted are those required to reduce deformity, and in which secure fixation is assured, has no relation whatever to the "breaking up of an impaction," so deplored by the authorities. The deformity in either variety of fracture having been corrected and the limb securely fixed, the first step, in a treatment which to assure functional cure should extend throughout a year, is accomplished.

In the fifth edition of "A Practical Treatise on Fractures and Dislocations," by Dr. L. A. Stimson, the following appears: "Whitman's proposal to abduct the limb under anesthesia until the trochanter rests against the ileum and then to force the abduction, using the trochanter as a fulcrum, so as to restore the normal angle, does not commend itself to me." From the sixth edition of the same treatise I quote further: "The generalization of this hasty, forcible correction by wide abduction has of late been urged, it seems to me, with more zeal than attention to the anatomy of the region and the pathology of the injury. No abduction which is wider than a normal neck will permit can recreate a normal neck. The alleged use of contact between the top of the trochanter and the ileum as a fulcrum for such abduction is fanciful, no dissected hip that I have examined would permit the trochanter to be brought within an inch of such contact while the head remained in its socket."

Comment on the main issue is unnecessary. There are, however, two minor points to which I would call attention. Dr. Stimson states that no dissected hip that he had examined would permit the trochanter to be brought within an inch of such contact. The context is obscure. If the dissected hips were specimens of Coxa Vara the abnormal interval was the inevitable consequence of the deformity and the limitation of abduction consequent upon it (Fig. 5). Furthermore, the trochanter is never used as a fulcrum under this or any other condition. It is this persistent misapprehension that I am attempting to correct. If he refers to the relation of the trochanter to the pelvis in full abduction under normal conditions I shall, in reply, quote from the investigations of Dr. A. S. Taylor on eight cadavers at the College of Physicians and Surgeons with reference to the abduction treatment. (*American Journal of the Medical Sciences*, May, 1905.) "Abduction was limited by (*a*) The inferior ligaments and capsule; (*b*) impact of the posterior part of the trochanter upon the soft tissues just above the acetabulum. Both of these obstructions seem to occur simultaneously. . . . Tension of the inferior capsule and its ligaments during abduction tended to cause spontaneous alignment of the fragments. The influence was more marked as the line of division approached the great trochanter."

I quote further from Dr. Stimson: "The maintenance of abduction which forms a part of the same proposed practice (abduction treatment) is also an imaginary difference, for continuous traction assures and always has assured abduction of the joint by tilting of the pelvis even when the limb is in line with the body."

The purpose of traction, as applied in the treatment of a fracture, is to draw the displaced fragment down to the level of its fellow and to maintain it there by preventing muscular contraction. If traction distorts the pelvis both fragments are drawn down, and in proportion to this distortion the direct effect is lessened. For this reason counter traction, to restrain the tilting of the pelvis, is always necessary if effective traction is required. Furthermore, this incidental abduction, whose advantages were not apparent to the originators of the traction ("extension") method, must be hampered by the long side splint, which, in routine practice, is bound to the body and the limb. I can not admit that this indeterminate degree of abduction obtained by traction in the line of the body, a traction that does not even assure reduction of the shortening, corresponds in the slightest degree with fixation in full abduction on a level pelvis, after the shortening has been reduced under anesthesia. The statement that the difference is imaginary is further evidence that Dr. Stimson does not understand the principles of the abduction treatment.

A final quotation, "The first indication is to save life, the second to get union, the third is to correct or diminish displacements." I suggest that all cases be divided into two classes, those suitable and those unsuitable for the treatment of the fracture as a fracture, the latter to include cases in which the saving of life is the first consideration, and, to limit the argument to the point at issue, all other cases, in which for any cause, real or imaginary, the application of surgical principles seems inadvisable. The remainder of the sentence might then be transposed to read as follows, The first indication is to correct or diminish displacements in order to obtain union and to restore function.

In other words, age and physical weakness should no longer set the standard of treatment nor be permitted to excuse results which are the inevitable consequences of inefficiency and neglect.

MEDICAL OFFICER OF EDUCATION BOARD'S REPORT—BELLADONNA IN DYSPEPSIA—AIR-DRIED CANCER CELLS—GASTRIC ULCER—YELLOW FEVER—OBITUARY.

LONDON, December 2, 1910.

THE annual report of the medical officer of the Education Board appeared on Wednesday. It is only the second of the series, but is a more important document than its predecessor, as sufficient time has elapsed to enable some summary to be given of what has been attempted by the local authorities. Indeed, Dr. Newman ventures not only to review the work, but to estimate the merits of the organization. In 314 areas schemes for medical inspection of the school children have been authorized. In more than two-thirds of these districts the medical officer of health has been appointed to the school office. The advantage of this is recognized, but it is admitted that the unification of the two medical services is not always possible or even desirable. Still, intimate co-operation between them is held to be necessary, for school hygiene "cannot be divorced from home hygiene on the one hand or from the health conditions of the community generally on the other." In respect to the connection between home and school the "care committees" formed in many places are cordially commended as an almost essential part of the organization. Voluntary service is recognized as quite as important as that of paid workers; accordingly, a pretty full summary of the duties of such "care committees" is embodied in the report.

The question of establishing school clinics, to which I have at times referred as under discussion, could not be ignored, and although a decided part is not taken the report seems to incline in favor of them. In London the hospital part of the county council's scheme is said not to have yet had a fair trial, and so no judgment is pronounced.

The extent to which physical defects have been revealed by inspection has created surprise in many quarters and excited public discussion, and the report gives some figures. Among the six million children in the elementary public schools of England and Wales about 10 per cent. suffer from serious defects of vision, from 3 to 5 per cent. from defective hearing, 1 to 3 per cent. have suppurating ears, 8 per cent. have adenoids or enlarged tonsils, requiring surgical treatment, 20 to 30 per cent. require dental treatment, 40 per cent. have unclean heads, 1 per cent. have ringworms, 1 per cent. are tuberculous, ½ to 2 per cent. have heart disease.

The unthinking part of the public express astonishment at the existence of this mass of disease, and cry out that something must be done—in some instances that something is suggested and is usually impracticable. Inspection, of course, shows the prevalence of disease in children, and the medical inspector who sees naturally would like to treat the cases. But it by no means follows that all these children are neglected. The pressure of an excessive supply of medical practitioners in almost every district, as well as the existence of numerous hospitals, should rather suggest that they are mostly under treatment. Those enamored of state interference in every direction are calling out for another set of official doctors to take charge of the children. They forget, or do not care, that to take all these cases away would spell ruin to a number of local practitioners who are thoroughly qualified to deal with them, and in whom the parents have every confidence. No doubt there are cases of neglect, but they are rare, and it would be better to compel such parents to do their duty than to encourage them in their evil ways and teaching them that the state will make good the results of their criminal negligence. To the profession as a body this question is of the greatest importance, but its leading members display little sympathy for their less prosperous brethren.

I suppose most practitioners have at some time or other tried the addition of an anodyne to mixtures directed to the relief of obstinate dyspepsia. Hyoscymus and belladonna are perhaps the most commonly used for this purpose. A paper on the value of the latter, read in the medical section (R. S. M.) by Drs. Craven Moore and L. Kilroe, is therefore calculated to attract attention. They found clinically that certain cases were relieved, and so they proceeded with a systematic investigation into the action of belladonna on the functional activity of the stomach. Their results confirmed and even amplified Riggel's earlier observations, which showed that the drug decidedly diminished secretion. Whether given with or shortly before a test meal a diminution of both acid and peptic values was observed. This was more marked in cases of hypersecretion, but still obtained in the opposite condition. The effect on the volume of the stomach contents was slight and variable.

So far the drug seemed to have little influence over the emptying of the stomach, but radiographic observations led to a belief that it had an influence in inhibiting and relieving spasmodic contractions.

Several speakers said their clinical experience was explained and confirmed by the author's investigations. One suggested that some variations in the results might be due to differences in the amount of the drug absorbed in different conditions. In duodenal ulcer it was said that when spasm was present so also was dilatation of the stomach. The president (Dr. Bruce) asked if the relief was permanent or did patients come to depend on the drug. Dr. Moore replied that the effect was not permanent any more than with other drugs, but it kept the local condition within normal limits and so overcame the tendency towards a vicious circle. Dr. Kilroe added that in some cases of spasm associated with hyperacidity definite relief had been obtained. Moreover, in a few cases of cancer marked relief had followed the use of belladonna.

Experiments at the Imperial Cancer Research Laboratories confirm Jensen's statement that the simple drying of cancer pulp in the air at body temperature is lethal to the cells. Messrs. Shattock and Dudgeon have reported to this effect to the Pathological Section of the Royal. We have very little evidence that cancer is ever air borne, and the experiments seem to indicate that the fatal effect of drying is the reason, for in the undried condition the vitality of the cells is remarkable. Mouse cancer cells suspended in salt solution were sprayed into the mouths of mice more than once without effect. The authors and others experimented with air-dried cancer by subcutaneous injection, and found this set up no immunity to subsequent grafting of undried growth. Nor did such injection have any effect on the growth of a graft which had previously been made. Equally inert was a centrifugalized extract, or, rather, the use of extract as a prophylactic served to accelerate the appearance of the growth instead of retarding it, as if a hypersensitiveness had been induced.

At the same meeting Dr. C. Bolton related some experiments made to determined the effect of diet on acute gastric ulcer set up by injecting gastrotoxic serum. He confirmed the view that gastric juice played a part in producing ulceration, as he found the longer its contact with the stomach wall the more rapidly could ulceration be produced. The epithelium would grow more rapidly over the base of the ulcer when the animal was kept on a milk than on a meat diet. On the twentieth day of milk diet the ulcer would often be covered, but on a meat diet this would not be the case. From this he deduced that the best treatment in the human subject was rest in bed with food that would not remain long in the stomach and the control of hyperacidity.

At the Tropical Society Sir Robert Boyce reported the results of his fourth expedition to inquire into yellow fever. It was undertaken for the colonial office and occupied June, July and August in examining the gold coast and Sierra Leone. He soon satisfied himself that the *Stegomyia calopus* was the commonest mosquito in West Africa. The history of epidemics and sporadic cases, and the absence of any destruction of infected stegomyia in the past accounted for the disease having been endemic on the coast. The reluctance to diagnose it had generally existed and continued to this day, so that some had supposed it only attacked new arrivals, while others were so fearful of exciting a panic that they made light of it, and some went so far as to justify a denial of its presence. Until the dreaded black vomit appeared experienced physicians hesitated to announce it, and meantime it had spread. Consequently, yellow fever masqueraded under a number of euphemisms, such as inflammatory fever, bilious remittent, or intermittent fever. In all the outbreaks he had investigated he had encountered these obstacles to diagnosis and notification, although writers on the disease had drawn attention to the matter. Carrol had said that the disease might be so mild that the most experienced would hesitate to diagnose it unless it happened to be prevalent at the time. Sir Robert seemed to agree with this, and he asserted that yellow fever was endemic in West Africa, where it was common in all its varieties. Consequently there was only one remedy—destruction of stegomyia. A marked improvement in the health and prosperity of the coast would follow such destruction.

Dr. T. N. Brushfield, formerly superintendent of Chester and Brookwood asylums, died yesterday, aged 80. He was a London Hospital student, took M. R. C. S. in 1850 and M. D. St. And., 1862. He was a fellow of several societies.

Dr. C. C. Forrester, M. B., C. M., Edin., died on the 28th of November. He was adviser of the University of the Interior in Egypt.

The deaths have also occurred of D. W. Marston Clark, M. O. H. for 26 years of Quickenham, aged 53, and Dr. Hugh Norris, a retired Somerset surgeon, aged 89. He was at one time president of the Royal Medical Society of Edinburgh, and corresponding member of the Paris Medical Society.

Fatal Chorea; Meningoencephalitis.—J. Lépine, A. Giraud, and J. Rebattu report the case of a female patient forty-nine years of age in whom a diffuse meningoencephalomyelitis manifested itself by means of a choreiform syndrome, and terminated fatally with septicemic symptoms. The lesions were revealed at autopsy. This case presented characteristics similar to those of cases of fatal chorea that have been reported.—*Revue de Médecine.*

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

CENTENNIAL OF BERLIN UNIVERSITY—ITS HISTORY—ENDOWMENTS FOR RESEARCH—PROMOTIONS TO DOCTORATE—THE LATE PROFESSOR VON LEYDEN.

BERLIN, November 15, 1910.

It is impossible to render a good report of medical life at Berlin without referring to the centennial anniversary of the University of Berlin, even though the medical faculty took but little part in the celebration. We have already described the jubilee of certain medical institutions early in the year. Nevertheless the celebration of the literary divisions of the University deserves at least a short notice. Like a mother in behalf of her children, she displays the same interest toward all branches of knowledge. The festivities began October 10, with a commemorative service. The great multitude did not take part in this ceremony, but on the evening of this day the entire city of Berlin was transformed into a festive city. Several thousands of students, males and females, formed a torchlight procession such as is rarely seen in this locality. It moved from the suburbs toward the University, while from thousands of throats the *"gaudeamus igitur"* of the ancient college song echoed throughout the city, and injected a truly ideal note into the noisy life of the never-resting city. In the new hall of the University, the former library, on the following day, there was given a festival play in the presence of the Kaiser and Kaiserin. This was made memorable by the speech of the rector, and the convocation of so many illustrious delegates from the republics of learning of all nations, and more so by the speech of the Kaiser. The rector began by recalling the two Humboldt brothers, whose monuments stand in front of the University, who represented ideally at the very foundation of the University the two great divisions of philosophic and natural sciences. He spoke of the distinguished teachers, Fichte, Schleiermacher, and Hegel, and of our own Liebig and Johannes Müller. He referred to the manner in which these latter laid the foundations of modern chemistry and medicine, not to forget the labors of the physicist Helmholtz. The present time demands a wider revelation of the University's treasures than formerly, nevertheless one must never forget that the foundations are not sunk upon a narrow level.

The Kaiser's speech culminated in the announcement that, according to the original plan of Wilhelm von Humboldt, the extension of the University in the establishment of institutions for scientific research would now be realized. With this end in view, a society has been organized under the presidency of the Kaiser, with the object of raising funds for this purpose. The first gifts that the Kaiser would hand over to science would amount to nearly ten million marks. This sum comes chiefly from commerce and industry, and is contributed substantially for research in natural science and in medicine. It is understood that there is next contemplated the establishment of a research institute for physical and for general chemistry; later an institute for the study of radium and the problems of immunity. A banquet in the evening closed the day's festivities. The following morning another celebration was held in the hall of the University, at which the Professor of History gave a lengthy lecture on the history of the

University. In 1810 the number of teachers was 52, and of students 256. To-day the teaching corps consists of 508 members, while there are 226 *privat docents,* 8,000 students, and 14,000 auditors. In the first decades the property of the University amounted to 300,000 marks; now it totals 5,000,000 marks. While formerly all branches of the University were sheltered under its roof, with the exception of the medical and surgical clinic, which had twelve beds in a lodging house, to-day not even the collective psychological sciences alone can find sufficient room within its walls.

Following this lecture there was an unusually large number of promotions to the doctorate, *honoris causa.* Particular applause greeted three promotions of the medical faculty, the poet Wilhelm Raabe, the painter Hans Thoma, and the composer Max Reger. The dean of the medical faculty, Professor Bumm, announced that these men had accomplished great services in medicine, for nothing so cheers and exhilarates the sick as genuine art.

A garden party in the afternoon with historic costumes and tableaux and an immense *commers* in the evening concluded the festivities.

Early this month there died a Berlin clinician who for decades has been regarded as the leading physician of Germany, Ernest Leyden. Throughout almost his entire life he occupied a prominent position. Without Leyden's familiar personality the medical life of Berlin is hardly conceivable. It was his fate to have sustained an accident that after many long months terminated in death. The living figure of the deceased was conjured up once more by those who took part in the memorial service, to which the Society of Internal Medicine had invited them at the Medical Clinic. Leyden had founded the society and had always presided over it. The eulogy was delivered by F. Kraus. "Work, service, and gentleness," began the speaker, "constitute the formula that sums up the life and influence of Leyden." After describing his life the orator referred to the deceased as clinician and investigator. Leyden was no specialist. His investigations embraced every branch of medicine. Imperishable were his services in the sanatorium movement, and his provision for those afflicted with cancer. If he had not attained any true success in this direction at any rate it must be admitted that the not distant future will show how full of blessings his work in this domain happened to be. The following day witnessed a similar celebration at the scene of Leyden's service of many years, the First Medical Clinic. The memorial address was delivered by Leyden's successor, Professor His.

What Medical Societies Can Do for the Health of the People. J. Ritchie.

Experiments on Transmission of Bacteria by Flies with Special Relation to an Epidemic of Bacillary Dysentery at the Worcester State Hospital, Massachusetts, 1910. S. T. Orton and W. L. Dodd.

Report of a Study of Brown Séquard's Epilepsy in the Guinea Pig. A. E. Taft.

An Extrauterine Pregnancy at Full Term. C. H. Hare.

Medical Societies and the Public Health.—J. Ritchie states that medical societies, representing the best thought in the medical work of a great city, can speak with a voice that cannot fail to be heard or ignored. They can have a decided power in suggesting and influencing appropriate legislation. The following subjects are mentioned in which medical societies can advantageously proclaim their attitude: the questions of tuberculous cattle, the city milk supply, pasteurization, the notification of infectious diseases, the contagious character of poliomyelitis, disinfection, the typhoidal oyster and the typhoid fly, vaccination, animal experimentation, the abolition of the public drinking cup, the hygiene of sex, and the relation of medical men to the public press. In regard to the last, it is possible that the essential matters of consequence in medical discovery may be given to the people in an interesting and trustworthy manner.

Bacterial Transmission by Flies.—S. T. Orton and W. L. Dodd investigated an epidemic of bacillary dysentery at the Worcester State Hospital occurring in July and August, 1910, with the object of ascertaining, first, the causative organism; second, the method of transmission from case to case; and, third, prophylactic measures against such transmission. They came to the following conclusions: An organism conforming to the Shiga type of *B. dysenteriæ* was recovered from 10 out of 15 cases examined. *B. prodigiosus* planted in the laundry was recovered from flies caught in traps in the scullery and five screened ward dining rooms at an interval of from two to six days after the original plant. It proves impracticable in most insane hospitals to keep the flies from access to fecal matter and from food when they are present outside in large numbers and, therefore, the best prophylaxis against fly-borne epidemics is in cleaning up the breeding places of the fly, to reduce its numbers or eradicate it. The typhoid fly—*Musca domestica*—breeds in tremendous numbers in decaying vegetable waste of varying sorts, and a search for maggot-infested places with subsequent attention thereto offers the best line of attack. The house fly's egg to adult cycle is ten days, so that vegetable waste should be cared for at least once a week during fly season. Horse manure may be treated by chemical means, but it is probable that, if it is kept dry and in the dark, but little breeding will take place. Mixing with many times its bulk of cow manure may prove effective. When possible, all waste material should be plowed into the land without accumulating. Spreading over the land will probably suffice to reduce the pest markedly. In hospitals surrounded by considerable ground it is probable that the great majority of the flies are home grown, and the extermination of their breeding places is an object which cannot be overlooked.

Brown-Séquard's Epilepsy in the Guinea Pig.—A. E. Taft found that lesions occurring in the cord or principal nerve trunks of guinea pigs produce a tendency to convulsions resembling epilepsy. The attacks, however, have not been proved spontaneous, but may be elicited by irritation of a specific zone of skin on the side of the face and neck corresponding to the injured nerve. The scratch reflex, the first manifestation of the nervous lesion, developed at the end of a period averaging eighteen days after the division of the nerve. The complete convulsion appeared on an average of one month and nine days following the injury to the nerve and eighteen days after the development of the scratch reflex. Age proved not to be an absolute factor in relation to the time of development of the convulsions. The zone of irritation varies in extent. The sensitive area is at first limited to the skin over the side of the face. This extends progressively with the further development of the convulsive tendency to include the shoulder and often some distance beyond the border of the scapula. The degree of sensitiveness varies in individual cases. Sometimes merely touching the hair will produce an attack, while in others definite molding of the skin is required. Trophic changes occur in the zone of irritation, manifested often by falling of the hair, leaving the skin exposed; or it may be the hair becomes brit-

tle and breaks off, thus causing a roughening of the coat. In extreme cases the skin may ulcerate. As a rule parasites accumulate over the area and there is some anesthesia. The convulsion follows irritation of the sensitive zone and is preceded by the scratch reflex. Following this, the animal falls on its back with eyes closed, insensible, and all its muscles in a state of tonic, followed by clonic, convulsion. The attack is usually brief, but may be spontaneously repeated several times. For some time following the return of consciousness the animal is somewhat stupid and dazed. The effect of convulsions was productive of a marked loss of flesh, and this bore no relation to the quantity or quality of food given. Lessened reproduction was also universal, and in almost every instance of birth of young they were not alive or died immediately after birth. This was proved not to be due directly to the division of the nerve, for by limiting attacks to not more than one each week, perfectly normal offspring were born. This would seem to show a marked disturbance in metabolism due to frequent convulsions. The study of 128 offspring of epileptic animals to observe the transmission of epilepsy, reported by Brown-Séquard to have been seen in his series, was absolutely negative. Four young were very weak at birth and died on the second day, but showed no other symptoms. The fact that convulsions in the offspring of epileptic animals always, in Brown-Séquard's experience, existed with a lack of toes, makes it seem possible that there may have been some prenatal injury which would produce the same effect as a division of the nerve. The thirteen young of the second and third generations were also negative.

Extrauterine Pregnancy at Full Term.—C. H. Hare reports a case of this condition in which he had made a diagnosis of abdominal pregnancy at full term with death of the child. Upon operation a dead baby, weighing four and three-fourths pounds, was removed. The patient made an ideal recovery. The author quotes the conclusions of Peterson recently published in regard to extrauterine pregnancy as follows: Whenever conditions permit, operation for the removal of the gestation sac is indicated in the first half of an extrauterine pregnancy since at this period the mother is in great danger from rupture and sepsis and the chances for the removal of the fetus are very poor. During the latter part of an extrauterine pregnancy the chances of rupture and fatal hemorrhage are very much less (4.8 per cent.), and the chances of survival of the fetus are very much greater. While malnutrition and malformation of the extrauterine child are more common than with the fetus under normal conditions, they are not frequent enough to contraindicate attempts at saving its life. Hence, under favorable surroundings, when the patient can be watched, she should be allowed to go within two or three weeks of term before operation. Since the maternal mortality is more than twice as great after operations in advanced extrauterine pregnancy where the placenta is left behind, its removal should be one of the cardinal principles of each operation. In the "discoid" variety of placenta, where only a small surface of this organ is not attached the blood supply must be controlled, either by tying the vessels or by compression of the aorta before an attempt be made to remove the placenta. When, for any reason, removal of the latter is impossible, the sac should be stitched to the parietal peritoneum and the placenta shut off from the peritoneal cavity by gauze. Dependent drainage through the vagina should be secured whenever possible.

606 or Dioxydiamidoarsenobenzol. E. G. Ballenger.
Hospital Day Address. C. W. Burr.
Some Remarks on the Differential Diagnosis of Typhoid Fever P. H. Markley.
The Present Status of the Psychoneuroses and of Psychotherapy. E. E. Mayer.
Acute Primary Polymyositis, with Report of a Case. C. F. Clowe.
Our Experience with Vaccine Therapy in Acute Infections. E. Martin.
Some Surgical Consideration of Nonmalignant Ovaries. R. F. Ward.
Report of a Case of Pelvic Peritonitis Complicated by Postoperative Hysteria. J. D. Whitall.
A Case of Hepatic Syphilis. M. Goldsmith.

Ehrlich-Hata Preparation.—E. G. Ballenger gives an account of his visit to Dr. Wechselmann's clinic in the Rudolph Virchow Hospital, in which 500 of the 2,000 beds are devoted to skin and venereal diseases. He admits that the results of the use of this remedy are marvelous and have exceeded all reasonable expectations. The more active the lesions and the more malignant the disease the better seem the results or, at least, the more apparent and startling. From a clinical study of the results and from a careful review of the reports upon this remedy the author feels justified in stating that it is the most wonderful therapeutic discovery the medical profession has ever made. In something like 13,000 patients treated with 606 there have been about twelve deaths in adults. Only one or two of these, however, were apparently due to the remedy itself, but most of them showed serious organic lesions or were already in a moribund condition, and should not have received the treatment. A few deaths have been caused by imperfections in the technique that have already been overcome. The mortality was rather high at first in luetic infants until the danger was more fully realized and the dosage reduced or preliminary treatment given. It has been reported that 606 applied locally to chancres promotes prompt healing when this does not follow quickly the injection. Nervous diseases which occur late as parasyphilitic affections and are not due to such lesions as gummata are apparently not benefited by 606. Beginning locomotor ataxia and beginning syphilitic insanity may be checked or cured by this remedy, but so far the results are not conclusive and one must wait for further trials before formulating a rule. If destruction of the nervous system has occurred it would be foolish to expect such lesions to be repaired by any remedy.

Hospital Day Address.—C. W. Burr states that one cause of failure with recent graduate nurses is forgetfulness of the human aspect of their work and an undue magnification of technique and scientific matters. Another cause of failure is lack of tact which in itself depends upon ignorance of human nature plus a contempt for such knowledge and forgetfulness of the fact that on it depends ability to manage people.

Differential Diagnosis of Typhoid Fever.—P. H. Markley states that examples of irregular typhoid are constantly encountered and present difficulties in diagnosis which, clinically at least, may be insurmountable, and in not a few instances defy even the bacteriologists, and are solved only by the autopsy. Typhoid fever is, perhaps, more often confounded with tuberculosis than with any other disease, especially with acute miliary tuberculous peritonitis, and with those cases of profound toxemia sometimes seen in cases of pulmonary tuberculosis. Of these the acute miliary is undoubtedly the most confusing. The Widal test, while not pathognomonic, is entitled to very great respect, being positive in about ninety per cent. of typhoid cases. The diazo reaction is of but little value in differentiating typhoid fever, being present in so many febrile conditions. Other bacteriological methods, such as the detection of bacilli in the blood, stools, urine, etc., are not available by the average practitioner, as the detection of the typhoid bacillus requires the careful technique of a skilled bacteriologist. Nor is the leucocyte count of value in differentiating typhoid fever from tuberculosis, as leucocytosis is not present in either disease; a differential count, however, may be of some value, as in typhoid there is an increase of the lymphocytes, constituting a relative lymphocytosis which is not present in tuberculosis.

Psychoneuroses and Psychotherapy.—E. E. Mayer discusses the inexactitude of terms and definitions, the nature of neurasthenia and of hysteria, the hysteria theory of Freud, the psychic epidemic among physicians due to the pernicious use of Freud's method of psychoanalysis, the theories of hysteria formulated by Babinsky and Janet, the relationship between psychoses and psychoneuroses, psychoanalysis, and simplified psychotherapy.

Acute Primary Polymyositis.—C. F. Clowe reports a case of this condition. Three distinct varieties of the disease have been described: 1. Simple acute myositis. Onset is with lassitude and mild constitutional disturbances, pain, and tenderness in certain groups of muscles. Patients either improve after a few days or the type lapses into one of the other varieties. 2. Acute infectious. Great lassitude and marked pain. Constitutional disturbances are severe. Affected muscles are prominent, very tender, woody, hard, or doughy to the feel, and sensitive. Patient takes position to relax the affected parts. When suppuration begins high fever, cutaneous eruption, and severe symptoms are present. Usually ends with diarrhea. 3. Primary subacute infectious. Prodromes are long, lasting from three to five weeks, pain, lassitude, slight fever, nausea, headache, and weakness, then chills, some fever, edema of face and extremities, pain, and redness, macular eruptions on the face and extremities, gastric disturbances, patient grows rigid and helpless; reactions and reflexes are much lessened or almost disappear, constipation marked, thirst, etc., occur. Form two lasts from five to twenty days, and most patients die. If they recover they do so in three or four months. In form one the patients as a rule recover unless they lapse into form two. Form three lasts from three to four months and few patients recover. If they do it is a matter of many months or of years before recovery is complete. Differential diagnosis must be made from rheumatism, typhoid, suppurative arthritis, trichinosis, multiple neuritis, and osteomyelitis. It is almost often and likely mistaken for multiple neuritis and trichinosis.

Vaccine Therapy in Acute Infections.—E. Martin reaches the following conclusions: 1. The opsonic index, as a guide to treatment, is not an essential element if the clinical symptoms be carefully observed and the dose regulated accordingly. 2. Acute infections, such as acne, furuncles, and subcutaneous abscesses, show brilliant and uniform results. 3. The best results are obtained when the dose is slowly increased through successive inoculations. 4. Autogenous vaccines are not essential in the treatment of staphylococcus processes. 5. The duration of infections is perceptibly shortened by the use of vaccines.

Nonmalignant Ovaries.—R. F. Ward states that sufferers from the different nonmalignant forms of ovarian inflammation and degeneration constitute one of the most satisfactory classes of patients upon whom the surgeon is called to operate, provided the greatest care and discretion are exercised in selecting the cases which really require operation, doing only that which is necessary, and always endeavoring to save as much ovarian tissue as is compatible with complete amelioration of the symptoms for which the operation was undertaken.

Pelvic Peritonitis and Hysteria.—J. D. Whitall, using his case as a text, makes a plea for the more thorough attention to the after-treatment of cases of pelvic peritonitis.

Hepatic Syphilis.—M. Goldsmith reports a case of this condition which does not correspond with any of the clinical types described, resembling hypertrophic cirrhosis more than any of the others.

Typhoid Vaccines.—J. M. Anders states that in serious cases of typhoid, when the system is overwhelmed with the toxins, the vaccine treatment may be a source of fresh danger and aggravate the symptoms. Typhoid is an acute bacteremia plus toxemia, often fulminating in character, and not a localized infection. Hence brilliant results from vaccine treatment can hardly be looked for. It is doubtful whether it is safe to use typhoid vaccines in severe cases. It is in chronic infections, in which the specific organism is walled off from the general circulation with slow absorptions of toxins into the blood, that vaccine therapy is most useful. In eight cases the author used small doses, 25,000,000 in the beginning and subsequent ones of 50,000,000 each, repeated as a rule at intervals of seventy-five hours. His observations do not show that small doses stimulated phagocytosis very much, but he thinks the effects of the vaccines on the leucocyte count should be carefully investigated. If, however, the process of immunization is dependent chiefly on phagocytosis, and it can be shown that the bone marrow can be thus stimulated, then vaccine therapy is advisable. The routine use of vaccines is not to be encouraged, but an antiendotoxic serum would, by neutralizing the endotoxin, be an ideal treatment. The author concludes that vaccines are of value as a means of prophylaxis: in suitable cases when continued during convalescence, to prevent relapses; to combat local infections with the typhoid bacillus, as, for example, bone suppurations which arise in the period of convalescence; and for the removal of the typhoid bacilli from the feces and urine in the case of typhoid-carriers.

Surface Wounds.—C. E. Tennant states that when infection is definitely present free incision and copious wet dressings which will raise the polymorphonuclear blood-content are advised to overwhelm the invading organism, and the simplest and safest solution to moisten the dressing is the hot sterile physiologic salt solution. Other safe solutions are equal parts of alcohol and saturated boracic-acid solution, which also stimulate the tissues to an active local hyperemia, or Thiersch's solution. Unless the dressings are large enough to retain moisture and heat for long periods of time they are worse than useless. They should be changed once in from twelve to twenty-four hours, according to the amount of discharge, but the solutions should be used as often as necessary, and a change from one to another solution is often of great advantage, especially if the alcohol solution has been used first. Where infection has not occurred and is not expected it is better to keep dressings from contact with the wound, especially if it is extensive and moist. It has long been known that burns and traumas of the face where dressings are not applied heal with little inconvenience and scar, and the same principle applied elsewhere is equally effective. It is difficult, however, to effect this, and surgeons have invented almost as many appliances as they number themselves. The author describes two methods which he has been using for a number of years with great satisfaction. One is the use of a sheet of light aluminum as a base on which is fastened a cage made of poultry wire of any size of mesh desired. This he has found of special use in extensive burns of the extremities. The other method is the use of copper or aluminum-coated fly screen cut to the desired size, bound with adhesive tape, and set on strips of adhesive felt sheet-

ing which have been first cut, fashioned, and attached to the skin about the outer margin of the wound. This is fastened by adhesive straps and covered by gauze dressing and bandaged, nothing directly touching the wound.

Effects of Bright Light.—J. H. Parsons directs attention to the effects of excessive light in the production of such conditions as snow blindness, ophthalmia electrica, and glass-worker's cataract. He gives the results of experiments which show that the lens has a very powerful capacity for absorbing ultraviolet rays, which is easily demonstrated by the strong fluorescence which occurs when these rays fall on it. There is no doubt about the absorption of those rays between 300 and 350 microns in length, and it is, therefore, not illogical to assume that these rays may produce pathologic changes in the eye. The pathologic changes in the lens in which bright light may be a prominent factor in glass-worker's cataract are mentioned. These are attributed by Schanz and Stockhausen to the ultraviolet rays, but Parsons is not satisfied that this is absolutely so. It is difficult to devise conclusive experiments for the elucidation of a problem in which the causal agent acts slowly over a very long period, and, until further experiments have been made to eliminate the heat factor, it would be unwise to make any dogmatic statement as to the true cause of glass-worker's cataract. The effects of light containing violet rays on the conjunctiva are also noticed, as shown in snow blindness, electric ophthalmia, and sunburn. Red vision, which is often a troublesome symptom after exposure to bright light, has also been attributed to the ultraviolet rays, but the author thinks we cannot consider them solely responsible. The protective measures which have been devised are noted and heavy flint glass is stated to meet most requirements, as far as impenetrability to ultraviolet rays is concerned, but its weight renders it unsuitable for spectacle glasses. He believes, however, that it will be easy to solve the problem of protective measures. Much still remains to be done in the direction of determining with greater accuracy the physiologic and pathologic potency of the ultraviolet rays.

Alcohol in Acute Infections.—J. L. Miller concludes that impairment of the vascular regulating mechanism is more apparent than active disturbance of the heart in the circulatory derangements of the acute infections. Treatment should therefore be directed to the prevention or correction of these vasomotor disturbances, and, while alcohol in small doses sometimes acts as a cardiovascular stimulant, its mode of action is not quite clear. In larger amounts, in individuals not accustomed to its use, it invariably acts as a depressant, paralyzing the vasomotor center. The borderline between doses that act as a stimulant and those which act as a depressant is very uncertain. Some investigators have been unable to detect a rise in blood-pressure, even with very moderate doses, and this uncertainty renders it an undesirable therapeutic agent. Even in small doses it may and in large doses it always depresses the circulation, and other drugs more constant in their action are advisable and less likely to affect the patient unfavorably.

Magnesium Poisoning.—W. F. Boos concludes that magnesium sulphate, in bulk or in concentrated solution, is absorbed, in part at least, from the gastrointestinal tract into the blood, and if a sufficient amount is absorbed at a time poisoning will result. Of the ten cases he has collected, six resulted fatally, and the symptoms and autopsy findings corresponded very well with those obtained in animals after intravenous injection of the salt. The slowness of its excretion renders its repeated dosage in concentrated solution risky on account of possibility of poisoning by cumulation. Under normal conditions and in proper dilution Epsom salts is a valuable cathartic, but it is not wise to give it indiscriminately in cases of possible obstruction of the bowel on account of the above-mentioned danger. Its subcutaneous use is not only irrational but dangerous. The symptoms of poisoning, as noted in the ten cases, are largely those of paralysis and irritation of the bowel, diminution of the urine and, in the majority, a marked paralyzing effect on the respiration. It has also an effect on the reflex centers of the cord and on the sensibility as shown by Meltzer. Boos questions Meltzer's recommendation of the subcutaneous use of magnesium sulphate, and says that it should be employed, if ever, only with the greatest care. In cases of suspected magnesium poisoning large quantities of normal salt solution should be given intravenously, and Meltzer's experiments on animals suggest the possible value of the subcutaneous use of lime salts in dilute solution.

Mediastinal Pleurisy.—A. Frick presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1,074.

Rupture of Male Urethra.—O. J. Gaub describes the anatomic mechanism of rupture of the fixed portion of the male urethra, and describes the methods of its treatment. He points out that it is an injury of serious import and should receive prompt attention when it occurs. If the condition of the patient permits immediate operation, the call to restore the natural passage is imperative. This can be done at any point of the urethra through a median perineal incision. The question of shock should be considered as a primary measure, and leakage of the urine in the early hours is not to be feared. Proper drainage should be instituted to prevent infection. The author lays special stress on the position of the patient during operation. The exaggerated dorsal position is advised, using the old Clover's crutch, supplemented by a sand bag under the sacrum, which flexes the pelvis on the vertebral column so as to bring the perineum in the horizontal plane and render the structures taut, permitting an anatomic dissection.

Arsenobenzol in Syphilis.—H. L. Elsner concludes as follows: The treponema is positively destroyed and the living contagion of syphilis removed by 606. It promptly and favorably affects visible and palpable syphilitic lesions, staying the destructive and onward march of ulcerations and causing rapid healing. It also removes deep-seated gummata. It is more rapid in its effects on specific disease and is likely to prove more valuable in the treatment of internal syphilitic disorders than any other known remedy. It cannot replace cicatricial tissue. Neither does it affect favorably chronic syphilitic nervous diseases in which there is a break in the continuity of the nerve-structure, though in some cases it seems to favorably influence the continuous crises of tabes. In all cases it causes leucocytosis and the formation of antibodies. It modifies, and, in most cases, ultimately negatives the Wassermann reaction. It unquestionably floods the circulation with endotoxins resulting from the death of millions of spirochetes, and in all probability an antitoxin is developed in the blood. These facts must be considered in connection with the treatment. In acute and threatening deposits in vital organs it may be life-saving by its prompt action. It ought not to be given to ambulatory patients, nor is it safe in the hands of careless or inexperienced individuals. The hospital is the best place for the use of the method, and patients who are injected should be kept in bed for seven days under close observation, and longer is needed. Second injections, if needed, should not be earlier than eight weeks after the first. Contraindications should be carefully considered. It should not be given when other infections than syphilis exist, however mild they may be, nor should the feeble or old, or those with other than specific organic disease, be injected. Congenital syphilis calls for the treatment, either directly or indirectly, through the mother. The living contagion is destroyed; hence, the spread of syphilis can be prevented by its early use, a point for sanitarians. In occasional well-selected cases the use of iodides by the method of

Wechselmann will increase the efficacy of 606 when second injections are necessary. Two to three weeks should have passed after thorough mercurial treatment when this has been used before the injection of arsenobenzol. While its effects are magical, it is not yet certain that a single injection will prevent the secondary or tertiary stages in all cases. Further observation is needed as to this point. The dose is given by the author as 0.5 gram for men, 0.45 gram for women, and there is a tendency to slightly increase this dose to 0.8 and 0.6. The dose for children ought not to be higher than 0.02.

Embryonic Tissue Growth.—M. T. Burrows describes the results of his experiments in cultivating the tissues of the chick embryo outside the body, in blood plasma of the frog.

Renal Activity in Pregnancy.—F. C. Goldsborough and F. C. Ainley conclude that normal obstetrical patients eliminate phenosulphonephthalein more slowly that normal non-pregnant women. Whether this is connected with the ordinary changes in metabolism observed at that time or is due to some other factor one is at present unable to state. In the last month of normal pregnancy the power to eliminate this drug may be very low and falls far below the limits set for non-pregnant individuals. Until more extensive observations are at hand this test should be applied with great caution in toxemic cases, although it is possible that further study will show that it may afford valuable diagnostic and prognostic information.

Bowell Obstruction and Dietl's Crisis.—R. Brown reports a case in which twisting of a kidney pedicle was a factor in causing adhesions to close the bowel lumen and blood-current.

Extracerebellar Tumor.—E. L. Moorhead reports a case in which at autopsy there was found a fibroma firmly adherent to the side of the pons, its origin apparently being from the auditory nerve.

Notes Upon an Outbreak of Illness Due to Tinned Meat in the City of Carlisle. J. Beard.

Exophthalmic Goiter.—W. Hall White states that in some persons, at least, there is a natural tendency for exophthalmic goiter to get well. No doubt this operates more often than figures show, for it must have helped some of those who improved while in the hospital. We also learn that some who are afflicted with this disease recover without treatment. We rarely see death due to exophthalmic goiter and we do not often see elderly women with it. These two facts illustrate the natural tendency of the disease to get well. It seems, however, a fair conclusion that the expected deaths among sufferers from exophthalmic goiter is somewhat, but not very much, greater than among the healthy—in other words, they are rather bad lives. If one follows the after-histories of cases of exophthalmic goiter they teach that the great majority do well. The private cases do better than the hospital cases, but really much better than the figures show, for the mortality is higher among the hospital than among the private cases. The private cases probably do better than the hospital cases because they are better able to rest. The proportion of four deaths out of eleven cases operated on is about the same as that given by Dr. Hector W. G. Mackenzie for similar operations. It must be specially remembered that this serious mortality of nearly forty per cent. is an immediate mortality, some of the patients even dying on the operation table, the others within twenty-four hours of the operation. If the patients are not operated on there is no immediate danger in the great majority of cases, the disease frequently gets quite well, and the actual deaths among those with exophthalmic goiter are not very many greater than among healthy females. A further argument against operation is that in several cases the patient is not cured by the operation. Inasmuch as in some patients there is a natural tendency for the disease to get well, it is difficult to come to a precise opinion about other treatments than the operative, but the author's belief is that the most important is absolute rest in bed for many weeks. During the daytime the bed should, whenever possible, be out of doors, and if the weather permits, the patient may be out of doors at night, at any rate she should sleep with her windows wide open. Next to rest, the most important feature of treatment is food; most patients with exophthalmic goiter are thin, and they will improve as they gain in weight; plain, simple food, and plenty of it, is needed. They must not be worried, the rest must be tranquil, they must be spared the housekeeping and other domestic duties, and it is because private patients can, so much better than others, rest quietly that they do better. It is extremely hazardous to try to estimate the value of drugs for this disease. Lately the author has often given Moebius' antithyroid serum. It may be given in milk, five-minim doses to begin with, but rapidly increased to thirty minims, three times a day. It has appeared to do good, and some patients think they are better for it, but certainly other patients do just as well without it. For extreme restlessness hyoscine is recommended.

Recurring Arterial Hypertonus.—W. Russell describes the importance of recognizing this condition with the aid of the hemomanometer, in granular kidney and in migraine. He reports illustrative cases. In the former condition he alludes to the phenomena which are commonly recognized as presaging paralysis, hemiplegia being the commonest, associated or not with aphasia. Very many of these cases are preceded for days or for longer periods by recurring sensations of numbness or tingling, by temporary slight loss of power in a hand, an arm, a leg, difficulty in articulation, temporary loss of speech, feeling of mental confusion, temporary loss of memory, and so on. All these are associated with arterial hypertonus and a high hemomanometer reading. The nervous phenomena can only be explained by the participation of the vessels in varying parts of the brain in a constriction in which the whole systemic circulation is affected. These local angiospasms in the brain lead to anemia of the areas involved, the clinical phenomena being referable to the areas so affected. The angiospasm in brain areas favors thrombosis, and its consequent deplorable brain softening, or leads to hemorrhage on the heart side of the region of spasm. Now if these phenomena are duly observed, correctly correlated and interpreted one has it in his power in many instances to save one's patients from disaster, preventing their being deprived of the power of locomotion, of speech, of mental power, perhaps for years longer than would otherwise be the case.

Cystic Disease of the Breast.—D'Arcy Power states that cystic disease of the breast is not a distinct entity. It is associated with almost every variety of disease of the mammary gland, and requires careful investigation, which is best carried out by a combination of clinical and pathological research. He describes the diagnosis and treatment of the different forms of benign and malignant cysts of the breast.

Heart Strain and Dilatation.—J. F. Goodhart sums up as follows: True heart strain—by which he understands

a state of muscle that, if not dealt with by retreat from all active exercise for long periods, leads to dilatation of the heart—is a rare condition. Dilatation of the heart, in its beginning, is evidently not easy to determine with certainty, for it may share signs and symptoms in common with many emotional and other nerve disturbances of which the heart is a past-master of expression. Cases of doubt one must admit to be common, and they call for circumspection as regards their management, but one must beware of timidity, and the author cannot but think that this has of late years been much abroad to account for the frequency and the looseness with which the term dilatation of the heart seems to have been applied.

Motor Functions of the Stomach.—H. M. W. Gray states that many observations show that a physiological "middle sphincter" exists, and that in normal stomachs the parts of the organ on each side of this "sphincter" must be regarded as acting separately. The "middle sphincter" can be likened in some manner to the pylorus in that it holds back the stomach contents in the cardiac portion until they are in proper condition for being passed into the pyloric tubular portion, just as the pyloric sphincter acts in retaining the pyloric contents till they are in proper physical and chemical condition to be treated in the duodenum.

Intramedullary Lesion of the Spinal Cord.—A. Bernstein reports the case of a female, aged eighteen years, who was admitted complaining of pain in the back of the head and neck with stiffness and weakness of the right arm and leg. She first noticed stiffness in the neck about three years ago. About two months ago there was slight pain in the back of the neck radiating over the back of the scalp, especially on the right side. There was also some numbness on the posterior right scalp. This had continued till the present. Later there was some weakness in the right arm first noticed in the shoulder, which gradually got worse, and extended down to the hand. About the same time there was weakness in the right leg, which also got steadily worse. There was no numbness, but some slight tingling in the finger-tips. The father died from phthisis. The mother and the other children had excellent history—no syphilis, cancer, or tuberculosis. The case improved rapidly under antisyphilitic treatment. The lesion in this case was evidently situated in the right half of the substance of the cord, especially the anterior horn in the upper dorsal region. But the nature of the lesion was more difficult to determine. Tumors of the cord, tubercle, a plaque of disseminated sclerosis, would hardly have cleared up so rapidly after advancing so far and so quickly. Neither would anterior poliomyelitis account for all the physical signs. Hysteria was excluded by the marked rapid wasting of the intrinsic muscles of the hand and the absence of other hysterical stigmata. The rapid development of all the symptoms followed by as rapid a recovery after antisyphilitic treatment seemed to point to the specific origin of the lesion, which was supported by the fact that mercury was so well borne.

Intestinal Obstruction.—D. M. Greig reports a case of this condition caused by an enterolith spontaneously cured by evacuation through an umbilical fistula.

Illness Due to Tinned Meat.—J. Beard reports an outbreak of sudden illness affecting 21 persons who had partaken of the contents of a tin of American corned beef. He states that outbreaks of food poisoning are not altogether uncommon and do not always terminate so favorably as the one under review. In this class of poisoning the ill effects are due to the ingestion of preformed poisons which are elaborated by the microorganisms in the infected food. The poisonous agent does not undergo any further bacteriological change in the human system, and thus, there being no period of incubation, the symptoms come on suddenly, which constitutes an important comparison to that class of cases in which the illness is due to the development or proliferation of the microorganisms within the blood or tissues of the body.

Proof of the Endemic Origin of Yellow Fever in West Africa. Sir R. W. Boyce.
Case of Fatal Trichocephaliasis in a Child. J. G. S. Jamieson and J. M. Lauder.

Prophylaxis in Obstetrics.—A. W. Russell states that a contracted pelvis is mostly a legacy of the rickety infant Much can therefore be done by way of prevention if enlightened attention is paid to the feeding and hygiene of the baby from birth. The education and physical culture of the growing girl must be supervised. This is specially important at the onset of puberty and during adolescence. The young woman should understand her functions, and in her work should be protected from debilitating influences. The young wife, and especially the expectant mother, should receive the further information that is necessary for her guidance in relation to the sexual functions and the preparation for motherhood. As to the complications of pregnancy it does not seem to be generally realized by the busy practitioner out of how trifling ailments overlooked the most serious troubles arise, and how much special obstetrical studies have in recent years contributed to their more scientific treatment. The author refers to pernicious vomiting of pregnancy, which so often develops out of the ordinary digestive disturbances, and eclampsia which results from renal or hepatic disorders which have not been looked for or have been left untreated. Abortion or miscarriage is really a miniature labor and should receive at least the same prophylactic care as ordinary labor. The mother needs to be taught this otherwise and earlier than by the unhappy lesson of a weakening hemorrhage or a septic infection. The induction of premature labor has still a place among obstetric operations, but it must be done after careful, and even repeated, examinations under an anesthetic, so that the pregnancy may be allowed to run as near the full term as is consistent with spontaneous delivery. When this is done the results are most satisfactory. The forceps should be considered a surgical instrument, and its use a surgical operation. As a consequence the sterilization of instruments and the disinfection of all parts of operator, nurse, and patient that are liable to be touched should be thorough, and this asepsis should be maintained.

Treatment of Hypertension.—H. B. Shaw describes the clinical associations of hypertesion, the method of its determination, the theories of its causation, which are either mechanical or chemical, and briefly discusses the treatment. This is mainly symptomatic. All patients with hypertension should be made to rest recumbent during a much longer period than is usual with them, the diet should be easily digestible, and purgatives should be freely used. The author states unhesitatingly that when the patient arrives—as he or she most surely will, provided other maladies such as pericarditis do not cause the closing scenes—at the stage of what one still persists in speaking of as uremia, one should not hesitate to bleed one's patients and use sedatives when the symptoms are convulsive in character, a condition in which lumbar puncture appears in some cases to give relief.

The Sphygmooscillometer.—K. Eckenstein describes this instrument and its advantages over the sphygmoma-

nometers already in use. One great advantage is the absence of the personal equation. Those who have worked with instruments of the Riva-Rocci type must have been struck with the difficulty that is sometimes experienced in determining the exact moment at which the registering finger can no longer distinguish the pulse. This difficulty may be made still more marked if two observers perform the experiment, one of whom is engaged in watching the sphygmomanometer while the other is occupied solely with feeling the pulse. With the oscillometer there is no such difficulty, as the disappearance or reappearance of the pulse is indicated by the needle. The oscillometer should be used exactly as a Riva-Rocci instrument—that is to say, the armlet should be applied over the brachial artery and the finger on the radial pulse.

Control of Venereal Diseases.—H. C. French advocates the thorough application of the modes of state intervention for the control of venereal disease, namely, constant sanitary supervision and compulsory notification of cases of venereal disease. It has been urged in favor of the latter method that it is not open to the objections brought against the former, as being unequal between men and women, or as encouraging immorality by superintending, in its interests, the health of those who minister to it.

Combined Use of Spinal and General Anesthesia.—A. E. Johnson states that by far the most important and interesting question in considering the advantages of spinal anesthesia is its action in the prevention of shock. It is now generally admitted that if all impulses from the area of operation or injury be prevented from reaching the central nervous system by the employment of this method, shock from this source is either absolutely prevented, or at any rate, minimized. It must, however, be remembered that psychic influences may bear no small part in the production of shock, and impulses from the highest centers may affect the vital centers just as seriously as the effects of trauma at the periphery. The author expresses the opinion that many advantages might be gained by the use of a combination of spinal anesthesia with a light degree of general anesthesia. By the spinal injection the vital centers will be protected from injurious impulses from below, while by general anesthesia the effects of fear will be prevented.

Thyroid Extract in Rheumatoid Arthritis.—H. Wilson reports two cases in which favorable results followed the use of thyroid extract. In the first of these the author had been struck with his rough, dry, harsh skin, crisp hair, husky voice, and deep suprasternal notch; the prominence of the trachea and apparent absence of thyroid gland, analogous to other conditions suggesting deficiency of thyroid secretion. In the author's opinion the group of cases likely to receive benefit are those in which changes are chiefly confined to the synovial membranes, without erosion of cartilage or eburnation of bone, such cases, in fact, as Schüller describes as "chronic villous arthritis." The theory of the improvement is open to much discussion, but the author is of the opinion that the cause of the pathological synovial change is metabolic, and that the chemical pathologist, rather than the bacteriologist, can find the key to the problem. Myxedema is characterized by an increase of connective tissue in and under the true skin, with more than the usual amount of that substance (mucin) in the subcutaneous tissue. There seems a distinct resemblance in the synovial deposits to the above condition in myxedema, which may account for the influence of the thyroid extract on the pathological metabolism.

A Case of Intestinal Reflex.—Sir E. S. Stevenson describes a case in which abdominal pain with periods of obstinate constipation, looseness, straining, together with the passage of blood and mucus, suggested intestinal ulceration. Upon operation, however, the trouble was located in the gall bladder and the bile ducts. Three calculi were found in the common duct, and many small ones in the gall bladder. Both gall bladder and bile ducts were greatly dilated.

The Endemic Origin of Yellow Fever in West Africa.—Sir R. W. Boyce from analysis of all the facts comes to no other conclusion than that a very large proportion of the "remittent" and "bilious remittent" fevers of West Africa to-day are the well-known mild forms of yellow fever. The African native is as saturated with yellow fever as he is with malaria, and his escape from severe yellow fever and its very frequent occurrence among the whites is proof of this contention.

Trichocephaliasis.—J. G. S. Jamieson and J. M. Lauder report a fatal case of this condition occurring in a child, and emphasize the necessity for examination of the stools in children suffering from anemia of unknown cause.

Berliner klinische Wochenschrift.

November 28, 1910.

Progress in Our Knowledge of Pancreas Necrosis.—In recent years, according to Coenen, the tendency has been toward an early operation in acute cases, thus paralleling the management of acute appendicitis. While we are far from having secured the object desired, we have at least secured the abandonment of the conservative therapy. Körte, who has had more experience in this affection than any other German surgeon, formerly (1898) advised against operation in acute hemorrhagic pancreatitis, regarding the collapse and prostration as contraindications. Seven years later, however, we find him recommending early intervention. In 1907 Ebner was able to show by statistics the great value of surgical methods on the mortality. In 1909 Dreesmann collected notes of 118 cases of acute pancreatitis and pancreas necrosis. In this series forty cases treated by early laparotomy and pancreas tamponade gave eighty per cent. of recoveries. The entire mortality of the 118 cases was fifty-five per cent. In regard to pathogenesis, the old controversy was whether microorganisms or enzymes were chiefly responsible for the necrosis. There is evidence that both agencies may be held to account. In many cases bile enters the pancreatic duct and the microorganisms therein may play a causal rôle. It is likely that the latter or their toxins may activate the pancreatic enzymes and set up autolysis. The mixed toxic substances not only cause necrosis and hemorrhage but also seep through into the abdominal cavity, with resulting lesions in the latter and general toxemia. An early operation is likely to be successful if done in time to prevent the escape of the toxins into the abdominal cavity. Mild attacks of acute pancreatitis may end in recovery. Diagnosis is naturally much more difficult than that of acute appendicitis. It is necessary to exclude dynamic ileus and perforative peritonitis, either of which, especially the former, closely simulates it.

Pathological Action of Ferments.—Wohlgemuth states that there is hardly a field in pathology in which enzymes do not take a prominent part. Wherever one finds living cells ferments must be actively present. Thus far an objective, that is a microscopically evident, location of an enzyme has never been demonstrated. We know that a single one, or many which cannot be differentiated, is present in all organs. This is the autolytic ferment, which in the liver appears to be indispensable in the pathogenesis of phosphorus liver and acute yellow atrophy. Next to the general autolytic ferment should be mentioned the enzyme of the leucocytes, which is particularly in evidence in pus, through its power to cause the breaking down of tissues. These enzymes, while pathogenic, may also exert a salutary rôle, chiefly in producing the absorption of clots, exudates, etc., and causing the reduction in

size of the pregnant uterus. Next to be named are the enzymes of malignant growths, which exert an autolytic action within the latter, and are also indispensable for the extension of the tumor cells into sound tissues. We see tumor ferments and tissue ferments antagonizing each other. A liver enzyme, probably a catalase, can destroy cancer cells, and a cancer enzyme tissue cells. Recent literature is replete with interesting data obtained as to enzymes in general, but thus far these do not suffice for the establishment of dogmas.

X-Ray Diagnosis of Gastric Ulcer.—Riedel's brief conclusions from his long article on this subject are as follows: Recent ulcers cannot be photographed. Deep, indurated ulcers, with or without perforation, may be recognized indirectly; that is the lesions which result in the periphery of the diseased stomach are rendered apparent. These lead to alterations of the form and size of the stomach proper and the pylorus. The diagnosis is of sufficient value for prognosis and treatment. The *x*-rays also make it possible to differentiate between gastric ulcer and carcinoma. The presence of the latter disease is recognized by the alteration in the stomach outline when bismuth is introduced.

Clinical Behavior of the Liver in Scarlatina.—Hildebrandt states that by far the greater majority of scarlatina cases show a pathologically increased urobilinuria, the curve of which is frequently parallel with the temperature curve. In certain cases the two curves do not correspond. In the convalescent period urobilinuria is generally present in normal degree. The presence of an unusually high degree of urobilinuria will even serve to differentiate scarlatina from measles, diphtheria, rötheln, anginæ, etc. The increase of urobilin excretion is believed to be due to a certain amount of parenchymatous hepatitis; hence, when the latter does not develop, as in very mild cases, we are not surprised to find the phenomenon absent. Increased degree of urobilinuria is typical of acute parenchymatous hepatitis, whatever the cause and nature of the latter. The author advises the practitioner to test the functional capacity of the liver with levulose whenever an acute infectious disease appears to be impending, as diagnosis by palpation and percussion is not always possible.

606 in Leprosy.—Gioseffi of Trieste has recently tested a single case of lepra with 606. The Wassermann reaction was negative and no spirochetes were found in the nodules. These precautions were evidently taken, not alone on general principles, but because clinically the nasal lesions suggested syphilis rather than leprosy. Records made before and after the use of 606 appeared to show definitely that the remedy neither destroyed Hansen's bacillus nor helped to form soluble toxins, nor in any way modified the leprous process. The author admits that his case was a very confirmed one, and believes that tests should be made on recent cases in which the disease has not progressed so far.

Adreninemia in Pregnancy.—Neu finds definite variations in the blood during gestation, labor, and the puerperium; also very high values in retroplacental hematoma and blood from the cord. The highest values of all were found in the serum of pregnant women suffering from glycosuria and in those who showed extreme degrees of chloasma uterinum.

December 1, 1910.

Recent Progress in the Topical Diagnosis of the Pons and Medulla.—Wallenberg and Marburg give separate reviews of this subject without coming to formal conclusions. In regard to characteristic disturbances of sensibility it is claimed that pain and temperature are conducted to the opposite side through the tractus spinotectalis et thalamicus, in the most medial section of which pain is conducted, while temperature travels through the most lateral sections. Heat proceeds in the outside of the tract, while cold lies between the paths of heat and pain. Deep sensibility seems injured when the fibers of the inner arch are implicated. In regard to motor phenomena unsteadiness of gait, rhythmic nystagmus, falling to one side, abnormal head positions, conjugate deviation, etc., are referred to Deiter's nucleus. Similar isolated generalizations are cited. We have progressed essentially since Nothnagel's monograph appeared, but no general advance has been made. What we have learned since consists of refinements of the older diagnostic methods. Some authorities regard such progress as tending to a narrowness in diagnosis, which loses sight of the entire pathological alteration. The authors hold to the contrary opinion, claiming that these refinements in the methods of diagnosis will also enable one to understand the evolution of the disease.

Bloodless Treatment of Phimosis in Childhood.—Stuhl refers to a substitute procedure for circumcision which may be done without narcosis, and the production of a wound surface with persistence of a so called preputial apron. The operation is not wholly bloodless, but no cutting instruments are used. The foreskin is gradually pulled back over the glans, one session or several being required. After the meatus is exposed a blunt sound may be used to separate adhesions. To avoid paraphimosis the prepuce must then be replaced. A very narrow preputial orifice must be dilated progressively for several days. If, despite this resource, paraphimosis result from the next exposure of the glans, this must be at once reduced, care being taken to avoid contact with the newly exposed surfaces. From four to eight days are required for the entire treatment. A few slight tears in the prepuce may be unavoidable and should be treated with some antiseptic dusting powder. Phimosis is often accompanied by an unusually short frenulum, which should in such a case be incised.

Tendinitis of the Quadriceps Femoris.—Bähr first refers to the term achillodynia, which is a symptom of several conditions including tendinitis. The tendon becomes hypertrophied and indurated in local areas. This condition seems to be of traumatic origin. Writers have described similar conditions in other tendons (peroneus). He then relates the case of an analogous lesion of the quadriceps femoris tendon of traumatic origin, to wit, a fall upon the knee. There was pain in the knee region, and the leg was bent at ninety degrees. The obstacle to complete extension was evidently a nodule in the quadriceps. Knee joint intact. No possibility of an old bony or cartilaginous deposit in tendon. The *x*-ray showed a shadow the size of a large bean *in situ*. The case was of some additional interest because patient was suspected by his employers of simulation.

Bursitis Over the Metacarpophalangeal Joint of the Great Toe.—The same author describes the case of a woman who after mountain climbing experienced pain in the extensor tendon of the great toe, which was found in hyperextension. Flexion was painful and could not be completed. Diagnosis lay between inflammation of the synovial sac described by Hartmann with or without participation of the tendon sheath and paratendinous tissue. The condition appears to be unique, differing from the so called hallux reflexus of soldiers in certain particulars; the latter, for example, exhibits flexion of the distal toe joint upon the proximal one. Nevertheless, the author thinks, the two conditions should bear some definite relationship to each other.

Book Reviews.

Vaccine Therapy. Its Theory and Practice. By R. W. Allen, M.D., B.S. (Lond.), Late Clinical Pathologist to the Mount Vernon Hospital for Diseases of the Chest; Late Pathologist to the Royal Eye Hospital; Late Gull Student of Pathology, Guy's Hospital. Third Edition. Philadelphia: P. Blakiston's Son & Co., 1910.

This work has been completely rewritten and brought up to date, and the attempt has been made to render available the experience of the past five years by including illustrative cases for the guidance of the general practitioner. The text covers completely the subject of the opsonins, the determination of the opsonic content of the blood, the preparation of vaccines, and the opsonic index in health and disease, and there are separate chapters on the various microorganisms and their toxins, their relation to pathological conditions, and to immunity. The chapter on the colon, typhoid, and dysentery groups illustrates the eminently practical nature of this work, since it includes the subjects of antityphoid vaccination and typhoid carriers and their treatment. The chapter dealing with the subject of the infections by the *Bacillus tuberculosis* group is masterly, omitting nothing that has been contributed to the knowledge of fighting the enemy with his own weapons, namely the various tuberculins and their specific indications.

Hydrotherapy. A Work on Hydrotherapy in General, Its Application to Special Affections, the Technic or Processes Employed, and the Use of Waters Internally. By Guy Hinsdale, A.M., M.D., Secretary of the American Climatological Association; Lecturer on Climatology in the Medico-Chirurgical College of Philadelphia; Fellow of the College of Physicians, Philadelphia; Corresponding Fellow of the Royal Society of Medicine of Great Britain, Balneological and Climatological Section, and of the International Antituberculosis Association; Ex-President of the Pennsylvania Society for the Prevention of Tuberculosis; Member of the American Neurological Association and of the American Academy of Medicine. Illustrated. Philadelphia and London: W. B. Saunders Company, 1910.

Although the use of water in disease may be traced back to the distant past as one of the first therapeutic resources, it is quite strange that hydrotherapy has only within recent years received due recognition as a science and as an art. A surprising realization of the numerous forms of the application of water in pathological conditions dawns upon the reader as he turns the pages of this book, which presents the subject in exceptional fullness, and free from the inaccuracies of enthusiasm and overstatement. The rationale of hydrotherapy, including the physiological effects of baths of various kinds, forms the introduction to the subject of special hydrotherapy, or its applications in different diseases, as in typhoid fever and tuberculosis; in the former the Brand baths and their modifications and substitutes are described in detail. In the section on diseases of the heart the Nauheim baths and Schott treatment are fully described. The section on the technique of hydrotherapy includes a description, with the aid of numerous illustrations, of the many diverse forms of hydrotherapeutic application, including the various rubs, douches, sprays, packs, hot-air and electric baths, artificial Nauheim, oxygen, mud, and sand baths. The recent methods of rectal proctolysis are described in detail. There is a chapter on crounotherapy or the use of mineral waters internally. One cannot conceive of a work more useful to the general practitioner than this, nor one to which he would resort more frequently for reference and guidance in his daily work.

Elementary Materia Medica for Pupil Nurses. By F. W. Scott, Jr., Ph.G., Instructor in Materia Medica, Long Island State Hospital Training School for Nurses, Brooklyn, N. Y.

This book is commendably small, and the main part of the work (pages 37 to 98) is well done. The chapter on solutions, a subject of prime importance, is too brief and at the same time too painfully accurate to be of any service to the class of readers for whom the book is intended. In Chapter 6 the Latin is as bad as it is in most books of this class; it should either be corrected or eliminated. The author's explanation of alkaloids is most unfortunate; he says they combine with sulphuric acid to form sulphates "just as metals do." But this is exactly what they do not do; for, whereas the metals replace part or all of the hydrogen of the acid, the alkaloids form salts without any elimination of hydrogen, behaving like ammonia rather than metals.

Practical Obstetrics. By E. Hastings Tweedy, F.R.C.P.I., Master of the Rotunda Hospital, and G. T. Wrench, M.D., late Assistant Master. Second edition. London: Henry Frowde, Oxford University Press, and Hadder & Stoughton, 1910.

The reputation of the Rotunda Hospital of Dublin has been justified by its numerous contributions to obstetrical science. Its present master, in speaking for himself, states that this book is a record of at least 30,000 cases for which he has been personally responsible, and to those who would differ from the method of treatment advocated, he pleads this large experience and the progressive improvement of results in every direction. This book deals almost entirely with the practical aspect of obstetrics. In this edition the chapters on the toxemia of pregnancy, uterine inertia, and contracted pelvis have been rewritten, and articles on subcutaneous pubiotomy, hysterotomy, and infant digestion have been added. In the articles on uterine inertia, the treatment of contracted pelvis and rupture of the uterus, the views expressed are somewhat different from those advanced in the first edition. One of the admirable features of this book is the clear and direct statement of the management of the normal and abnormal phases of obstetrics by methods that have been tried out in extensive hospital experience. In the treatment of eclampsia the authors do not advocate *accouchement forcé* in any form. They wait until the os is sufficiently open and the head fixed enough to apply forceps, or the os is sufficiently open to deliver as a breach. The chapters on puerperal infection are a masterly presentation of this subject and strictly modern in their recognition of the advances made in serum and vaccine therapy.

The Surgery of Childhood. Including Orthopedic Surgery. By De Forest Willard, A.M., M.D. (University of Pa.), Ph.D., Professor of Orthopedic Surgery, University of Pennsylvania; Surgeon (26 years) to the Presbyterian Hospital; Surgeon-in-Chief Widener Industrial School for Crippled Children; ex-President American Surgical Association, American Orthopedic Association, Philadelphia Academy of Surgery, Philadelphia County Medical Society; ex-Chairman Surgical Section American Medical Association, Fellow Philadelphia College of Physicians, etc., etc. With 712 illustrations, including 17 in colors. Philadelphia and London: J. B. Lippincott Company, 1910.

The recent lamentable death of the author of this treatise occurred shortly after its publication, before he had an opportunity to witness the appreciation with which the medical public would receive his last literary labors. As an orthopedic surgeon he was peculiarly well fitted to prepare a work upon the surgery of childhood in which orthopedic surgery forms the major part. For this reason, also, the chapters dealing with the diseases of the bones and joints form the most valuable and complete portion of the work, and one that can be of the greatest value to the general practitioner. The wealth of photographic reproductions, including many of *x*-ray plates, is an admirable feature. The non-surgical treatment of bone and joint diseases is presented with full appreciation of modern teaching and practice. The surgical aspects of poliomyelitis are described with a comprehensiveness and minuteness of detail demanded by the growing importance of this subject. Those portions of the book dealing with the surgical disorders of childhood that are not essentially within the province of the orthopedic surgeon, while presenting many excellent features, are not entirely without defect, which is probably to be attributed to the impossible task of presenting the extensive subject of pediatric surgery within the limits of one volume. Nevertheless, some of the subjects that appeal strongly to the needs of the general practitioner are given but scant attention. Thus, tonsillar hypertrophy and adenoids are dismissed in two pages. The modern operation of tonsillectomy is not at all mentioned, the old-fashioned operation of guillotining the tonsils being the only one described, and that in the most cursory manner. The operation of adenectomy is merely alluded to in five lines of text. It is quite natural that in the midst of active professional labors, the preparation of this book did not prevent errors from creeping into it. Thus the statement is obviously incorrect that the bacteriological examination of the cerebrospinal fluid has not thrown any light upon the diagnosis of tuberculous meningitis, nor will any one perceive the reason for the employment of antimeningococcic serum in this condition. Nevertheless, in spite of these and a few other shortcomings, this book, on the whole, is a valuable contribution to pediatric literature.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, Held November 17, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Objections to Proposals of Further Legislation to Regulate Animal Experimentation. — Dr. WM. H. WELCH of Baltimore said that he thought it might seem somewhat out of place for one to come to New York at this time to present the subject of animal experimentation in any of its different aspects, because they had had their attention drawn to this important subject probably more in this than in any other State in the country. Among the most important contributions to the campaign on which the medical profession was obliged to enter were those issued from the State of New York. He referred especially to the leaflets that were issued by the New York State Association. Dr. Welch said he had some hesitancy in speaking on a subject with which his hearers were doubtless familiar and which had been brought to their attention many times so forcibly. However, this was a subject in which he had been interested very much and some twelve years ago he was compelled to be active in the efforts to prevent injurious legislation on this subject of animal experimentation in one of the national congresses. He did not believe any apology was necessary in bringing this subject before the members of the Academy of Medicine, because it was of such great importance and the issues which were connected with it were of such import for the future of medicine that it behooved them to give it all possible attention. In view of the perils to the advancement of the science of medicine and the medical knowledge concerned in this crusade, it behooved them to be vigilant and active. What would be the state of medicine to-day if only thirty years ago such prohibitory legislation had been successfully enacted and placed in operation. Great advances had been made possible through animal experimentation especially in their knowledge of the causes of infectious diseases; the possibilities based upon that knowledge which made possible measures toward the restraint and control of these diseases were evident to all. Therefore, this subject of animal experimentation was one of vast importance because it involved the progress of medical science and the possibility of restraining the spread of disease and controlling the suffering of mankind. There were, however, many aspects of this subject of animal experimentation, but only one theme concerning this subject had been assigned to him, namely, "Objections to Proposals of Further Legislation to Regulate Animal Experimentation." There were several points upon which it was extremely important that the general public, as well as the medical profession, should be informed, and one of them related to the very fundamental, ethical, and moral questions involved; some authors on ethics had written pamphlets for the general public setting forth what was correct and ethical and moral. In his opinion the efforts of these antivivisection agitators were antihuman, indeed inhumane, and they were so because at the bottom they set the lives and sufferings of the lower animals above the lives and sufferings of man. They need not fear the judgment of fair-minded men in this respect, nor the judgment of posterity. Another very important aspect was the question of the utility of animal experimentation. Such experimentation was the greatest lever of advance. They were right, therefore, in laying so much emphasis upon the question of the utility and service to mankind resulting from animal experimentation in medicine. Dr. Welch recalled a hearing some ten or twelve years ago before the Senate Committee in Washington on a Federal bill; it was then remarked that it was not necessary for any one to speak on the subject of the utility of experimental research; that was granted. All that it was necessary for them to do was to point out in what regard any specific provisions in the bill interfered with legitimate experimentation. All members of that committee practically conceded that mankind was benefited by experiments on animals. Many physicians thought that the real foundation of medicine rested upon a knowledge of the structures and functions of the body; this knowledge came partly from observation and partly from experimentation; it was possible to unravel the intricate weaving together of observation and experimentation. Any physician who thought at all on this subject realized that he could not interpret the significance of pulse, nor the significance of the respiratory disturbances, the digestive disturbances, nor the significance of urinary disorders without the knowledge that came to him from experimental methods. When talking about the benefits to mankind of experimental research, and when one singled out striking instances which might be said to be arguments for the man of the street, one must realize that such arguments were limited and gave an inadequate view of the situation. Dr. Welch thought it was very important that the general public and the profession at large should have clearly in mind what were the conditions and methods of progress in science; they should be made to understand just what rôle experimentation played in this. The phenomenon with which they were dealing was the experimental, produced experimentally by nature. Disease in fact was an experiment upon a human being, but the interpretation of this phenomenon was not clear; the conditions were too complex to permit of clear deductions. They must bring about some phenomena under control conditions which would enable them to make proper deductions. In educating the general public they should present statements regarding all the conditions which surrounded their experimental work; they should make clear just what the conditions were in the laboratories. More education was required which related to the sentiment prevailing on the subject of the cruelty to animals. They should not be lacking in participating in movements against cruelty to animals. Dr. Welch said that the theme assigned him related to the question of the legal restrictions which should be placed about experimentation on animals; there was a demand loudly expressed for control by legislation of such experimentation; this was not a new demand; the agitation for it was older in this country than it was on the other side. What was the nature of this demand for the legislative control of experimental medicine? The backbone of the movement which had been designated the "antivivisection movement" was this: Did not the majority of the women place philozoic movements before the philanthropic? They all must recognize the fact that these advocates for severe prohibitive legislation of this kind had always existed and had always assumed this attitude toward scientific research. One might call them obscurantists if he liked. They were so constituted that they were unable to appreciate the advantages of scientific knowledge, or the conditions under which progress was secured. It seemed that the opposition to scientific research had gradually subsided except in the field of medicine. However, there were those who remained fair minded and who were able to judge whether or not further legislation was needed in animal experimentation. Doctors, as a rule, were busy men, and they had little time to meet these statements which were spread broadcast before the general public. These fair-minded people were not misled by the statements of these agitators in the antivivisection cause; they were the ones they were trying to reach by arguments. They were open to argument in this matter and it was their duty to try to influence these individuals who made up a part of the opposition. Should there not be legislation to reach the alleged abuses? There must be, of course, legislation which prevented cruelty to animals used for experiments as well as

legislation which prevented cruelty to animals in general. Their contention was that animal experimentation was as much under statute control or law as that which controlled the subject of cruelty to animals. As far as New York State was concerned, he said that it had one of the most drastic laws in existence anywhere. The question arose, did animal experimentation come under this law? This was a question or issue to be decided by the high legal authorities. Were the conditions which surrounded animal experimentation under the statute law which related to the general subject of cruelty to animals? That was the question for the legal authorities to settle. The practice of animal experimentation certainly was under legal control, and convictions had already been secured in two instances under this law. That this law was sufficient for the purpose was the attitude of the medical profession. It had been claimed that the pathologists, the physiologists, and the bacteriologists were the ones to be watched and who were not to be trusted; that was an imputation upon the character of those engaged in medical research; it was an outrageous imputation. Certain contentions were based upon the abuses in animal experimentation, but in Great Britain not one single instance could be learned of. These abuses were imagined. Such abuses must not be sporadic, but so common as to constitute a public scandal; but no such abuses existed in this country. The question then arose, if such special legislation did not interfere with proper experimentation, why not allow it to be enacted? Could any think of the enactment of any bill that could be acceptable to those engaged in this work? Not one would be enacted but what would contain provisions which would hamper experimentation and, therefore, the progress of medical science. There would be too many vexatious restrictions in these laws. Dr. Welch, in closing, called attention to some of the salient features of some bills that were injurious to the progress of science and which did not deserve support. He ridiculed particularly some of the British bills, with their licenses and certificates issued by the Home Secretary or by some one under his authority, persons who were absolutely incompetent to judge of these experiments It was placing the whole matter in the hands of those who could not be able to judge of the qualifications of those engaged in this work. Even Lister crossed to France in order to avoid the humiliation involved in asking for certificates which granted him the privilege of doing certain work for the bettering of mankind; he said that such laws as they had on the subject should never have been passed and should be repealed. The restrictions, the details, and the formalities were so irksome in such legislation that as early as 1876 they had been warned not to make the mistakes that had been made in Great Britain. The public should come to the aid of those engaged in the advancement of medical knowledge: their work should not be hampered by any such restrictions or such provisions as were embodied in some of the bills.

Some Characteristics of Antivivisection Literature.—Dr. Walter B. Cannon of Boston read this paper. Last year he obtained from the four prominent antivivisection societies of the country copies of the pamphlets and leaflets which had been distributed widely to school teachers, clergymen and others who were influential, but not medically instructed persons. He had also obtained letters and articles which had been published on the subject in the daily press and in magazines. In all of this there was the dreary iteration of the same opinions, the same "eminent authorities," the same tales, etc., and these publications, sent broadcast, were used again and again for texts, examples and references by contributors to newspapers and journals. Any one whose intelligence was not stupefied with weariness could perceive that if the identical names and phrases, with the identical instances, had to be cited continuously the cause must be short of both men and ammunition. To go through these writings with serenity was a difficult task. One found foolish misrepresentations, garbled and inaccurate accounts, base imputations against good men, cunning tricks long ago exposed and all these were put into the hands of persons whose experience had given them no sure basis for judgment. There was little wonder that poets and artists and novelists, and representatives of the church and the law could be found willing to express opposition to the methods of medical research when both the methods and the results were presented to them so falsely. One of the most impressive displays which the antivivisectionists made was their list of "eminent physicians" whose opinion they quoted. The author proceeded to examine this list and showed that many of these "eminent physicians" had been dead many years and that many others were aged men unfamiliar with modern methods, while still others were prominent in literature or other lines and were likewise unfit to make authoritative statements on the subject of vivisection. The vast majority of these opinions were advanced before the discovery of anesthesia and before many of the great discoveries of recent times were made. Lawson Tait had been widely quoted, but he was one who had been described by a competent and trustworthy surgeon as a "man of wild statements." Again it was said of him "he enjoyed being in the minority, and this led him to champion many lost causes." Among the living men quoted by the antivivisectionists Sir Frederick Treves was most prominent. In 1898 he stated incidentally that some experiments which he had performed on the intestines of a dog had done little but unfit him to deal with the human intestine. Sir Frederick was quick to point out the false implication placed upon him. He wrote: "Those who are familiar with the controversial methods of the antivivisection party will not be surprised that certain of my remarks have been cunningly isolated from the context, and have been used in advertisements, pamphlets, and speeches, to condemn all vivisection experiments as useless. The fallacy of vivisection can hardly be said to be established by the failure of a solitary series of operations dealing with one small branch of practical surgery. No one is more keenly aware than I am of the great benefits conferred upon suffering humanity by certain researches carried out by means of vivisection." This was written more than eight years ago, yet Treves continues to be quoted as opposed to vivisection. The speaker cited a number of similar instances in which medical writings had been misrepresented by taking portions from the context and by omitting parts of sentences. When the attention of the antivivisectionists had been called to these errors and the real facts laid before them they had failed to make the corrections. Dr. W. W. Keen had written a paper nine years ago pointing out a number of these misrepresentations and thus far the antivivisectionists had made no retraction. In this pamphlet were mentioned Dr. Berkeley's observations on the effects of administering thyroid extract to insane patients. Although Dr. Keen showed that the therapeutic use of thyroid extract varied between 15 and 60 grains per diem, and that Dr. Berkeley's maximum dose was only 15 grains per diem, the vivisectionists did not distinguish between the toxic effects of these small doses in some cases and the beneficial effects in others, but declared that Dr. Berkeley was poisoning his patients The pamphlet stated that "Two patients became frenzied, and of these one died before the excitement had subsided." In the original the sentence was completed by the words "the immediate cause of the exitus being an acute disseminated tuberculosis." The absurdity of attributing death by galloping consumption to thyroid tablets, which had not been given anyhow for seven weeks, was clearly explained by Dr Keen in his paper nearly a decade ago. A decent sense of honor would have impelled an instant correction of this

wrong, yet the antivivisectionists had continued these nine years to deceive the credulous public without any moving consideration that their imposture involved a man's good name. Antivivisectionists had persistently ignored in their lectures and publications the fact that anesthetics were used in animal experimentation and even after their attention had been called to this omission repeatedly, still continued to ignore the fact. Experience had proved that the false story once well told need not be withdrawn or altered, even if its falsity had been exposed, for that part of the public that liked to be humbugged was ready to listen and to give its humble credence. Dr. Cannon then outlined the great discoveries and benefits that had resulted from animal experimentation and said in conclusion that before the antivivisectionists could command the respectful attention of intelligent people they must fundamentally change their tactics. They must clear their literature of the anachronistic hostility of men long since dead, men who had no conception of the merciful procedures of modern experimentation, nor of their lifegiving results. They must rid their publications of the testimony of spurious experts whose reputations were made in literature, art or theology, and not in the service of healing. They must purge their propaganda of the trickery and evil insinuation that had for years characterized it. The process of making their methods clean and their ways straight involved paying some respect to the high purpose of biological investigation and its beneficent achievements for human welfare, which together gave meaning and sanction to the experimental use of animals.

SECTION ON SURGERY.

Stated Meeting, Held November 4, 1910.

Dr Charles N. Dowd in the Chair.

Large Benign Tumor of Bladder Removed by the Intraperitoneal Route.—Dr. A. A. Berg presented this specimen which the microscopist pronounced to be a pure fibroma. The patient came to the Mt. Sinai hospital during the early part of June because of vesical symptoms, painful micturition and increased frequency of urination. Her pain was not very severe. There were no uterine disturbances and her menstruation was normal. The physical examination revealed a round smooth tumor, that had close relations with the anterior wall of the uterus. He took it to be a myoma of the uterus pressing upon the bladder and causing symptoms referable to this organ. About the middle of June the abdomen was opened; the uterus was found to be normal in size, and the tumor was not connected with it. The latter could be readily raised from the uterus; it was incorporated with the base and posterior wall of the bladder, was the size of a fist. The bladder was opened through the peritoneal portion of the posterior wall by a vertical recission. The lining mucosa was everywhere intact and normal and the right ureteral orifice was readily identified and probed. The left ureteral orifice could not be seen. The mucous membrane was divided in the median line over the tumor from before backwards, and the tumor shelled out from the muscularis of the bladder, leaving a very large cavity which could not be entirely obliterated by sutures. The cavity was obliterated as much as possible and then a drain of small size was inserted. The patient made an uneventful recovery. He presented this patient to draw attention to the advantage of the intraperitoneal route in attacking tumors of the bladder and for all operations upon the bladder attended with aseptic condition of the bladder interior. Access to the tumor was immensely better by this route than by the extra-peritoneal route; in this way one came down directly upon the tumor. Again leakage would not occur as often as through the supracystic route. The objection to the intraperitoneal route was based on the possible infection of the peritoneal cavity. Dr. Berg said he had operated upon four cases of malignant disease of the bladder and on one of benign nature, and in no case had he witnessed any tendency toward infection of the peritoneal cavity. By the intraperitoneal route the healing was quick and convalescence was rapidly established.

Dr. Martin W. Ware claimed for Rydygier priority in the performance of intraperitoneal operations. He believed that any extirpation of trigonal tumors by that route, if they were then radically performed, ought always to include an operation on the ureter, ending in its transplantation. This procedure necessitated extraperitoneal transplantation of the ureter in addition.

Cases Illustrating Method of Nephrectomy and Ureterectomy.—Dr. Howard Lilienthal presented these cases, which illustrated his method of nephrectomy and ureterectomy. Briefly this method consisted of extraction of the lower part of the ureter through an inguino-abdominal incision instead of the prolonging of the nephrectomy wound. If this method was more generally adopted a great many more ureters would be removed than were removed at present by the old methods.

Stab Wound of Heart; Recovery.—Dr. John F. Erdmann presented this patient. (See page 1095.)

Pneumococcus Peritonitis.—Dr. George Woolsey read this paper. He said that after the full development of the surgery of the appendix it was an opinion generally felt and often expressed that acute peritonitis was always due to an inflammation of the appendix, or a pelvic viscus, or a perforative lesion of one of the abdominal viscera, or of the abdominal wall. As experience increased cases of acute peritonitis occurred in the experience of many surgeons which could not be accounted for by any of these causes. The peritonitis might be a part of a pneumococcus septicemia, with multiple foci of infection, but more often it was secondary to another pneumococcus focus as a pneumonia, empyema, etc., "secondary cases," or it was the first point attacked by the organism, "primary cases." Among the secondary cases the primary focus was pulmonary in the great majority of the cases. Next in frequency came otitis media and throat infections. In cases secondary to pulmonary lesions did the infection reach the peritoneum through the blood or by penetrating the diaphragm? There was no evidence of the latter course. It had been definitely established and accepted that the infection might and did occur from the gastrointestinal tract in primary cases and the condition of this tract appeared not to have been investigated in secondary cases. Quervain thought the appendix the commonest source of origin of the peritonitis in primary cases. Of 91 cases collected by Annend and Bowen, 73 per cent. of all cases, 84 per cent. of the primary cases and 67 per cent. of the secondary cases were females. This suggested as an important etiological factor the female genitals. But there was little pathological support to this theory. It was possible that the pneumococci might pass through the tubes causing but little local reaction; but it must be admitted that there was singularly little pathological proof of the genital being the common channels of infection. It was quite possible that in some cases the pneumococci had entered the circulation through an apparently intact mucosa and found in the peritoneum conditions favorable for development. Clinically as well as pathologically two types were distinguished, the circumscribed and the diffuse forms. The difference was one of degree only. Dr. Woolsey said his experience was limited to the diffuse form. The characteristics of primary diffuse pneumococcus peritonitis were the acuteness of the onset and the severity of the symptoms, intense pain, vomiting, diarrhea and prostration, passing on to the terminal symptoms of peritonitis if unrelieved by operation. The

temperature, pulse and leucocyte count were all high. The signs were those of a diffuse septic peritonitis. In the primary circumscribed form the onset was acute with abdominal pain, vomiting and diarrhea. The fever and other constitutional symptoms subsided in ten or fourteen days. In this form the inflammation became encapsulated by adhesions and the fibrinous character of the exudate, so that in the second stage they had the formation of an intraperitoneal localized abscess. From the brief summary of the clinical manifestations of pneumococcus peritonitis, it was observed that there was little to distinguish it at the onset from an appendicular or perforative peritonitis. The fact that pneumococcus peritonitis occurred most often in children and in females and that it was regularly accompanied by diarrhea were the only distinctive features to assist in the diagnosis. The secondary diffuse form was no easier of diagnosis, for in more than half the cases the onset was obscured by the symptoms of the primary infection or by other secondary lesions. In the circumscribed form unless the history of the acute onset, or, in some cases, of the previous pneumococcus infection, was obtained the diagnosis was not likely to be made until the appearance of the localized abscess. Sometimes it had not been made until the latter burst, or was on the point of bursting. At the time of operation the gross pathological character of the pus was sufficiently marked to suggest the diagnosis, for the pus was odorless, yellowish, or greenish-yellow, and was distinguished by fibrinous flakes or masses in the pus, and on the bowel. Whether the peritonitis was primary or secondary did not appear to affect the prognosis. The treatment was surgical. Early operation afforded the best prognosis. The operative treatment was the same as that of other varieties of diffuse or circumscribed peritonitis, except that there was usually no portal of infection that required removal or local treatment. It was probably better for each operator to follow the technique he was accustomed to in acute diffuse peritonitis from other causes. Personally he generally employed drainage. In the encapsulated form the operation merely consisted in opening and draining the localized intraperitoneal abscess.

Dr. A. A. Berg said that it was his privilege to see a patient with basilar pneumonia of the right side; the pneumonia existed for four days; then there developed symptoms referable to the right hypochondrium. He thought there might be a perforation of a pyloric ulcer, and he kept the patient closely under observation for forty-eight hours. The question of a diaphragmatic pleurisy came up. Finally the question narrowed itself down to whether there was a peritonitis or a liver abscess which was approaching the liver surface causing peritoneal signs. When the peritoneum was opened there was a gush of almost clear fluid. Flakes of fibrin were noted on the right lobe of the liver. There was no perforation of the stomach or duodenum. He neglected to have a culture taken of the peritoneal fluid. He was surprised not to find any perforation. He was unable to state whether or not the exudate contained pneumococci. This patient went on to complete recovery. With regard to pneumococcus appendicitis he recalled the case of a physician who, after a severe pneumonia, developed a pneumococcus appendicitis.

Dr. Charles R. L. Putnam reported a case of pneumonia; the patient improved and developed pain in the abdomen which directed attention to the appendix. The abdomen was opened and the appendix was found to be normal, but the peritoneum was covered with flakes of fibrin such as were seen in pleurisy. No culture was made, but a smear revealed the pneumococcus. The patient died. One year ago he saw a patient with a localized pneumonia on the right side, but without very severe symptoms. There was extremely severe pain in the appendix. The abdomen was opened and the appendix was found to be but slightly inflamed; on account of the severe pain, the appendix was removed and there was no more trouble. This was a case of localized pneumococcus irritation cured by appendectomy.

Dr. Howard Lilienthal said that the care of these cases differed according to whether they were due to focal disturbances or not. If the appendix was the cause of the disturbance it should be removed; remove the focal cause of the disease whenever possible. It was not understood how the pneumococci gained entrance to the peritoneum. Patients with peritonitis of this nature usually got well without operation. The time to operate was when it was thought that there was a suppurative peritonitis; before that time it was better to play a waiting game.

Dr. George Woolsey said that often the diagnosis of these cases was not made until operation.

Tumors of the Bladder.—Drs. John F. Erdmann and Joseph F. McCarthy presented this communication. As a preliminary procedure in determining the nature of the surgical intervention to be followed one should, by means of cystoscopic examination, ascertain the exact location, whether the cause for removal be single or multiple, pedunculated or sessile, villous or cauliflower in appearance. The occasion for such examination would prove to be an intermittent spontaneous hematuria which was capricious, entirely independent of external causes. It was more marked when the patient was in bed, disappearing and reappearing without discernible cause. There might be intermittent obstruction to the outflow by either the mass or fragments plugging the internal orifice, as observed in one case of papilloma. For the cystoscopic examination it was best to employ an instrument carrying a direct and an indirect telescopic tube, thus giving a vertical as well as a horizontal picture. In this way one obtained a better idea as to the extent of the pedicle, a most important item in determining the mode of approach. Careful but thorough irrigation was a very important requisite in the conduct of this procedure. Beyond ascertaining the exact situation, the extent of the pedicle and the size and general physical characteristics of the growth one should not go. Least of all should one attempt anything more than a tentative diagnosis, inasmuch as pedunculation was by no means a definite indication of benignancy. Too much dependence should not be placed on the microscopic examination of particles expelled spontaneously and frozen sections at the time of operation might also be misleading. An induration of the pedicle at the site of implantation might be the result of a hypertrophy of the connective tissue element of a benign growth, rather than an indication of malignancy. It was well to reinforce a cystoscopic examination with a stone searcher examination as by this means one might determine fairly accurately the degree of infiltration present. Rectal palpation should always constitute a step in examination. It might also be advisable to catheterize the ureters before operation. Inasmuch, however, as the growth in the majority of cases was situated near one or the other of these orifices this procedure was frequently impossible. In the event of complete obstruction of one orifice the other should be catheterized to serve as a guide in locating the obstructed orifice. This should be attempted with the indirect prismatic cystoscope, or, this failing, with the Buerger cystourethrascope, or the aspirating cystoscope of Luys. The operative procedure would depend upon the pathological appearance, the location of the tumor, the type of attachment and whether one had a single growth or multiple ones with which to contend. Tumors which presented an appearance of infiltration about the pedicle or about the margins in sessile growths should be as fully removed as those pronounced malignant. In the soft pedunculated and

sessile type excision through the mucosa was all that was necessary. One could not attack a growth in the immediate vicinity of the ureteral orifice without being prepared to do a new implantation. When multiple growths were present either a wide removal of the surrounding mucosa or a partial resection of the bladder might be found necessary. Pedunculated growths of an apparently benign character situated in the immediate vicinity of the ureteral orifice might be removed as in another situation, without much fear of injury to the ureter. Infiltration growths situated about the ureteral orifice or on the anterolateral wall near the internal vesicle opening required fairly extensive resection through the entire bladder wall, at least two centimeters beyond the infected area. Infiltrated growths of questionable malignancy from a clinical standpoint and necessitating the removal of considerable bladder area might be removed after the method of Charles Mayo (*Annals of Surgery*, Vol. XLVIII, p. 107.) In view of the great number of intraperitoneal ruptures of the bladder operated upon, both by the general and special surgeon it appeared rather strange that the transperitoneal operation for the removal of bladder tumors had not been advocated years ago. In this operation, having stripped the peritoneum laterally down to and beyond the ureter, one resected through the entire bladder wall, either from without inward, or from within outward, as the case might be, employing the tumor mass and the ureter with its catheter as a pedicle. The bladder wall should be cut so as to permit of proper closure of the wound. The ureter might be implanted in that angle of the wound approximating its original situation, or it might be relocated by buttonholing the bladder wall, having in mind at all times the desirability of placing it as near its original position as possible, as well as the avoidance of kinking. Cystoscopic operative procedures should be limited to small pedunculated growths and the alleviation of hemorrhage in extensive recurrences. In three cases of well-pedunculated growths operated upon by Dr. Erdmann, the usual suprapubic operation was performed and it was found that a small portable electric light and a Kelly proctoscope or Ferguson speculum were of decided benefit. The former allowed of free inspection of the bladder, while the latter was a useful contrivance during cauterization, preventing burning of the healthy bladder beyond the seat of involvement. Although they did not close the bladder in these three cases of pedunculated papilloma Dr. Erdmann stated that he would certainly do so in any subsequent non-infected cases. The writers of this paper called attention to the effect of fulguration, which, although it was too soon to make definite statements, seemed to bring about a cessation of the hematuria in the vast majority of cases and this in itself was a distinct gain. The authors reported in detail ten cases and drew conclusions which were published in the MEDICAL RECORD, October. 22, 1910, p. 739.

Dr. MARTIN W. WARE spoke of the relative hopelessness of these cases; one could not tell whether or not such growths would become malignant. In the face of such a proposition they were only prepared to recommend operation on the basis of some strict indication. Was the growth obstructive? Was hemorrhage very excessive? Dr. Ware thought it was advisable to have a cystoscopic examination made if there was hematuria present. If there was not much obstruction and if the growth appeared benign it was advisable to watch the tumor for a while, asking the patient to return at stated intervals in order to determine if there was much increase in size of the tumor. In the mere presence of a growth, if there was not much bleeding, or if there was no strict indication, why interfere? He recalled a case that had been under observation for seven years; every once in a while there occurred a hematuria, but he was not much concerned regarding this. At last he removed the growth and promptly another growth appeared in the line of the cicatrix, and also a much more severe hematuria, and finally this patient succumbed. So far as the extraordinary radical operation for tumors of the bladder was concerned, the fact that there was a death rate of over 50 per cent. was a deterrent factor. With regard to the recommendation to remove the lymphatics concerned, that hardly seemed tenable. The observations of French urologists showed that there was nothing to fear in malignant disease of the bladder, on the part of the lymphatic glands such as they had to fear in malignant disease of the breast. In tumors of the bladder the essential thing was the infectious involvement of the kidney and ureters; this had culminated in the teaching of Watson of Boston that they should do something to prevent an eventual infection of the kidney by the performance of ureterotomy. If the hematuria was slight and the tumor was small, and if the patient could be kept under observation, operation was not indicated. The high frequency current had been effective in a few instances.

Dr. BENJAMIN S. BARRINGER said he was very much interested in the use of fulguration in the treatment of bladder tumors and had had the opportunity to assist Dr. Keyes in a number of cases. He had seen ten cases and there were two points in which he differed somewhat with what had been said by those preceding him. First was the ease with which fulguration was done. In the ten or more cases he had had there was no more difficulty in applying the wire to the tumor than there was in catheterizing the ureters. It was the mere matter of touching the tip of the wire to the tumor. Secondly, there was nothing unusual about the effect of fulguration; this was simply an intense cauterization.

Dr. LEO BUERGER said that fulguration was not a difficult procedure at all and was productive of very satisfactory results. He recalled one case of a large papilloma of the bladder situated over the left ureteral orifice. This case was under observation for some time. After the hematuria ceased the growth was removed. He also reported one case of a small papilloma in which but one treatment caused its disappearance. The fulguration treatment in his opinion was an excellent method.

Dr. A. A. BERG took exception to Dr. Ware's attitude that because of the high mortality attending operative removal of malignant disease of the bladder one should remain inactive and do nothing for this disease. That was by no means the attitude of the advanced surgeon. Malignant disease of the bladder, if left alone, would cause the death of the patient. He did not think that fulguration would be of much benefit in malignant disease of the bladder. He was unwilling to admit that carcinoma of the bladder was an inoperable and incurable condition. If one could readily get at the disease and resect a sufficient portion of that viscus, say one-half of it, there would be a chance for a permanent cure. In cases of pure papillomata of the bladder fulguration might offer the best treatment.

Malignant Growth Implanted on Cystocele.—Dr. A. E. GALLANT presented this specimen. The growth was as large as a child's head and so interfered with locomotion that it was removed.

Method of Preparing 606.—Kromeyer recommends the following method of preparing Ehrlich's arsenobenzol, 606: A stated amount of the drug, 3.0, for example, is thoroughly rubbed up in a mortar with a small quantity of liquid paraffine, and more and more is added up to 30.0; then each cubic centimeter will contain 0.1 of 606. Put up in dark glass-stoppered bottle and keep in a dark place. With this emulsion the intramuscular injections are made precisely as is done with that of salicylate of mercury, slowly, to prevent tissue damage, using also a somewhat stouter needle. In the course of 100 injections made, neither severe pain nor swelling was observed, and the clinical effect was prompt. Dr. Treupel and others believe that Kromeyer's way will very probably be followed by most practitioners.—*Berliner klinische Wochenschrift.*

Philadelphia County Medical Society.

At a stated meeting held October 26 Dr. G. Betton Massey exhibited a series of cases of malignant disease in various situations treated by means of zinc-mercury cataphoresis. The results were excellent and in some instances of long standing. Dr. Frances Ashley Faught read a paper entitled "The Clinical Value of Blood-Pressure Studies." He pointed out numerous directions in which estimation of the blood-pressure can be made of value in the recognition of morbid states and in the determination of therapeutic indications, and he contended that the sphygmomanometer should have a place in clinical medicine alongside of that of the thermometer and the stethoscope. Dr. Samuel D. Risley presented a communication entitled "Ocular Manifestations in Cardiovascular Disease." He described the thickened spiral retinal arteries of arteriosclerosis, with their marked light reflex, and compressing veins over which they passed as distinguished on ophthalmoscopic examination in cases of arteriosclerosis. Retinal hemorrhages may be due to the same cause, and hemorrhagic glaucoma may have a like origin. A number of illustrative cases were cited in which the underlying vascular condition was discovered on scrutiny of the fundus of the eye, with gratifying results from appropriate treatment. Dr. George W. Norris discussed "Sphygmographic Studies from a Case of Valvular Heart-disease, with Especial Reference to the Effects of Medication." He demonstrated by means of tracings the phenomena developed in the peripheral arteries as a result of disease of the heart, muscular and valvular, and the therapeutic indications derived therefrom, as well as the actual results of treatment. Dr. Henry D. Jump presented a communication entitled "The Value of Blood-pressure Estimation in Clinical Medicine." He pointed out the value of high pressure as a sign of arteriosclerosis and of its usefulness in the recognition of impending eclampsia; the occurrence of low pressure in typhoid fever, except on the occurrence of perforation of the bowel; of the indication for stimulating treatment in cases of pneumonia, when the pulse-rate approaches in number the blood-pressure expressed in millimeters of mercury; of the value of differences in pressure between the lower and upper extremities and between one side and the other in cases of aneurysm of the aorta. Drs. Myer Solis-Cohen and Albert Stickler presented a paper entitled "The Leukocyte Picture as It Reflects the Progress of Disease, Especially in Pulmonary Tuberculosis." They found that as the disease advances an increase takes place in the number of polymorphonuclear leucocytes, with a corresponding diminution in the number of mononuclear cells. Dr. Gordon J. Saxon discussed the question of "The Needle versus the Scalpel in Intravenous Saline Infusion." He pointed out the inconveniences of making an incision for the isolation of the vein and the introduction of a cannula, as contrasted with the simplicity and the convenience of merely introducing through the sterilized skin a needle attached to a rubber tube and a funnel.

The Hypophysis and Castration.—G. Fichera gives a résumé of the papers that have been written on the effect of castration on the hypophysis cerebri. In a case on which an autopsy was performed after castration it was found that congestion of the pituitary gland was marked; there was a condition of hyperactivity of the gland with chromophile cells. In animals an increase in volume of the hypophysis was noted and a functional hyperactivity. The whole gland was increased in size and the blood supply was increased by new capillaries. All the various authors speak of the hypertrophy of the gland after castration. In early pregnancy the gland hypertrophies, but this condition is only transitory.—*Il Policlinico.*

A CONSIDERATION OF SURGICAL METHODS OF TREATING HYPERTHYROIDISM.*

BY CHARLES H. MAYO, M.D.,

ROCHESTER, MINNESOTA.

IT is only within a comparatively recent period that our knowledge of diseases of the human body has progressed beyond new growths, degenerations, and infections. At the present time there is a return to the study of physiology, and many investigators are working actively on the normal and abnormal functions of the various glands of the body. While all of the glands may be classified as nutritive, eliminative, and protective, they are, nevertheless, so intimately associated in their function that it is difficult to estimate observations made upon healthy animals that are unable to record their sensations. In some of these cases the glands studied are evidently of much less importance in the economy than are the same glands in the human being.

The glands of elimination are provided with ducts, as are some of the glands of nutrition, and they are subject to intermittent discharge, while a few of the more necessary glands, so far as their secretion is concerned, are more slow in delivering an active secretion through the lymphatic system. The thyroid, parathyroid, and hypophysis glands belong to the latter classification.

It is difficult to estimate the degree of hyposecretion. Its entire absence could occur and ill effects be prevented by the activity of other glands of associate function. It is equally difficult to estimate the quantity of oversecretion which may be neutralized by the glands and organs of elimination.

From observations made in over 2,000 operated cases of thyroid disease, it is evident that there is a wide range in the changes manifest in the gland before it produces symptoms which we are able to recognize. Most of these glands are securely hidden from view, and observations as regards their condition have been developed upon the firm basis of pathologic study rather than the far less accurate observation of symptoms.

For a century and a quarter many observers reported well-investigated cases of hyperthyroidism from the standpoint of symptoms, and it was not until 25 years ago that Moebius advanced his theories regarding the disease known as exophthalmic goiter, Morgagni's disease, Flagani's disease, Graves' disease, and Basedow's disease, a condition due to an increase or perversion of secretion of the thyroid gland. The thyroid gland, which is usually accessible and even visible in the neck, is but little in advance of the other ductless glands in having established an accurate record of its diseases. The thyroid gland is of invertebrate origin and was originally a sex organ. This association is still retained, and is seen in the goiter of adolescence, in the goiter of pregnancy, and in goiters which not infrequently accompany uterine tumors and the temporary congestion of the thyroid at the menstrual epoch.

The changes seen in the thyroid gland, other than malignant or infectious, will be found to fall into one or more forms of the brief classification given by Dr. MacCarty:

1. The process of goiter may be a process of reversion of the thyroid gland to some former function.

2. Hyperthyroidism is a toxemia, the result of absorption of the products of the hyperactive thyroid.

3. The stimulus causing the hyperactivity may be the same that stimulated the thyroid activity in primitive man.

4. This stimulus was then probably a normal stimulus to the gland, just as we have normal stimuli for glandular activity in man in his present condition.

5. This stimulus may still be present in the food or water formed through some process in the intestine or in the metabolism of the body, or it may exist in the air.

6. The types of goiter are probably not types but stages in a general process.

7. Goiter may be classified upon a pathologic basis as follows: (*a*) Cystic goiter (thyroidea cystica); (*b*) hypertrophic parenchymatous goiter (thyroidea parenchymatosa hypertrophica); (*c*) papillary cystic goiter (thyroidea cystica papillare); (*d*) hypertrophic fetal thyroid (thyroidea fetalis hypertrophica); (*e*) fetal adenoma of the thyroid (thyroidea fetalis adenomatosa).

8. Hyperthyroidism always occurs in *b* and *c*, and may occur in *e*.

The surgical treatment of simple goiter is so nearly crystallized there is little to discuss concerning it. The operative mortality is very low, being reduced to complications and accidents. The operative treatment of hyperthyroidism is an entirely different proposition. The condition itself often causes death, and patients who suffer from it may be incapacitated, helpless individuals for long periods of time.

The greater number of patients who seek relief from goiter are to be found in these two classes; viz., simple goiter and hyperthyroidism. The first condition, which causes more or less pressure, is a nuisance to the individual affected, while the second condition causes ill health, affecting nearly the entire body. The local symptoms or size of the growth are of secondary importance.

It must be admitted that reversion of the structure toward simple goiter may occur at any time or

*Read before the New York Academy of Medicine, December 1, 1910.

stage of the condition, with, so far as is known, no more cause than that due to its origin. Other cases are apparently favorably influenced by some form of treatment. It is a matter of common observation that hyperthyroidism seldom progresses continuously without intermission toward a fatal termination of gland destruction unless it results disastrously during the first few weeks. It is now generally conceded that a reduction of the secretion is desired in hyperthyroidism, and to this end many varieties of treatment are employed.

From a surgical standpoint the ligation of vessels with nerves and lymphatics included seems to favor a reversion of the hyperthyroid condition to one of simple goiter. Dr. Miles Porter believes that the injection of a small amount of boiling water into the gland substance, after the Wyeth method in angioma, accomplishes the same purpose.

The early surgical work in hyperthyroidism, to a large extent, was done upon the most aggravated types of cases which had resisted other forms of treatment. The mortality of early operations made operative procedures almost prohibitive. The present low mortality has resulted less from an increase of operative skill than from a selection of the time for operation with reference to the activity or severity of the condition, and the type or extent of the operation.

The history of chronic hyperthyroidism usually gives many periods of fluctuation from mild to almost moribund conditions. The condition in the majority of cases is not so extreme that a partial thyroidectomy cannot be made with comparative safety. In the severe cases preparation of the patient should be an important consideration before advising any kind of operative interference. Early cases which might possibly be benefited for a time under medical treatment are often delayed until a condition develops which justifies a thyroidectomy. Such cases are now being treated by an early safe ligation of vessel groups at the upper poles. Very serious conditions complicated with dilatation of the heart, fatty degeneration of the heart and liver, nephritis, and possibly edema and cerebral incoordination are also benefited by a ligation of the vessels at the upper poles, at the same time or at separate operations. The mortality in these cases is about the same as it is for thyroidectomy, but the operation enables the operator to make an effort to relieve some of the patients who are so near moribund that an extirpation can not be considered.

The average gain in weight following operation upon patients below average weight is twenty pounds within four months. At this time, or later, a partial thyroidectomy can be made with almost no mortality, especially if patients who have relapsed are again tided over the exacerbation period by the ligation of one inferior artery, with an interval of a few months before extirpation is made. These conditions are due to an activity of function of the gland, and some few cases do not recover their normal health after operation because either too little of the gland was removed or the remaining portion of the gland increased its size and output of secretion. Such cases require ligation of some of the vessels, and a resection of the remaining lobe may even be necessary at a later period.

Over 1,100 patients have been operated upon for hyperthyroidism in St. Mary's Hospital. The mortality following ligation is 3 7-10 per cent., and that following extirpation is 3 9-10 per cent. This includes the high mortality of our early work when surgical deaths included many that should have been medical. It is true that we could count out continuous runs between deaths of 76 cases and 90 cases, even 150 cases with two deaths, but the general average is not so good. About 70 per cent. of the patients consider themselves cured, and apparently they are well. The others are improved but not well. Unfortunately they were not operated upon until they were suffering from extensive secondary degeneration and cytolysis of the gland. While the operation checked the toxemia, the result may be compared to that following the removal of a bullet from its location in the neck, without removing the damage done by its passage through the body.

The anesthetic given in these cases has usually been ether, preceded by 1/100 gr. atropine and 1/6 gr. morphine. Local anesthesia is occasionally considered best for the patient when the general condition is serious, or there are heart complications.

EXPERIENCES WITH ARSENOBENZOL.*

By WILLIAM S. GOTTHEIL, M.D.,

NEW YORK.

I DESIRE to put on record a series of cases of syphilis treated with "606" in my service at the City Hospital. The drug itself I owe to the courtesy of Dr. Flexner, and Dr. Noguchi of the Rockefeller Institute did many of the injections and most of the Wassermann tests. The remainder were done by the assistant visiting physician on my service, Dr. Satenstein, and the Sage Institute of Pathology connected with the hospital. I shall not refer to chemical, theoretical, or historical considerations about the drug, but shall confine myself to recounting my own experiences. These, I may say at the start, while in general satisfactory, have been in no way marvelous from the syphilographer's viewpoint. I must also premise that everything herein recorded refers to immediate results alone; there has not been time to form any opinion as to permanence of effect, and it must long still remain entirely uncertain whether that most devoutly to be wished for result, the complete and permanent cure of the luetic infection, can be attained by the new method or not.

The Cases.—Up to date I have given thirty-one injections in twenty-nine cases, two of them receiving it twice. A few of these cases are useless for our purposes, the patients for various reasons having disappeared from observation immediately after the injection or the treatments having been too recently administered. There remain twenty-five cases which have been observed for a minimum time of one week in one instance to three months. These were all hospital cases, under control and close observation, and they were watched and the results noted not only by myself, but by the assistant visiting, the house staff, the experienced permanent nurses in the wards, and various colleagues.

The patients themselves were of the types usual in a large public hospital, mostly rough and careless individuals of the lower classes, not sensitive to pain, and attracted to the hospital by the newspaper publicity that the new remedy has unfortunately got prematurely, and filled with the hope of getting rid of their infection at once and permanently. Their disease manifestations embraced the ordinary types, from the initial lesion to the late gumma, and a few

*Read at 104th annual meeting Medical Society of the County of Rensselaer, Troy, N. Y., December 15, 1910.

of the unusual ones also. Most of them, of course, showed more than one type of lesion, so that the twenty-five cases included four chancres, sixteen general secondary eruptions, eight cases of mucous patches, two cases of iritis, four cases of condylomata, six cases of tertiary ulceration of the skin and mucosa, and four gummata.

The Injections.—In the first sixteen injections the emulsion was employed, injected into the muscles of the subscapular region. In the remainder the clear solution was used, three cases receiving the medication in the two buttocks, divided into two equal doses, and the remaining six being injected in the right quadratus lumborum muscle. Almost without exception the injections were very painful. Even our very insensitive patients, on whom we make biopsies without local anesthesia and often without complaint, had to have morphine hypodermically at once, and now we give it in every case immediately after administering the arsenobenzol. Even with its aid there are always one or more pain-filled and sleepless nights. The one or two patients who did not complain loudly afterwards acknowledged the pain and insomnia.

At the present time we are using the clear solution and the quadratus lumborum route exclusively. The emulsion made after the method of Wechselmann, and injected into the deep muscles below or between the shoulder blades, gave us in almost every case a large persistent induration. In many instances it was the size of an orange, and in five cases it gave the patients so much trouble that interference became necessary. In about six weeks after the injection incision and drainage had to be done; there was always a small amount of arsenic in the fluid center of the tumor, but the most striking change was in their thick walls. The subcutis and muscle were in a state of dry necrosis, deep black in color, and entirely insensitive. In none of these cases that are still under observation has the process of slough extrusion yet ended, and it is a question whether the extensive tissue destruction by the arsenic has not to some extent interfered with the absorption and activity of the drug.

The gluteal site was rejected after trial on three cases. There was intense discomfort occasioned by having both glutei occupied by large, tense, tender infiltrations; the patients had to lie on their abdomens in bed, and could not sit down at all. In these three cases the clear solution was used, and the infiltrations did not require subsequent interference.

The quadratus lumborum site seems to be distinctly the best. In some of the six cases where we have used it a large, tense mass, extending down to the front of the abdomen, was formed; in one of these the skin over the tumor became dusky red, and it seemed as if something would have to be done, but it retrogressed in the course of three weeks, like the others. Of course, the occurrence of a necrosis like that observed with the emulsion in the subscapular injections would be a serious matter in the lumbar site, so near the kidneys and the abdominal organs, but we have not observed this necrosis in the nine cases in which the clear solution was used. The pain was about the same whichever method was employed.

The dosage has been practically uniform—0.6 for men, and 0.5 for women.

Renal Effects.—In not less than ten out of the twenty-five cases there occurred after the injections distinct symptoms of renal irritation in varying degree. This was shown by the presence of red blood cells in the urine, usually appearing the third day after the injection, but in four cases not seen until the seventh to the fourteenth day. In three cases this was merely temporary, the abnormal find disappearing in from two to twelve days, and in another case, in which albumin was also present, the same occurred. Three patients who left the hospital shortly after their injection still had red blood cells when last seen. In the three remaining cases hyalin and granular casts appeared later, and persisted up to the time of discharge, which in one case was two months afterwards. Every one of these injected patients had a negative urine before the medication was administered, since it was not deemed proper to inject it where there were any renal changes, and the patients were kept under observation for a few days before it was given. That the use of the emulsion cannot be blamed for this by-effect is shown by the fact that four of these ten renal cases occurred after the injection of the clear solution into the quadratus lumborum site.

Therapeutic Action.—Since my observation of the therapeutic effects of the new remedy differ to some extent from the unreservedly laudatory and almost hysterical praise with which it has been received, it will be well to intercalate here the briefest kind of a synopsis of the histories of the cases from which my conclusions are drawn. I submit the following cases:

Case I.—William H., 26; June, 1910. Pharyngeal mucous patches and eruption; 0.3, 606, Fordyce. Disappearance of mucous patches in two weeks; improvement of throat. By end of July mucous patches again, and moist papules of scrotum and prepuce (patient's history). October 6, 606, 0.6, emulsion, subscapular. In six days disappearance of moist papules; mouth unchanged. In two weeks, extension of mouth lesions; in fourth week, improvement; disappearance in six weeks, in spite of disadvantageous circumstances.

Unsatisfactory results from 0.3 dose; relapse; two weeks after 0.6 dose, extension of mucous patches; improvement in four and disappearance of lesions in six weeks. Successful case, but not comparing favorably with Hg. in time required. Steady diminution but not disappearance of the Wassermann.

Case II.—Alfred J., 20; colored. General miliary and pustular syphiloderm. October 11, 606, 0.6, emulsion, subscapular. Lastingly painful. No result in one month; new skin lesion, mucous patches, cephalalgia. November 11, 606, 0.5, solution, quadratus lumborum. Skin lesions still appeared; marked subjective symptoms, remittent fever. Ten days after second injection, sinovitis of left knee. Seven weeks after first injection, three weeks after second, patient left with skin eruption unproved and sinovitis still present. Red blood cells in urine one week after second injection still present when discharged.

Unsuccessful, in spite of two injections, one emulsion, and one solution. Marked renal irritation after the second. Six weeks' observation.

Addendum, Case II, December 18, 1910—Report by Dr. C. W. Bonney, Philadelphia, and Dr. E. H. Funk, Jefferson Hospital: Skin eruption unchanged; much joint pain; palpitation; urine negative. "A very low grade optic neuritis, not amounting to swelling or choking. No loss of visual activity; fields are normal."

Case III.—Mary G., 19. General macular; muc-

ous patches throat and labia. October 27, 0.5, 606, solution, buttocks. Pain and disability. In thirteen days slight fading af macular, disappearance of labial and buccal patches.

Fair result; time of observation too short.

Case IV.—Alice C., 50. Exulcerated gumma of leg. November 12, 606, 0.5, solution, quadratus lumborum; very painful. Stayed only one week in hospital; very slight improvement.

Time of observation too short.

Case V.—Sophie H., 22. Gummatous ulceration of palate and fauces. October 26, 606, 0.5, solution, buttocks; moderate pain. In two weeks marked improvement.

Good result; not striking.

Case VI.—George A., 29. Rupial general syphiloderm, pharyngeal ulceration, uninfluenced by short Hg. course. October 11, 606, 0.6, emulsion, subscapular. Improvement for three weeks; then periostitis patellæ. Refused a second 606 injection. Satisfactory improvement under mercury.

Failure, in spite of improvement of skin lesions.

Case VII.—Charles J., 23. General maculopapular eruption, angina, etc. September 30, 606, 0.6, emulsion, subscapular. Prompt disappearance of cephalalgia, spirochetes, and diminution of the Wassermann. In two weeks disappearance of eruption, save on palms. In four weeks, reappearance of the general and palmar eruption, with cephalalgia and general symptoms, increase of intensity of positive Wassermann and reappearance of spirochetes.

Failure; refused a second 606 injection.

Case VIII.—Edward B., 39. General tubercular syphiloderm, angina; mucous patches. November 11, 606, 0.6, solution, quadratus lumborum. In two weeks disappearance of the patches, considerable improvement in the eruption; patient then left. Red blood cells in urine one week after injection; present three days.

Good result, so far as observation went.

Case IX.—Frank K., 40. Chancre and macular exanthem, present since August. October 6, 606, 0.6, emulsion, subscapular. In three days initial lesion healed (patient's statement); in fourteen days eruption disappeared. The chancrous induration and the adenopathy remained, however, during the six weeks of observation. Red blood cells appeared in urine on fourth day post injectum and then disappeared.

Moderately good result; chancre had been present over two months and exanthem over one month when injected and were due to disappear. Wassermann practically unchanged twenty days after injection.

Case X.—Annie L., 46. Gummatous ulceration of palate and tonsil for six weeks, interstitial keratitis. October 13, 606, 0.5, emulsion, subscapular. Pain. Throat improved by fourth day, renewed ulceration on fifth day, then steady improvement and healing of throat in eighteen days. Eye lesion unaffected; serum test unchanged; induration mass at injection site. Time of observation, one month.

Fair result, with intercurrent relapse, in three weeks for throat; no effect on keratitis.

Case XI.—Isaac J., 18. Tuberculoulcerative syphilitic glossitis. October 11, 606, 0.6, suspension, subscapular. In two days pain in tongue gone, improvement beginning; in ten days erosions healed, ulceration less deep, tubercles smaller. Subscapular mass.

Fair therapeutic result in ten days.

Case XII.—Thomas A., 30. Extensive general tuberculoulcerative syphiloderm; retrogressing; iritis. October 13, 606, 0.6, emulsion, subscapular. In first week, exacerbation of iritis, increase of the skin lesions; in two weeks, iritis gone, skin lesions improved; in three weeks skin lesions healed; Wassermann positive reaction but slightly lessened.

Good result in three weeks.

Case XIII.—John H., 47. Papulosquamous syphiloderm, body, palms, and soles; moist papules of prepuce; nocturnal pains. September 26, 606, 0.6, emulsion, subscapular. No retrogression in one week, then pharyngeal mucous patches; Wassermann strongly positive. Urine, red blood cells; eruption got worse. In one month first betterment of eruption and moderate improvement in Wassermann. In six weeks marked improvement in eruption and negative Wassermann.

Neither subjective nor objective symptoms improved till four weeks; new symptoms had appeared. Noticeable betterment in six weeks, such as has occurred several times before under treatment (patient's statement). Time of observation, seven weeks. Improvement only; not successful.

Case XIV.—Charles K., 28. Extensive rupial general syphiloderm; mucous patches, tonsils, and velum. Wassermann strongly positive. October 2, 606, 0.6, emulsion, subscapular. Pain, forty-eight hours. Improvement began in three days, when red blood cells appeared in urine; later hyalin and granular casts repeatedly. On fourth day some new dermal lesions; on tenth day a new mucosal one. By fifteenth day most of the skin lesions were cicatrizing or healed, but by eighteenth day many new lesions and ulceration of tip of nose. In fourth week was given two salicylate of mercury injections, and then, through error, 606 again, 0.6 solution, buttocks. For four days after this general condition and lesions got worse; then steady improvement. All through November albumin and hyalin casts persisted. Large mass at site of first injection, with fluid inside containing some arsenic. Steady improvement in Wassermann until negative. December 11, all skin lesions healed.

Malignant case of doubtful significance; nine massive Hg. injections, as well as the two 606.

Case XV.—Ernest A., 29. Two exulcerated chancres, macular eruption, buccal mucous patches. October 13, 606, 0.6, emulsion, subscapular. In seven days slight improvement in symptoms; same in three weeks. Then periositiis of tibia, gumma of skin of leg, anal moist papule, faucial mucous patches. Large indurated injection mass, necrotic, with fluid containing arsenic. One month after first injection patient refused a second one.

Practical failure of 606; improvement slow and halting, as if with no treatment at all, and with new symptoms. Observed one month.

Case XVI.—Gustav J., 28. Phagadenic chancre, tuberculoulcerative and rupial general syphiloderm, mucous patches, ulceration of ala nasi. Many of the lesions retrogressing and partly cicatrized. September 26, .05, 606, emulsion, subscapular. The skin lesions improved for fourteen days, many of them healing; but in the third week there set in periostitis of a metacarpal bone of each hand, followed by periostitis of the malleoli; the nasal and penile ulcerations extended, and the general condition got much worse. The patient implored that something be done for him and he was put on a vigorous Hg. and K. I. treatment under which for two weeks he

improved only moderately. All treatment was then stopped, and under absolutely nothing but feeding and hygiene improvement was extremely prompt. Its beginning was apparent in two days, and in less than three weeks all the lesions had healed, ten pounds in weight was gained, and the patient was up and felt entirely well. He left the hospital in excellent health one month after all treatment was stopped. This patient also showed red blood cells in the urine for a few days after the 606 injection.

This must be put down as a failure; temporary improvement and then relapse with symptoms of serious import. In my opinion he was suffering from mercurial and iodic intoxication as much as from his infection.

Case XVII.—Andis D., 24. Indurated remains of chancre, palmar and plantar syphiloderm, papules of penis, mucous patches of lips, fauces, and uvula. Wassermann and spirochetes positive. October 7, 606, 0.6, emulsion, subscapular. Improvement in three days, but spirochetes still plentiful and red blood cells and granular casts in urine. Distinct improvement in six days, spirochetes disappeared, urine normal. One month after injection renewed outbreak of pharyngeal mucous patches. Being a recent immigrant, the patient was then deported.

Non-success. As usual, mucosal symptoms responded quickly, but relapsed first.

Case XVIII.—William L., 33. Exulcerated gumma of glands and sheath, very extensive; buccal mucous patches; Wassermann strongly positive. October 14, 606, 0.6, emulsion, subscapular. Improvement for several days, then stoppage and subsequent extension of ulcerative process. New gummata appeared and the ulceration was not entirely healed in six weeks. Large tumor at injection site, finally incised and found to contain arsenic. Patient refused a reinjection of 606.

Time of observation, six weeks; improvement extremely slow and hesitating.

Case XIX.—Gustav N., 30. General macular syphiloderm, condylomata, and moist papules of anus, perineum, and scrotum. November 19, 606, 0.4, solution, quadratus lumborum. Next day, red blood cells in urine, persisting one week. Prompt improvement in all the lesions; in seventeen days they had disappeared entirely.

One of the most successful cases, in spite of the small dose; renal irritation marked.

Case XX.—Elizabeth M., 30. Multiple chancres of labium majus, general maculopapular syphiloderm, angina, mucous patch of tongue. Eruption was already fading (patient's statement). October 27. Has had 1½ grains Hg. Sal.; 606, 0.5, clear solution, both buttocks. Much pain; no sleep. One week later genital lesions looked cleaner, otherwise unchanged; the eruption was still fainter and the mucous patch was gone. During the six weeks since that time the chancre has been steadily healing, but very slowly; it was still present and exulcerated on December 8. New moist papules have appeared on labia and perineum. Painful buttock induration persisted one month.

Practically a failure in six weeks.

Case XXI.—Sadie D., 20. General macular syphiloderm, angina; condylomalata of vulva and perineum. November 19, 606, 0.5, solution, quadratus lumborum. Much pain. Two days later, red blood cells in urine, persisting, with a trace of albumin for a week, and then disappearing. Condylomata disappeared in ten days, skin eruption in nineteen days.

Successful case, though not remarkably fast; marked renal irritation. Time of observation, three weeks.

Case XXII.—Isabella F., 23. Secondary macular syphiloderm, mucous patches of genitals, partly exulcerated. Wassermann positive. October 11, 606, 0.5, emulsion, subscapular. In two weeks all symptoms had disappeared (local treatment was used also). In third week relapse of plantar papules, lasting only one week. Induration mass troublesome and incised at sixth week. Necrotic tissue and some fluid containing the arsenite found.

A fairly successful case; symptoms disappeared in two weeks, with a temporary relapse in the third.

Case XXIII.—Annie S., 45. Induration of chancre in labium, with genital moist papules; general macular and papulosquamous syphiloderm; iritis; vaginal mucous patch; palmar and plantar syphiloderm. The iritis was retrogressing under atropin. November 11, 1910, 606, 0.5, solution, quadratus lumborum. Very painful, but gave no further trouble. In four weeks all lesions had disappeared. Red blood cells in urine two days after injection, persisting twelve days, then disappearing.

Successful result in a fairly malignant case; not especially rapid; marked renal irritation.

Case XXIV.—Louise C., 53. Ulcerated gummata of both legs. Wassermann very strongly positive. October 7, 606, 0.5, emulsion, subscapular. Painful. Red blood cells in urine once, three days after injection. Moderate improvement in gummata for ten days, then an intercurrent attack of erythema multiforme; stoppage of the improvement; new gumma one month after injection. No further improvement up to eighth week; then put on Hg.

Distinct failure. The erythema multiforme appeared ten days after the injection; query as to possible connection between them.

Case XXV.—Abraham G., 45. Extensive gummatous ulceration of dorsum of penis and glans. Under local treatment alone this has been steadily getting cleaner and smaller. October 6, 606, 0.6, emulsion, subscapular. Its influence on the gummatous ulceration was very slight; healing continued to progress slowly for six weeks and then stopped. Patient put on mercury and potassium iodide. Large injection site mass opened six weeks later, with the usual findings. Time of observation, eight weeks. Patient refused another 606 injection.

Failure; very little arsenic was found in the fluid of the injection tumor.

In the observation of these cases it has been my earnest endeavor to preserve an impartial attitude, and in judging of the results attained the purest objectivity has prevailed. Neither our natural and proper disapprobation of a proprietary remedy that has been marvelously exploited in the public press on the one hand, nor our respect for the great teacher who has proposed it and the many authorities who have advocated it on the other, should greatly influence our decisions. Of course the latter factors necessitate the greatest care in drawing conclusions, and more especially require a full consideration of any special factors that may have been the occasion, in part at least, of a record of results that are not in entire accord with those of others.

Two other points deserve consideration here. The attitude of the syphilographer, who sees lues every day, is very different from that of the general

practitioner toward it. The former finds in syphilis, in the vast majority of cases, a tractable and readily controllable disease; and he has, in the remedies habitually employed, most potent weapons that very rarely fail him. He is not surprised to see them effective in a few hours, or a day or two. It is of common occurrence to see a subjective symptom like the cephalalgia relieved in an hour and gone in a day after an effective mercurial dose; to note a gumma of the tongue, softening and threatening to break, disappear after one dose; or to find distinct signs of improvement in ulcerative lesions that may have been present for months, in two or three days. These things seem wonderful to those who do not see them often; but they are of everyday occurrence to those dealing largely with the affection. Our judgment, then, of the action of a newly proposed remedy for the disease is made by comparison with what we should expect from the older method of treatment in similar cases.

The second point is of equal importance. There is a radical difference of attitude to the disease in many parts of the Continent of Europe from that entertained here and in England and France. We look upon the malady as a long continued infection of gradually decreasing severity, to be treated with more or less persistence, symptoms or no symptoms, for long periods of time. On the Continent each outbreak is looked upon as an entity, a relapse, and each cessation of symptoms as a cure, at all events temporarily. More especially is this the case when in addition to the cessation of ordinary signs the serum reaction becomes negative. Looking over the lists of cases published in many of the European journals one cannot but be struck with the frequency with which patients in whom the symptoms have disappeared and the Wassermann has become negative are discharged as cured cases. The same thing occurs every day with mercury; yet we do not consider these cases as cured.

Analyzing the list above presented, it is evident in the first place that arsenobenzol exercises a distinct and powerful immediate curative effect on the manifestations of the luetic disease. The exceptions to this were only cases 2, 24, and 25, in which in six to eight weeks there was practically no effect. But in cases 6, 7, 13, 15, 17, and 20, while there was improvement, it stopped after a time, or there appeared new symptoms of the disease. Case 6 had a periostitis patellæ after three weeks; case 7 had a reappearance of eruption, general symptoms, increased Wassermann, and spirochetes once more four weeks later; 13 had new mucous patches at the fourth week; 15 had periostitis of the tibia, skin gummata, and moist papules at the same period; 16 had renewed ulcerations, bone, and general symptoms at a like time; 17 had mucous patches after one month, and 20 had new moist papules five weeks post injectum. Now I hasten to say that of these ten practical non-successes eight had been treated by the subscapular emulsion method and had larger or smaller persistent tumors; two of them were subsequently operated on, with the finding of necrotic tissue and arsenic-containing fluid in their mass. The other six, however, had the tumors that usually occur under this method, disappearing spontaneously in time. Of the two remaining failures one was treated in the glutei and the other in the quadratus lumborum, with the clear solution. It is quite reasonable to suppose that in some of these cases, at all events, and especially in those in which necrosis occurred, absorption of the arsenic was greatly interfered with; yet in the remaining six non-successes treated in this way there was no necrosis, and six other cases, with the same method, showed better results. I think it is fair to put down eight as the number of non-successes, possibly due in part to the method employed.

Nine cases I have noted as moderate successes, the symptoms either improving very slowly or the patients leaving the hospital prematurely. These are 1, in which it took six weeks for the mucous patches to disappear; 3 and 5, only under observation two weeks; 4, in the hospital one week; 9, in the hospital three weeks; 10, in which the interstitial keratitis remained unaffected; 12, in which the first improvement was not noted till twelve days after the injection; 14, in which two injections and six weeks were needed to make the symptoms disappear, and 18, which also took six weeks. Of these nine partial successes six got the subscapular emulsion and two were subsequently operated on; two received the clear solution in the buttocks and one in the quadratus lumborum muscle.

Frank and gratifying success was achieved in six cases; 8 had his mucous patch disappear and his exanthem almost go, though he was only observed two weeks; 11 had his pain in the tongue quickly relieved and many of the ulcerations healed, though only under observation one week; 19 showed disappearance of his macular eruption in one week and of his genital papules in two weeks; 21 lost her condylomata in ten days, her skin eruption in nineteen; 22 had her eruption and exulcerated mucous patches disappear in two weeks, and 23 had her skin and mucous membrane lesions and her iritis healed in one month. Some of these results were probably quicker than could be got from mercury; but in most of them our judgment was that it was about the same. Of these six best cases three received the subscapular emulsion and three the solution in the quadratus lumborum. One of the former (23) was a necrotic and operated case, and four of the entire five showed marked renal symptoms.

Out of the entire twenty-five cases there is no one that could be classified as an unusual or astonishingly brilliant result. The very best one or two were perhaps quicker than might be expected from mercury; but some of them were slower than we are in the habit of seeing. On the whole, and leaving out of account the necrotic subscapular emulsion cases, in which it may be assumed that arsenical absorption was largely interfered with, we concluded that similar results in a similar series of cases treated with mercury could be regarded only as moderately satisfactory.

General Considerations.—It seems probable that with the new drug we have to reckon with the possibility of damage to the kidneys in a certain proportion of cases. How large that proportion is, or how permanent the damage, are some of the many questions that only the observation opportunities of private practice can determine. Ten of our twenty-five cases had renal symptoms, in most instances transitory; but some had them when last seen, and one or two had casts. Similar occurrences under mercury are extremely rare; so rare that we practically never take them into account.

Severe pain seems to be an inevitable feature of the arsenobenzol injection, however administered.

This is controllable, of course, by morphia; but I am sure that some of our more sensitive private patients will demand anesthesia.

Rest in bed under skilled observation for several days or a week I consider an absolute necessity. A preliminary careful physical examination, to determine the absence of possible contraindications to the treatment in the form of lesions of the internal organs should never be omitted.

It seems premature for the present to attempt to give the indications for the use of arsenobenzol in syphilis; but it is my opinion that it is not as yet the treatment of choice in the ordinary run of cases. Definite lesions of the internal organs, syphilitic or other, are recognized contraindications and have so been proclaimed by Ehrlich. On the other hand, there are cases, though extremely rare, that are recalcitrant to the mercurial medication of a rational kind; these are subjects for arsenobenzol. And there are cases also in which, for personal and other reasons, haste is necessary, and in which any treatment that offers a chance of relief more quickly and more permanently than the mercurial one should be employed.

Of course the foregoing statements are based on our present knowledge of the drug, which is as yet without data as to the future fate of patients treated with arsenobenzol. If it should turn out that one or two injections, or a whole series of them, will permanently and indubitably cure the disease, then all considerations as to pain, hospital care, etc., will be entirely negligible; and even some degree of danger will be no contraindication. It cannot be said, however, that we have attained that knowledge as yet.

Finally, I may mention incidentally a fact of interest as regards our patients' attitude to the treatment. In our dermatological ward in the City Hospital this fall we had a regular syphilis club. Patients came in attracted by the knowledge that the treatment was given there; they watched all the cases and compared observations. It is a noteworthy fact that four patients there refused reinjection absolutely; one said that "he would not take it if it were offered to him on a golden plate," and the three others declared that they would leave unless they were given murcury.

I think I may venture from the foregoing to formulate certain statements premising that they are based on a comparatively limited experience.

1. Arsenobenzol is of undoubted efficacy in syphilis of various forms, more especially in early cases and in mucosal lesions.

2. Its immediate effect may be better, in some cases, than that of mercury; in others it is slower and less certain. In some cases it fails.

3. It must be used with care, since we are by no means fully informed as to its effects on the kidneys and other internal organs.

4. It should never be given in ambulant or office practice; the patient should be carefully examined before it is administered and should remain in bed under observation for several days after.

5. It is indicated in especially severe or malignant cases, in cases where mercury has failed, and in other instances in which there are reasons for unusual antiluetic measures.

6. While the luetic symptoms usually recede after one or two doses, we are as yet without knowledge as to the permanency of its effects.

MENTAL DISTURBANCES FOLLOWING TRAUMATISM; MEDICOLEGAL CONSIDERATIONS.*

By ALFRED GORDON, M.D.,

PHILADELPHIA, PA.

ASSOCIATE MEMBER OF THE SOCIÉTÉ MÉDICO-PSYCHOLOGIQUE, PARIS, FRANCE; NEUROLOGIST TO MOUNT SINAI, NORTHWESTERN GENERAL AND DOUGLASS MEMORIAL HOSPITALS.

Nervous and mental disturbances may occur after a traumatism of any intensity. They may develop immediately after the injury, or sometimes later, and in other instances at a very late period. The character of the disturbances may vary considerably, viz., from an ordinary irritability or slight mental obtusion to a high degree of mental confusion, with or without hallucinations, or else to a group of phenomena simulating the classical psychoses. Neuroses, such as traumatic hysteria and neurasthenia, will not be considered here. Although hysteria is a psychic malady, nevertheless this great neurosis with its physical and well-known phenomena, such as we observe in various forms of insanity, will be discussed in the present essay. A series of thirty-seven personal cases have been studied by the writer during a period of eight years. Great care was taken to accumulate only such cases, in which the onset of mental symptoms was in a more or less direct relation to traumatism. Consequently individuals, who, in the course of previous mental disorders sustained a traumatism and thus aggravated the preexisting mental malady, were not included in my series.

My thesis deals exclusively with cases apparently free from diseases, but in which mental manifestations made their first appearance either immediately after a traumatism or some time later. The conclusions at which I endeavored to arrive concerned four special problems: First. Does, scientifically speaking, a mental disorder follow traumatism? If so, what must be the nature and severity of the traumatism? Second. To what particular psychosis do posttraumatic mental disturbances belong? Third. What is the relation of traumatism to paresis as cause and effect? Fourth. What are the medicolegal inferences to be drawn from this study? The thirty-seven cases are an especially selected group out of several hundred traumatic cases which came under my observation for neurological reasons. The study was undertaken without any preconceived idea and irrespective of similar studies of other writers.

The first problem, viz., the relation of trauma to mental disorders as cause and effect, can be answered in the affirmative by all the thirty-seven cases. In twenty instances the mental derangement followed immediately the accident. In fifteen of the twenty there was loss of consciousness, and in five consciousness was preserved. The mental manifestations made their appearance as soon as consciousness was regained and continued for a period of from three days to three months. The nature of the manifestations will be discussed later. The minimum and the maximum of duration of the disorder in the twenty cases is pointed out as termination, either by recovery or death. It should also be mentioned that no history of mental disturbances preceding the traumatism could be elicited after a most diligent investigation among relatives and friends. In the remaining seventeen cases con-

*Read at the meeting of the Pennsylvania State Medical Society, held at Pittsburg, October 3-7, 1910.

spicuous mental phenomena began to make their appearance at a period varying from five weeks to three months after the traumatism. In order to determine the direct relationship of the latter, a prolonged and most careful investigation of the patients' previous medical life was undertaken. A special questionary was submitted to every one of the relatives, also to a number of friends and neighbors, and their answers compared and studied. Some of the cases were seen by me from the time the accident occurred. The conclusion at which I arrived was that, while the prominent mental disturbances appeared some time (see above) after the accident, nevertheless mild, almost imperceptible signs of some disorder relating to the psychic sphere were present in every one of the seventeen cases. Insomnia, more or less pronounced, irritability, slight lapses of memory, tendency to automatism in action and words, some indifference or indolence, frightful dreams are all symptoms which have been traced and observed. The latter subject is of a great practical value, as the slight or very slight degree of the disorder may be frequently overlooked and lead to erroneous etiological diagnoses. The recognition of these apparently insignificant manifestations is a weighty element, also in the medicolegal diagnoses where the determination of trauma as an etiological moment is of paramount importance, but this subject will be discussed later.

It is, therefore, evident that while the conspicuous manifestations of mental derangement made their appearances in the seventeen cases only after a more or less considerable period of time following the accidents, nevertheless some mental phenomena existed in a so to speak prodromal stage and prepared the individuals to grave disorders at a later stage. The latter can be considered as the result of a final and logical evolution of the former.

From an etiological standpoint it is important also to consider the patient's neurological status of health prior to the accidents. A very careful investigation in every one of my cases revealed the fact that all belonged to the category which it is customary to call "neurotic." While they were almost all free from well-defined nervous diseases, nevertheless a more or less marked degree of functional nervous disturbances was present. As soon as the trauma occurred, the latter became accentuated, new symptoms developed, or else the former went to the background to be overshadowed by manifestations of a more serious or more turbulent nature, and, as we have seen above, either immediately or some time after the accidents. The problem, therefore, of individual predisposition should be always taken into account while considering the etiological moments in the broadest sense of the term. The occurrence of such a predisposition existed in all the thirty-seven cases studied.

Having answered in the affirmative the direct relation of trauma to mental disorders, let us consider for a moment the nature and severity of the traumatism. In the majority of my cases (25) the accidents were of no serious immediate consequences as far as solution of continuity of tissues or organs is concerned. There were no fractures of the skull, no hemorrhages, no paralysis, or other apparent material damage visible to the naked eye. Intentionally is the latter circumstance emphasized, as absence of it does not always exclude a possibility of small hemorrhages within the cranial cavity, and in the brain, hemorrhages so situated as not to infringe upon important portions of the cerebrum the disturbance of which gives rise usually to external manifestations of paralytic or convulsive nature. This is the so-called "concussion of brain" cases. But the term concussion may imply a simple circulatory disorder which is momentary or else a genuine damage to the blood-vessels. Under the term "concussion" cases have been reported in which, in spite of a prompt recovery of consciousness and apparent freedom from immediate paralytic symptoms, serious organic conditions gradually and insidiously developed. In such cases there was a primary disturbance of blood vessels (nerves and arterial walls). Hyalin degeneration and round cell infiltration of arterial walls, dilation of blood vessels, aneurysms, and premature capillary endarteritis with obliteration of their lumen have been observed. As a secondary condition, degenerative changes in neuroglia and ganglion cells, with vacuolation, chromatolysis, varicosity, and atrophy, and finally disappearance of cells naturally follow. In cranial traumata of old or very old standing the following conditions had been found on autopsies: Cranio-meningeal, or meningocerebral adhesions, osteophytes, foci of softening, cicatrices, cysts, aneurysms, and neoplasms. Such conditions, as I said, have been observed in so-called concussions. This term, therefore, does not imply absence of serious damage. Kocher says that even after restoration of cerebral functions momentarily suspended from the shock one is never certain whether there is nothing left that may eventually create serious disturbances.

Ten out of the twenty-five cases lost consciousness, but promptly recovered. The others were merely stunned, severely shocked, but apart from a momentary vertigo, consciousness was preserved. In the series of twenty-five cases of which I am now speaking, without apparent material damage, are included twelve cases in which the conspicuous mental disturbances developed some time after the traumata. These findings are of great importance, as they tend to show that apparently insignificant accidents may lead to grave mental disorders and therefore, in any apparently slight trauma, the prognosis must be guardedly announced. This fact should always be taken into consideration when one is confronted with medicolegal problems. Concussion does not always mean a recoverable traumatic shock.

As to the character of the traumata in my cases, falls from a height were in the majority of the accidents; in some cases patients were thrown off trolley cars and train cars, and in some cases intentional blows on the head with heavy objects occurred. In all cases the head was the principal part of the body which sustained the injury.

Of the entire group of cases (37), twenty-five, as it was mentioned, suffered no external injury. The remaining twelve patients received quite serious injuries. There were six fractures of the skull and six patients with deep lacerated wounds of the scalp. In the latter class one could not tell whether in addition to the scalp condition there was not some small fracture of the inner table of the skull or meningeal hemorrhages. In the cases with the fractured skulls four were at first in a comatose state and grave psychic disturbances began to develop as soon as consciousness was regained. They all became hemiplegic on the left. Two patients did not lose consciousness, but im-

mediately showed abnormal mental manifestations, such as hebetude, confusion, amnesia, also delirium. The six patients with lacerations of the scalp, apart from a slight mental hebetude, which naturally would follow such a shock, began to show their conspicuous mental disturbances, but a more or less long time after the injury, viz., between two and six weeks. However, strictly speaking, they were not entirely free from symptoms during the interval. Mild, and very mild signs of abnormal cerebration could be detected by a close examination. Disturbance of attention, rapid fatigue when a conversation was carried on, and a certain degree of indifference to surroundings were some of these mild manifestations, but they were not sufficiently striking to attract a casual observer's attention. Here again we see that, should the slight symptoms occurring during the interval be overlooked, one would hesitate to explain the onset of the mental phenomena by the traumatic injury after a period of six weeks. The medicolegal importance of the subject is self-evident.

Let us now take up the second problem in our investigations. To what particular psychosis do posttraumatic mental disturbances belong? Do the latter present a special or a well-defined clinical picture? First of all, my cases show that slightness or severity of trauma does not always lead to corresponding clinical consequences. Some cases without apparent immediate results were followed by mental symptoms of a very serious character. On the other hand some of the cases with fractured skulls and with lacerated scalps remained mildly affected. However, it is safe to assert that generally speaking mild injuries and mild immediate symptoms are frequently followed by transitory mental disturbances. Loss of consciousness is equally not a guarantee for development of serious mental manifestations, as in some of my cases the consequences were not as tumultous and not as durable as in the cases without loss of consciousness.

Among various manifestations met with in various forms of insanity a *confusional state* occupied the first place in my cases. The majority (25) showed immediately or shortly after the accidents conditions that are not infrequently found in intoxications or infections of any origin. Loss of realization of things, impairment of memory, narrowness of the field of conscience, disorientation in space and time, and impairment of perception and comprehension were the chief manifestations of the confusional state of my patients. In certain cases delirious outbreaks with and without hallucinations of visual and auditory character, or else hallucinations in the sphere of general sensibility, were added to the above confusional phenomena. There is a symptom which was quite frequently encountered in the confusional cases. It is the so-called "Ganser's symptom" (*vorbeireden*). It is characterized by senseless answers to elementary questions asked of the patient and it is due to disorientation in space and time. Such patients give the impression of feeble-minded individuals or of simulators. Ganser himself (*Archives für Psychiatrie* Bd. 30, H. 2) believes it is specifically a hysterical symptom, but we know that it may be encountered in other conditions and affections, such as hebephrenia and catatonio. I have observed it in chronic intoxications and in confusional states, as also in hysteria. The symptom, therefore, cannot be considered characteristic of hysteria, as some writers with Ganser are prone to believe.

Several of the patients presented confusional states only periodically with intervals of apparent lucidity. One of them had four such attacks, the first immediately after the accident and lasting two weeks, the last one six months later. He finally recovered. Five patients of the confusional type died from intercurrent diseases, such as pneumonia and profuse diarrhea, at the end of between three and nine months after the trauma. While individual symptoms of the confusional state became ameliorated, nevertheless a gradual slowness of mentality with depression developed. It is difficult to say whether the dementia would have disappeared if death had not supervened. Complete recovery occurred in the majority (19), even in a few of the patients with severe injuries (3).

Five of the patients in whom immediate mental disturbances appeared and who lost consciousness, after a period of confusion, as described above, eventually, at the end of five months, simulated the picture of dementia precox and particularly the catatonic form. They showed a certain degree of resistiveness and negativism. They would not obey promptly the orders to move about, to take certain food, to answer certain questions, to sit down or get up. On rare occasions they would refuse altogether to carry out any of these orders. At all events there was a certain delay in actions. The analogy with catatonia appeared still greater at the time when they began to assume certain fixed positions. For several hours, for example, they would remain either sitting or standing and gazing in one direction. Curiously enough, in spite of this fixed attitude, they did not refuse food when offered. When not in the position, they were responsive to stimuli, would answer certain questions. The catatonic manifestations eventually disappeared, but a certain mental weakness remained for eight months. Four of these five patients recovered completely, one died.

Were they cases of true *dementia præcox?* At a superficial examination the picture just described reminds one of this psychosis, but a careful analysis of the phenomena forces us to reject that diagnosis. The resemblance is only apparent, but not a profound one. The chief characteristics of dementia precox are entirely wanting. The profound disturbances in the spheres of will, initiative, memory, attention, the lack of interest, the feebleness of affective sentiment, the absence of fear, hopes, and desires, the presence of apathy, indolence, abundance of hallucinatory images, which are all fundamentally characteristic of dementia precox, were completely absent in my patients. Besides, the absolute recovery without the least trace of remaining perversion of mentality or of affect is another argument against the above diagnosis. Moreover, the picture of catatonic stupor was very fragmentary and incomplete in my patients. Stereotypy was totally absent. The negativism and resistiveness were of very short duration and came on at rare intervals. The absoluteness in resisting all external influences, which is so typical of catatonia, was wanting here. We have seen above that, in spite of this somewhat continued fixed attitude, the patient did not refuse food. This easy breaking up of a catatonic position is very unusual, if not impossible, in genuine catatonia as a variety of dementia precox. As a last differential feature of the diagnosis should be mentioned the absence in my cases of a gradual accentuation of mental enfeeblement. It is, therefore, evident that the five cases with mental dis-

turbances following traumatism did not belong to the classical psychosis dementia precox, although at a superficial examination they could give the impression of the latter.

Three patients of the entire series were men somewhat advanced in years, above sixty. One of them fell down in a cellar and sustained a fracture of the skull, the other two belonged to the group with deep lacerations in the scalp. Two of them lost consciousness and their mental disturbances began to be manifest only two weeks after the accidents. Gradually delusive ideas developed in these individuals. Persecutory ideas of the vaguest nature and directed against the physician in charge, the nurse, the wife, and neighbors, all in succession, never persistent, not complete, changing the subject of persecution from day to day and sometimes in the same day—such was the state of mentality of my patients. One of the patients developed auditory hallucinations which did not enter into the delusional conceptions. The third patient had a hypochondriacal delusion with reference to the brain, which he claimed was replaced by sand. All the three patients were extremely emotional and restless. The hallucinatory patient either cried or screamed at the top of his voice, hearing spirits talking about him. At other times he was depressed so much that there was great difficulty in feeding him. In this state there were involuntary micturition and defecation. Gradually two of three patients lost their former delusions, lost their outbreaks of excitement, and imperceptibly began to develop the picture of pathological senility with impairment of memory, deterioration of judgment and comprehension, and loss of sustained attention. One lived five and the other eight months. The man with the fractured skull began to improve, and finally, at the end of the twelve months, made a complete recovery and resumed his former occupation as clerk.

Do these three cases belong to the group of *senile dementia?* The fact that their age was above sixty does not constitute a sufficient reason for the diagnosis of senile dementia. While delusive ideas and hallucinations, also depressive or exciting phases, are usually present in senile dementia, nevertheless they alone do not justify such a diagnosis, as these phenomena are observable in other psychoses. What characterizes senile dementia is a gradual and progressive deterioration of mental faculties. A progressive loss of memory, especially for recent events, with preservation sometimes of memory for old events, loss of knowledge of dates, absolute inability of holding attention, inability to acquire new facts and to retain them for any length of time, these are the main symptoms which are characteristic of senile dementia. Delusions, hallucinations, and illusions are not infrequently superimposed, but they do not necessarily characterize the psychosis. In my three patients the evolution of the symptoms differs totally from the picture just described. Recovery of senile dementia is an impossibility. My third patient, while he presented some manifestations of senile dementia, made, nevertheless, a complete recovery. In the other two patients the course of events does not justify the diagnosis of senile dementia. The mental disturbances, therefore, in the three aged individuals simulated, one may say, the clinical picture of senile dementia, but do not constitute a type of the latter affection. We cannot say that trauma is a direct cause of senile dementia.

The symptoms of the *manic-depressive* psychosis were observed in four patients. In them, shortly after the trauma, there developed a state of depression which was more or less marked in every one. A prolonged observation revealed the fact that the depression was not continuous, but it was frequently and sometimes very frequently interrupted by excitability. For example, in the morning a patient is morose, inaccessible; would sit in one place, refuse food, and be apparently deep in thought. Then a couple of hours later he would become very irritable and scream out, order people around, and move about. But what is particularly interesting is the state of confusion, with occasional delirious behavior, that predominated in these patients. At times they appeared to have hallucinations, as they gesticulated and talked to themselves. This group of symptoms was not complete in all the four cases, but the general picture was identical in each case.

To be sure, at first glance the elements of the manic-depressive psychosis are to be found here. Do they, however, constitute the typical picture of this form of insanity? In the first place, the individual phases of the latter are of longer duration. The patients usually go through the entire state of depression or excitement, get apparently well, and then, after a certain interval, which may be weeks or months, a new phase sets in, which again lasts a certain length of time. In my patients the morose, depressed attitude was frequently broken only for a very short while (half an hour or an hour). Besides, the excitement manifested was not of that vivid, alert state of mind characteristic of the maniacal phase of the manic-depressive group. My patients merely remained depressed, and showed rather outbursts of anger, irritability, than genuine gaiety, and overflow of mental and physical activity, which are so characteristic of the genuine psychosis. What particularly speaks against the latter conception is the state of extreme confusion observed in my patients, which is usually not present in the typical psychosis under consideration. The condition of my patients continued unaltered for a period of from three to nine months. Three made a complete recovery and one died from pneumonia, contracted during his depressed state.

A chapter of unusual importance is the relation of trauma to paresis. Much has been written on this subject and, while the majority of competent writers deny any relationship whatever, others consider trauma as an indirect cause, and still others (very few, however) look at trauma as a direct cause of paresis. Let us consider the problem as it presented itself in six of my entire series of patients.

One patient, a male of forty-six, business man, began to show suspicious symptoms on the fifth day after the trauma. Tremor of hands, lips, of speech, some ataxia of the lower extremities, increased knee-jerks, inequality of pupils, but no Argyll-Robertson pupils, and some mental depression with insomnia were the initial symptoms observed. They gradually became accentuated and a weakening of memory for recent events imperceptibly developed. The patient soon began to lose in weight, suffered attacks of *petit mal*, had several seizures in which he lost his speech for a period of two or three days, and complained of vertigo and of paresthesias in the lower extremities. At the end of three months he presented an unmistakable picture of paretic dementia of the depressive type.

The second patient, a bookkeeper of thirty-nine, developed symptoms of paresis eight days after a trauma. There was loss of consciousness during the first ten hours and then a semi-comatose state for twenty-four hours. The shock evidently was severe. Among the paretic symptoms the tremors were the first noticeable. Euphoria was the first mental manifestation. Self-contentment, with a tendency to expansion in every mental operation, was strikingly marked. The physical symptoms rapidly made their appearance, and when he came under the writer's observation he presented a typical picture of paresis.

The third patient, a man of fifty, business man, developed symptoms of general paralysis immediately after an accident. There was no loss of consciousness following the trauma. Rapid loss of mnemonic faculties, with a certain amount of depression, gradual loss of moral sense, and a tendency to excesses were the mental manifestations which developed rapidly. The usual physical signs were all present. The patient had also occasional attacks of *petit mal*. The course of events proved it to be a case of typical paresis.

The fourth patient, a man of fifty-eight, a tailor, sustained an apparently slight trauma. He fell down a flight of stairs, striking his head against the sharp corner of woodworks in the hall. There was no loss of consciousness. He got up and went about his work as usual. On the next day he complained of severe headache, had several chills, and felt weak. He remained in bed three days, still complaining of frontal pain and photophobia. He then had an epileptic convulsion of the general type. Mental hebetude followed for several days. His wife then noticed a peculiar manner of speaking, which gradually became more and more accentuated. Soon other typical signs made their appearance. He then began to have sudden paresthesias in the right arm and leg, but no convulsive seizures. Mentally, he was exceedingly depressed. His indifference and indolence to surroundings and to his family, of which he was very fond, became particularly striking. The picture was that of typical paresis.

The fifth case was that of a middle-aged man who fell down in a cellar. There was no loss of consciousness. On the next day his speech was so much affected that he could not be understood. Soon a tremor of the hands made its appearance. The speech became more distinct, but it was slow, and the r's and m's could not be pronounced without difficulty. The rapidity with which the symptoms developed was astonishing. At the end of three weeks he presented the typical picture of paresis. The mental manifestations consisted of a marked depression and total indifference to conventionality. He would urinate and defecate in presence of people and was extremely unclean about himself. Subsequent course proved the diagnosis to be correct.

The sixth case was that of a man of forty-three butcher by occupation, who was known to the writer for six months prior to the accident. The latter consisted of a fall from a trolley car. There was no loss of consciousness and no external injury. Before the accident the patient presented a slight inequality of the pupils, and a very slight intention tremor of the fingers. He also complained that for the last six months he would quite frequently make mistakes in figuring and in names. However, he attended to business regularly. Fatigue was also his frequent complaint. The sleep was somewhat disturbed. The knee-jerks were slightly increased. These few symptoms were, of course, insufficient for a final diagnosis. During six months there was no change in the patient's condition. When the accident occurred, the most remarkable transformation took place. On the next day a generalized tremor was noticed. Severe headache, with a slight elevation of temperature (99.5°), appeared. The speech became indistinct. The knee-jerks were much increased. Micturition was somewhat embarrassed, so that at times catheterization had to be done. Mental hebetude became apparent. At times he had visual hallucinations. The memory became markedly deficient. Gradually the entire picture of typical paresis became evident. In this case the symptoms of paresis were evidently present before the traumatism, but they were extremely slight, inasmuch as the relatives did not suspect the least disturbance, and I was consulted exclusively for the sense of fatigue. For six months the condition remained unaltered; the accident undoubtedly was a very violent stimulus for a rapid aggravation of the old symptoms and for development of additional symptoms of paresis.

A review of the six cases related would lead *a priori* to the conclusion that there is a direct relationship as cause and effect between trauma and paretic dementia. A careful analysis, however, does not permit such a conclusion. A close investigation of the previous medical histories of the first five patients revealed the fact that some of the manifestations of paresis existed before the traumatism. Relatives had been repeatedly questioned in that respect and in all cases, without exception, there were evidences of a gradually oncoming meningoencephalitis. In all I succeeded in obtaining a history of neurasthenoid manifestations with some weakening of mnemonic faculties. In all a certain tremor of the hands was mentioned. Vertigo with lapses of words was related as being frequent, and in case three a sudden loss of speech and two mild attacks of right hemiplegia six months before the accident were cited by the patient's wife. It is true that conspicuous mental manifestations were absent, as otherwise they would have been noticed by the patient's relatives, but that mild physical and very mild mental disturbances were present was proven beyond doubt after a very close questioning of relatives and friends. Moreover, suspicious evidences of a syphilitic infection were equally present. The first two patients gave a history of three and five miscarriages, respectively, the third lost his hair at the age of thirty-two and had ulcerations in the pharynx, the fourth patient presented thickened areas of both tibias, with four large scars in front of the legs; his wife had three miscarriages and one stillborn child that had patches on the face. The fifth and sixth patients presented cicatrices on the prepuce. With the exception of the last case, in which unquestionably paresis existed before the accident, the five patients presented strong evidences of the existence of paretic manfestations prior to the traumata, and the latter, however mild they might have been, were undoubtedly an exciting cause for a *further* development of the preexisting morbid condition. In the last case this cause was very conspicuous.

The six observations, therefore, do not permit one to assume that an external violence is capable

of creating an affection which ordinarily is independent of an accidental lesion. There is no probability that even very serious traumata could be the sole cause of paresis. They may serve as stimuli to a more or less rapid development of preexisting morbid phenomena. The latter may be so mild that they may pass unnoticed. In such cases trauma appears to be the direct cause of paresis, but, as we have seen above, the causation is only apparent. All that can be admitted is that it is possible that paresis without a traumatic shock would have perhaps developed less rapidly and followed a slow or a very slow course.

Medicolegal Considerations.—A problem of a most difficult and delicate nature is that of the relation of traumatism to mental disturbances from a legal standpoint. Not infrequently the physician is asked to determine whether a more or less old accident may be followed some time later (weeks, months, or even years) by morbid mental manifestations, such as dementia, paresis, etc., and whether the latter can legitimately be connected with the former. On the other hand, when mental disturbances make their appearance immediately or very shortly after a trauma, it is important to determine to what extent the traumatic shock enters as a causative factor in the etiology of the disorder. Finally, is trauma the only cause or does it play the rôle of a revealing agent, which acts on a brain endowed with a latent morbidity?

For a judicious discrimination of all the points bearing on the solution of these problems a knowledge of the pathogenesis and prognosis is essential. All cranial traumatisms are not followed by serious results. Sometimes severe traumata pass without consequences, but sometimes most insignificant traumatic shocks are followed by very serious results. Then again, if conspicuous mental phenomena develop some time after a traumatic shock, after the patient has resumed his usual mode of living, the expert should, in his investigations, consider also other exciting or predisposing elements that may lead to nervous and mental disorders, such as worry, undue fatigue, excesses, mental preoccupation, etc., which *per se* are sufficiently powerful factors in causation of mental disorders. It is, therefore, evident that no strict rules can be laid down for medicolegal diagnosis, but that each case must be studied on its own merits.

An examination must be conducted on the broadest principles. A careful and repeated investigation of the previous medical life of the patient is essential. Various diatheses and intoxications should never be overlooked. Syphilis or heredosyphilis, alcoholism, and saturnism may remain latent for a long period and be awakened by a traumatism. Alcoholism will alter the character of a posttraumatic delirium. Besides, a man may become a dipsomaniac following a shock and later on present mental disorders of alcoholic nature. In such cases there will be a striking disproportion between the physical or mental shock and subsequent mental disorder.

The most important element in the medicolegal arguments of cause and effect between the psychosis and traumatism is the presence of cerebral symptoms at the time of the accident and *their persistence*, even in the mildest form, during the interval between the traumatic shock and the confirmed insanity. Another important feature in posttraumatic psychosis is the appearance of mild and even insignificant symptoms immediately after the shock. They will remain as such a certain time and even a very long time, so that the impression is formed that the patient has recovered. Nevertheless these slight manifestations exist and may at any time, under the influence of some cause, become accentuated and become so conspicuous as to necessitate commitment of the patient to an asylum.

The histories of my six paretics are very instructive from this standpoint, that, while the morbid phenomena became manifest almost immediately after the traumata, nevertheless the latter were not the direct cause of the psychosis. A very careful investigation demonstrated the fact that imperceptible phenomena of a paretic nature were in existence prior to the traumatic shocks, but in all patients the symptoms were so mild that they could readily be overlooked. Should such a possibility be ignored or overlooked, grave errors will be committed, as otherwise the psychosis will be attributed directly and exclusively to the trauma, while, in reality, the latter was only an exciting factor for the rapid development of a grave cerebrospinal affection which had already existed in a mild form. It is, therefore, the expert's duty to bend every effort to make in every instance a most thorough investigation before rendering a medicolegal opinion on the relation of trauma to psychosis. This investigation must bear upon the following elements: Time of appearance of the mental phenomena; their character and intensity; their persistence or disappearance and reappearance; their amelioration or aggravation; the date of improvement or aggravation; the degree of improvement; the degree of aggravation; the existence of mild morbid phenomena before the traumatic shock, which can be determined only after a close and repeated questioning of relatives and friends. The medicolegal expert is also obliged to determine the curability or incurability of the mental disturbances, although this question is one of the most difficult ones, as it is impossible to ascertain in advance the damage done by the traumatism in spite of total absence of clinical manifestations. General experience teaches that delayed mental disorders, or those that appear conspicuously late after the trauma, are particularly grave. An apparently rapid recovery from the trauma does not always imply a favorable prognosis, as in some cases slow and insidious alterations may develop gradually a progressive mental deterioration.

Conclusions.—The present study permits one, I believe, to formulate the following remarks: Trauma may be a determining cause of abnormal psychic manifestations. The latter may follow immediately or some time after the trauma. When they become apparent weeks after the shock there is a suspicion that in a mild form they existed immediately after the accident. A thorough investigation will frequently reveal the presence of mild symptoms. Sufficient precaution should be exercised in regard to a possible existence of mental disturbances prior to the trauma. Trauma may act as a powerful stimulus to further development or accentuation of a preexisting psychosis.

Confusional states and delirium are the most frequent forms of insanity that follow traumatism and are caused by the latter. There is nothing especially characteristic in the traumatic confusional and delirious states that can differentiate them from similar states caused by other factors, such as intoxications and infections. Delusions and hallucinations may accompany the psychosis, but again they do not present special characteristics.

Dementia may be the ultimate result of persistent confusional and delirious states. There is, however, nothing characteristic in the slowness of mental processes and in the intellectual feebleness, and the inability of retaining various impressions typical of all dementias. Manic-depressive insanity, dementia precox, senile dementia are not caused by trauma. Traumatic psychosis may simulate some of the elements of these psychoses, but there is only a *simulation* and *not identity*. Paresis does not develop as the result of trauma, but the latter may hasten the development of the disease, and sometimes the development may be exceedingly rapid. This contention is in accord with the extensive researches of Gudden, Siemerling, Wollenburg, and others (see E. Meyer, *Deutsche medizinische Wochenschrift*, page 1329, 1905). On the whole it may be said that traumatic psychoses do not present a strictly defined morbid picture, but present a great variety of psychic manifestations which partly suggest the well-defined psychoses and partly are unclassifiable. Finally disturbances of a psychic order develop after a trauma, particularly in predisposed individuals whose nervous system is constantly threatened with a break and who are easily influenced by a shock of any origin. They are the so-called neurotic individuals.

LONG-CONTINUED HIGH BLOOD PRESSURE;

ITS RESULTS AND PREVENTION.

By WILLIAM HILLS SHELDON, M.D.,

NEW YORK

CLINICAL ASSISTANT, MEDICAL CLINIC, CORNELL UNIVERSITY MEDICAL COLLEGE.

In these days of conservation it seems not unreasonable to speak of the conservation of elderly persons. Now we no longer consider the person of ripened years an encumbrance, but rather pay him our highest tributes. Unfortunately, it is but too common to read in the daily papers of this or that prominent citizen stricken by cerebral hemorrhage or slowly dying of a failing heart. Can we do aught to prevent these numerous casualties? Can we do aught to conserve the strength of this or that useful personality that it may continue to contribute to the good of the world? I think we can, and the excuse for this paper is to point out some results produced by long-continued high blood pressure, which could be prevented if attention were paid to the first evidence of increased pressure.

Much is written about high blood pressure as if it were a disease in itself. Let us call it a condition rather than a disease. Its causes are diverse, and I wish to emphasize the fact that *its relief can be attained only by removal of those causes* and *not* by methods directed to relieve the high blood pressure itself. When high blood pressure has been long established a pathological condition is produced which is such that medical reduction can do little, if any, good. Long-continued high blood pressure produces a condition whereby there is a leakage of cardiac energy. Just as in the case of a badly leaking mitral valve there is an uneconomical waste of force, so is there in these cases. Moreover, while in the mitral cases we cannot measure the leakage, in these cases we can.

Let us review a few facts. With each systole of the ventricle blood is thrown into the arterial tree and distends it. It is by virtue of the elasticity of the vessels that diastolic pressure is maintained. Of course, we are assuming that the capillary and arterial resistance remains the same at diastole and systole. Now if the pressure is increased, the elastic traction is increased also. This, however, is only true when dealing with normal arteries. Whether arterial degeneration precedes or comes after high pressure matters little in the discussion. All admit that increased tension causes changes in the walls of the vessels. If we have a degenerated artery we would naturally expect reduced elasticity and, therefore, a failure of diastolic pressure to maintain its normal relation to systolic pressure. That is exactly what I have found to be the case in a series of thirty cases of high systolic pressure.

In the series given below records of systolic blood pressure and diastolic blood pressure were carefully taken by the Erlanger Graphic Blood Pressure Apparatus. They were chosen from several hundred records for the reason that none of the patients had valvular lesions. Many of the cases answered the description of chronic diffuse nephritis, in others the causes of high pressure were difficult to determine. I do not go much into the etiology of the production of the high pressure as I wish to point out the *results* and I think the various causes all lead to the same result. The ages of the cases given varied from forty-two to eighty years and, as frequently happens among persons of this class, many presented a diversity of conditions —cirrhosis of the liver, varying degrees of emphysema, etc. They all, however, had three features in common, sclerosed vessels, high blood pressure, and enlarged hearts.

Average.....	187.2	108 7	78.5

It is to be noted that the average systolic blood pressure in these cases is 187.2 and diastolic blood pressure 108.7, giving an average pulse pressure of 78.5. These figures give some interesting percentages.

Systolic pressure is made up of diastolic pressure and pulse pressure. The latter is obtained by subtracting diastolic pressure from systolic pressure. If we divide the pulse pressure by systolic pressure and diastolic pressure by systolic pressure we get the percentages of which systolic pressure is made up. Taking a normal systolic pressure of 130, diastolic pressure of 90, we have the

highest normal limit of pulse pressure, *i.e.* 40. By simple calculation we learn that systolic pressure is made up of 69 per cent. diastolic pressure and 31 per cent. pulse pressure. Now by a similar calculation of the averages given above we find that systolic pressure is made up of 58 per cent. diastolic pressure and 42 per cent. pulse pressure. It is evident, therefore, we have decidedly altered conditions to those we have normally.

The question naturally arises: Is the high systolic pressure in the nature of a compensatory act? If we have an arteriole that requires a pressure of 108 m.m. to force blood through it and the arteries are so degenerated that they require a systolic blood pressure of 187.2 to produce that pressure at diastole, it is evident that here there is a condition of decided loss of energy. To explain this a little more fully—the active energy of the circulation comes from the systolic contraction of the ventricles, the passive energy results from the storage of part of their energy in the elastic coats of the vessels. Anything that interferes with the efficiency of the latter increases the work of the former. If there is required a diastolic pressure of 108 a normal arterial tree will support such a pressure if systolic pressure is 148, therefore, we can measure its loss of energy, as it requires a systolic pressure of 187.2 in these cases: thus, $187.2 - 148 = 39.2$ m.m. A loss of 39.2 m.m. per beat of the heart is one of considerable importance. I wish to emphasize the point that blood must flow through the arterioles during diastole and that when there is an increased resistance and there are degenerated arteries, the systolic pressure output of the heart is enormously increased. The result of this is a tremendous strain upon the heart which, perhaps, is already infiltrated with connective tissue. The result of the strain is cardiac hypertrophy and later dilatation with failing compensation. Another question arises. Why are there signs of poor circulation with high systolic pressure? The answer is that diastolic blood pressure is not high enough to force the blood efficiently through a contracted vessel or if the vessel be dilated the diastolic blood pressure falls too low to allow of a perfect circulation.

As regards treatment, I think it is clear that in cases where high tension has been long continued we have an unalterable pathological condition. Therefore, we must concentrate our efforts on prophylaxis. As long as physicians neglect to include in routine examination the taking of blood pressure we shall see these advanced cases. An apparently insignificant rise of 20 m.m. to 40 m.m. is worthy of attention, and it is the duty of the physician to ascertain the cause of this increased pressure, and to remove it, thus preventing the inevitable bad results. In a number of cases the cause of heightened pressure is simply an irrational mode of life, and when this is corrected the pressure falls to normal again. Careful attention to the many etiological causes of high blood pressure will suggest its cure in the early stages. Too often the high tension is treated with vasodilators, as if it were in itself a disease, whereas observation should have been directed to the cause and its removal. One cannot lay too much insistence on the fact that high tension is only a signal with its red light to warn the physician of a danger that lies in the pathway and menaces the life of his patient.

When the high pressure has been long continued and a pathological condition established, efforts must be directed toward maintaining compensation. In one respect at least we are dealing with a condition similar to that which exists in valvular lesions, namely, a leakage. If, as often happens, the arterioles are incapable of dilatation we must consider the effect alone on the heart. The question arises: Is or is not the heart compensating? If it is, we must do all we can to keep it so, urging an easy life with much rest and moderate exercise, a sensible diet, baths, and massage. If the heart is not compensating the high tension seems no contraindication to digitalis. Indeed, I have seen the alternating pulse disappear under the use of that drug, which is contrary to Dr. MacKenzie's experience. Chloral sometimes has a magical effect in restoring the circulation without very often greatly affecting blood pressure. I am at a loss to explain its effect unless a greater amount of sleep and a sense of equanimity are responsible. Potassium iodide after prolonged use in some cases reduces systolic pressure and lowers the pulse pressure. Its effect, therefore, must be attributed to the actual changes it brings about in the arterial wall. The ordinary vasodilators have not met with favor as I have been unable to reduce the blood pressure with them and have produced disordered stomach and headache. Moreover if the arteries are so degenerated that they will not maintain normal pulse pressure, it seems illogical to try to dilate the arteries, as by so doing we would too greatly lower diastolic blood pressure and the heart responding to the reflex would have to pump the harder to maintain a balance. With regard to the headache and dizziness supposed to be due to high pressure, I have again and again seen them disappear with laxatives and diet, with no change in blood pressure. Most of the cases given above had excessive indican in the urine and I am inclined to believe that the headache and dizziness are due more to intestinal putrefaction than to high pressure.

Lastly I wish to urge the use of instruments in taking systolic and diastolic blood pressure. The usual method of taking it, by watching the movement of a mercury column, is misleading and, therefore, worse than useless. The graphic instruments of Gibson and Erlanger are admirable, but are too bulky and expensive for ordinary clinical work. An instrument has been devised by Mr. Nathaniel Fedde, a student of Cornell University Medical College,* which seems to meet all clinical needs. I have tested it, comparing its reading with those of the Erlanger instrument, and found it remarkably accurate. By this sphygmomanometer advantage is taken of the air compression produced by each pulse beat. The alternating increase and decrease which have so little effect on the mercury column cause oscillation of a pithball, the movements of which are of sufficient amplitude to be easily discernible and the last point of maximum excursion can be determined without difficulty.

Conclusions.—1. Attention should be drawn to the fact that high blood pressure is a condition and not a disease.

2. Long continued high blood pressure produces a condition whereby there is leakage of cardiac energy.

3. The arterial tree in health maintains diastolic pressure in normal relation to systolic. In cases of long-continued high blood pressure there is failure of diastolic pressure to maintain its normal rela-

*Medical Record, July 16, 1910.

tion, therefore, there must be lessened elasticity of the arteries.

4. The increased strain on the heart is in accordance with the amount of diastolic failure.

5. In a series of thirty cases the average pulse pressure was 78.5 m.m. while a normal arterial tree will give a pulse pressure of 20 to 40 m.m. Therefore, there was a loss of 38 to 58 m.m. of high pressure.

6. It would seem that in these cases the high systolic pressure was in the nature of a compensatory act, as in order to maintain a diastolic pressure of 108.7 it was necessary to have a systolic pressure of 187.2.

7. There are signs of poor circulation with high systolic pressure if the diastolic pressure is relatively too low.

8. If attention were paid to the first indication of increased pressure and the cause removed, the inevitable bad results noted could be prevented.

9. When the pathological condition of failure of diastolic pressure has been established our efforts should be directed toward maintaining the compensation of the heart.

I wish to acknowledge the courtesy of Professors Thompson, Coleman, and Meara for the opportunity afforded me to work in their wards in Bellevue Hospital and also for their kindly criticism and encouragement.

THE APPROXIMATE ESTIMATION OF PROTEIN (GLOBULIN?) CONTAINED IN THE CEREBROSPINAL FLUID.

By D. M. KAPLAN, M.D.,

NEW YORK.

DIRECTOR OF LABORATORY OF NEUROLOGICAL INSTITUTE, NEW YORK; SEROLOGIST TO MONTEFIORE HOME.

A few years ago Nonne introduced the ammonium sulphate test for the detection of globulin excess in the cerebrospinal fluid, and from the degrees of opacity obtained with this reagent arrived at conclusions which for a time attracted considerable attention. I followed closely the results of his work, but could not obtain sufficiently constant reactions to be able to depend upon it to any great extent. In America the butyric acid test introduced by Noguchi promised better results. He does not arrive at any quantitative conclusions, but claims that a negative butyric acid reaction indicates the absence of syphilitic changes in the nervous system. The butyric acid test was performed by me in a large number of cases, and although this is not the place to go into the comparison of results by different methods I am, however, prepared to say that a negative reaction with the Noguchi method performed *lege artis* does not always signify the absence of syphilitic change from the nervous system. In my opinion an increase of protein does not mean syphilis, nor is an absence of an excess of protein a guide sufficiently safe to point to the non-specificity of a given case. The only safe and more or less certain indicator of a syphilitic involvement of the nervous system is the presence of an unquestionable positive Wassermann reaction in the serum together with a marked pleocytosis (increase of cells in cerebrospinal fluid) and a strong globulin reaction, using minute quantities of fluid.

Using the Nonne reaction one has to become familiar with degrees of opacity in the fluid, which requires a retentive memory and a trained eye; a rather difficult state of affairs where standards are absent. The four degrees of opacity suggested by Nonne are empirical and by no means easily grasped even by experienced workers.

For the last six months I have endeavored to obtain a test which would not depend so much upon personal equation, as is the case with the Nonne method, as upon actual test tube appearances. I worked at first with various ammonium sulphate concentrations in decreasing quantities from 0.1 c.c. to 0.5 c.c., using increasing quantities of cerebrospinal fluid—from 0.1 c.c. to 0.5 c.c. No reliability was obtainable as the end reaction was never sharp enough nor constant enough to warrant its adoption for further study.

Having abandoned the ammonium sulphate method, I have experimented with the Noguchi butyric-acid test. Using 0.1 c.c. of cerebrospinal fluid, I was able to obtain tolerably sharp end reactions, but when I used larger quantities of fluid my aim of obtaining a more or less useful quantitative method was frustrated. It was impossible to obtain constant results, using the original Noguchi prescription of 0.1 cerebrospinal fluid 0.5 c.c. 10 per cent. butyric acid and 0.1 c.c. normal NaOH.

The chief reaction takes place between the fluid and the acid, and very little improvement or clearness in the end result is added by the use of NaOH. Bearing this in mind, I tried the butyric acid in much smaller amounts and obtained quite satisfactory results. It became apparent that the reagent, which will bring out in unmistakable clearness the end result, will also be able to show this in small quantities as in larger amounts of cerebrospinal fluid.

Ammonium sulphate added subsequent to the addition of the butyric acid seemed to do this admirably. I used increasing quantities of cerebrospinal fluid, starting from 0.1 c.c. up to 0.5 c.c., 2 drops of a 5 per cent. butyric acid solution, and 0.5 c.c. of a solution saturated with ammonium sulphate. Every case showing a lymphocytosis (I have access only to neurological material) also showed unmistakably the butyric acid-ammonium sulphate reaction, and the greater the lymphocytosis, the sharper the end reaction and the more constant its appearance in the tubes with the smaller quantities of cerebrospinal fluid. This finding impressed me very favorably, and I resolved to follow up its behavior in various conditions. Undoubted syphilis with a positive Wassermann reaction always gave the reaction when a pleocytosis was obtainable. Where no cells were found no reaction was evident.

I do not cite the number of cases this test was applied to, but I feel satisfied that preliminarily this reaction will be readily accepted, for the reason that its end results are conclusive and sharp, and that its appearance in the smaller quantities of cerebrospinal fluid could permit of quantitative deductions. The technique is as follows:

1. Centrifugalize the fluid and use the supernatant liquid.

2. Into each of five small test tubes introduce from 0.1 c.c. to 0.5 c.c. of clear fluid. The obtained fluid must be blood-free.

3. Heat the first tube (0.1 c.c.) gently and add 2 drops of a 5 per cent. butyric acid solution and heat until it bubbles—but does not spurt.

4. Holding the tube almost horizontally permit 0.5 c.c. of a supersaturated ammonium sulphate solution to float on top of the cerebrospinal fluid. The same is performed with the other tubes.

5. Stand aside, noting the time when the last portion of ammonium sulphate was added to the 0.5 c.c. tube.

In case of a protein excess a distinct ring appears in the middle of the fluid. This ring appears from 5 to 25 minutes after being set aside, is of a coarse granular appearance (cheesy) of a cream color. The greater the protein content the more apparent the appearance of the ring in the tubes with the smaller amounts of cerebrospinal fluid. The rings that appear later than 25 minutes are not characteristic. Negative fluids at times show a ring, but it takes from 30 minutes to over one hour before its appearance and the rings in this case are not composed of the coarsely granular material which is seen in the case of fluids with a protein excess.

Compared with other methods, my reaction, as said before, conforms to clinical diagnosis and other laboratory results oftener than the protein reactions of Nonne and Noguchi.

To illustrate: Mr. Z., 352 cells to the c.mm. Globulin reaction: Nonne method + No. 1; Noguchi method —; D. M. Kaplan method 0.1 +, 0.2 +, 0.3 +, 0.4 +, 0.5 +. Wassermann reaction serum +; cerebrospinal fluid —. Clinical diagnosis Lues of brain and cord.

Mr. O. R. No cells in fluid. Globulin reactions, Nonne, + No. 1; Noguchi — E; D. M. Kaplan, 0.1 —, 0.2 —, 0.3 —, 0.4 —, 0.5 —. Wassermann reactions, —; serum, —; cerebrospinal fluid.

Mr. R. Ten cells to the c.mm. Globulin reactions: Nonne —, Noguchi +; Kaplan 0.1 —, 0.2 —, 0.3 +, 0.4 +, 0.5 +. Wassermann reaction, serum —; cerebrospinal fluid —.

Mr. H. L. Forty-one cells to the c.mm. Globulin reactions: Nonne —, Noguchi —; Kaplan, 0.1 —, 0.2 +, 0.4 +, 0.5 +. Wassermann reaction: serum —; cerebrospinal fluid —. Clinical diagnosis — general paresis.

Mr. H. L. Forty-one cells to the c.mm. Globulin reactions: Nonne —, Noguchi —; Kaplan 0.1 —, 0.2 +, 0.3 +, 0.4 +, 0.5 +. Clinical diagnosis — general paresis.

The above cases are but a few of a larger number tested with the various globulin reactions. The D. M. K. reactions never showed the slightest trace of a positive outcome when the Nonne and Noguchi and the cell count were negative. The last case shows a negative Nonne and Noguchi—a positive D. M. K.—and a positive cell count. In one instance it gave a negative result together with the Nonne and Noguchi methods. No cells in the cerebrospinal fluid—with a positive serum Wassermann and a negative cerebrospinal Wassermann; the patient gave a history of lues. In another instance all globulin reactions were negative, 24 cells to the c.mm. were found in the cerebrospinal fluid—with a positive serum and a negative cerebrospinal Wassermann—in a patient with tabes.

I am at present engaged in a more extensive trial of this method and have in view the possible differentiation between cerebrospinal syphilis and general paresis, using the above test as my globulin indicator as well as other tests in vogue in serological research. My conclusions regarding the above test are rather brief; I wish, however, to emphasize: (1) The clearness of the end reaction; (2) Its possible use as a quantitative method; (3) Finally, the distinct differences between positive and negative fluids.

MERCURY SUCCINAMID IN THE TREATMENT OF TUBERCULOSIS.

By LEROY S. PETERS, M.D.,

SILVER CITY, NEW MEXICO.

The treatment of tuberculosis by the hypodermic injection of mercury has risen, flourished, and fallen; at least few men have been able to get results as claimed by Surgeon Wright of Fort Lyons, Col. The treatment created more or less interest both among the laity and physicians in general; among the laity, perhaps, owing to the wide advertising given it by the associated press dispatches; among physicians, no doubt, by the eagerness of the profession to grasp at any new remedy that offers a possible chance of curing the disease or lessening the ravages of the great white plague. We as physicians are a little too prone, perhaps, to rush in where angels fear to tread, and yet without this spirit of curiosity the science of therapeutics would forever be at a standstill and medicine to-day would stand where medicine stood in the dark ages.

Still the fallacy of all new methods of treatment, the use of old or new remedies now for a period of time, then the replacing of these same curealls on a corner of the back shelf and the trying of a new specific all point to the timeworn fact that nothing has been found in the drug line that justifies us in announcing a cure or even a remedy that works wonders, so to speak, in the treatment of tuberculosis. It is true that a few measures aid us in the fight, but as for knowing of any remedy that even hints at a specific we are as much in the dark as ever. It was not so many long years ago that Robert Koch announced to the profession a cure or what he thought might prove curative in tuberculin. Then as a body we flew to the new discovery, and even tuberculin fell into disrepute until recently and now again in a far less degree it is being used in suitable cases with apparently good results. I say apparently good results, because no one can say just how many given cases would or would not have attained the same happy outcome had the usual routine treatment and that only been followed. And now what I have said in general applies to the hypodermic injection of mercury in particular. With all due respect to Surgeon Wright I feel that he is wildly enthusiastic over the use of this drug, and that he has let his enthusiasm blind him in his reports from time to time. He has let the pendulum swing too far on the high road to recovery, and now after about two and a half years it has returned with a resounding whack and shattered all the fondest dreams of those who looked for wonderful results from the hypodermic injection of mercury. It is true, I suppose, that the doctor still has faith, and possibly a few others that have had better results than the majority of us less fortunate fellows. But from a study of current literature over this period of time and from personal experience covering a year and a half I fail to see why this particular method should longer be held up to the profession as a wonder worker or even a possible aid in our fight against tuberculosis.

A year ago, after six months' use of mercury, I predicted this outcome in a paper read before the New Mexico Medical Society at Roswell,* and now after adding another twelve months I feel that I have no reason to step aside from the stand I took at that period. Years ago this selfsame drug was used in the treatment of tuberculosis but with apparently no effect, and was then discarded for other

**New Mexico Medical Journal,* November, 1909.

"sure specifics" until the work of Wright again gave it impetus, and now a second time other investigators having proven its uselessness it is doomed to be cast into the field of oblivion and we trust allowed to rest in peace as far as its value in tuberculosis is concerned.

The other syphilitic who failed gained for a time, but from a pulmonary standpoint was hopeless in the beginning. Of the two non-syphilitic individuals one improved and one made a cure. However, I am firmly convinced that either would have done the same under any treatment, for both were excellent

Abbreviations used: station., stationary; hemor., hemorrhage; tb. int., tuberculous intestines; syph., syphilis; imp., improved, fist. fistula.

This much credit can I give, and my statement is borne out by the appended table. In cases giving a history of syphilis marked improvement is seen from the beginning of treatment. And here it is well to state that although Wright has excluded syphilis to his own satisfaction, no doubt much of his apparent success has been due to a syphilitic taint perhaps undiscovered, but nevertheless a silent factor. I cannot agree with Hartz of Philadelphia* when he claims that equally bad results are obtained with syphilitic and non-syphilitic individuals, and of course his work lacks weight when we consider the dosage he used—grain 1/5. This I found too high in the very beginning, and, as I showed in my first report, I was compelled to cut this in half in order to give the drug at all. The past year I have followed Wright's technique exactly, making my dilutions so that ten minims equal one-fifth grain, starting then with three minims and increasing one minim a day until the maximum dose of ten minims was reached, then after a few injections dropping back to seven and holding this to the end of the first series, unless contraindicated.

My work covers a series of twenty-three patients treated in a closed institution under perfect dietetic and hygienic conditions, and by following the tabulated report one can easily see that the results are far from confirming the work of Surgeon Wright, and that they do conform to the results of the majority of investigators along this line.

From an analysis of the foregoing table we get the following results; Stationary, 6; died, 2; failed, 9; improved, 4; cured, 2. It is interesting to note that of the six patients classed as improved or cured four were syphilitic and two cases of simple tuberculosis. One syphilitic made rapid gain under mercury but developed in the course of treatment a neuritis which was extremely painful and because of it we abandoned the injections. He went down rapidly from then on and is now a hopeless case.

*Journal American Medical Association, September 10, 1910.

patients with little pulmonary involvement. The nine who failed and the six remaining stationary were non-syphilitic with the exception of the two cases mentioned, numbers 18 and 7. Case No. 23 also developed a neuritis of the 3rd division of the 5th nerve and the injections had to be abandoned.

The two who died were also free from any syphilitic taint, one dying of bronchopneumonia following hemorrhage and the other was sent home as hopeless and died a few months later.

The number of cases would not justify one in making radical or dogmatic statements regarding the use of this particular form of treatment were it not for the fact that my observations are borne out by other investigators, and until we get a drug, serum, or what not that shows results that cannot be disputed, let us not be too prone to herald the long-looked-for cure for tuberculosis.

Value of Radiography in the Treatment of Adenopathies.—P. Oudin and A. Zimmern says that in several forms of adenopathies the use of the *x*-rays causes diminution of the size of the glands. The method, when properly controlled by shields over the normal parts, is without danger, and the only unpleasant effect observed is pigmentation of the skin. Irradiation much less in strength than to cause skin burns will destroy lymphocytes. The rays diminish the size of the glands in inflammatory swelling of the glands, in lymphatic leukemia, in cancer, and in tuberculosis, when treated early before caseation has occurred. Lymphosarcoma may be successfully treated with the rays. In tuberculosis of the glands we get first a parenchymatous reaction with proliferation of the gland follicles. Later the connective tissue elements undergo hypertrophy, followed by sclerotic action. Early tuberculosis offers a rich field to the treatment by the *x*-rays; in the stage of suppuration if the pus be evacuated a cure may be obtained; in the stage of atrophic sclerosis they have no further action. In chronic adenitis just below the skin the action is most remarkable. The glands soften gradually and finally entirely disappear. There is no reason to fear generalization of the disease as a result. The best method of treatment is by a series of short sittings. When atrophy is complete we should continue the sittings in order to prevent recurrence. The rays have an excellent effect on old fistulæ.—*Gazette des Hôpitaux.*

New York, December 31, 1910.

SURGICAL VERSUS EXPECTANT TREATMENT OF BRAIN TUMORS.

THE latest word on this subject emanates from the acknowledged master of brain surgery, Sir Victor Horsley, who in the *British Medical Journal*, December 10, 1910, surveys the experience of the past twenty years, which shows that the time has arrived for a complete reconsideration of the subject. The so-called expectant treatment is a delusion, he says, the administration of drugs for intracranial tumors is wrong, because it is useless. With this sweeping enunciation Horsley urges the absolute necessity of a recognition of the earliest pathological manifestations of brain tumor in order that surgical intervention may be prompt and therefore more probably effective.

These manifestations may be those of overaction, the irritative effects of lesions, or those of want of action, the destructive effects of lesions. The following propositions are advanced, namely, every case of focalized epilepsy not definitely proved to be idiopathic in origin must be treated by exploratory operation; the latter should be resorted to also in every case of progressive motor or sensory paralysis of intracranial origin. It is important to recognize the earliest symptoms of destruction in the various lobes of the cerebrum. The more frequent and systematic clinical inspection of cases will reveal the early deterioration of mental powers so characteristic of tumors of the frontal lobes. In lesions of the Rolandic region so much attention has been bestowed on coarse motor loss that the far earlier loss of Munk's "memories of movements" has been overlooked. Atopognosis may be present for months before there is any detectable loss of motor power, while astereognosis does not develop until motor paralysis is well marked. The early recognition of commencing restriction of the fields of vision, of alteration in tone appreciation, and of slight disorders of equilibration will secure early treatment of tumors of the occipital and temporal regions. Operation is thus indicated on the detection of earlier sensory loss; the loss of motor power, which is the last phenomenon to appear, is the one usually waited for before surgical steps are undertaken.

The conclusion is reached that every case of intracranial tumor definitely diagnosed must be treated according to its situation, either by removal of the neoplastic tissue or by release of the intracranial hypertension. Although Horsley has already observed that a simple decompression operation may cause arrest and complete degeneration of a glioma, he believes that, except in the case in which the field of removal involves direct destruction of the representation of such a single faculty as speech, free extirpation of neoplastic tissue should be the rule and mere decompression the exception. There are two conditions under which a palliative operation of simple decompression should be employed, namely, cases in which the neoplasm is known to be situated in a position from which it cannot be safely dislodged, and cases in which no localization is possible. In both these instances, Horsley maintains, the careful execution of a subtemporal decompression operation is the best procedure.

In regard to the treatment of syphilitic tumors of the brain, Horsley takes a stand directly opposite to the usual procedure in neurological practice. In the case of tumors which in spite of a negative Wassermann reaction cannot be pronounced definitely and at once as non-syphilitic, he urges, as he did seventeen years ago, that six weeks of antisyphilitic treatment is the utmost that should be allowed and that unless within that period not merely temporary alleviation but very substantial improvement occurs, the case should at once be treated surgically. Furthermore, it is noted that Sir William Gowers first pointed out the fact that syphilitic lesions of the brain are not really cured by antisyphilitic treatment and that after a period of respite the symptoms tend to recur. Horsley declares himself a partisan of this opinion and holds it applicable to gummata, pachymeningitis (including hemorrhagic pachymeningitis), both acute and chronic, and also the so-called syphilitic optic neuritis.

Sir Victor Horsley therefore declares himself absolutely against the proposition that was originally advanced by von Bergmann and that has been accepted as an axiom by the surgical world, namely, that syphilitic lesions, especially gummata, ought not to be subjected to surgical treatment. Horsley believes that the present lines of treatment should be remodeled in view of the analogy between the subdural and the intraperitoneal spaces. In cerebrospinal syphilis, just as in tuberculous peritonitis, he has obtained the most rapid improvement by opening the subdural space and irrigating with sublimate solution (1 to 1,000). Further, he suggests that since a gumma consists of a wholly necrotic focus of infective material it is important that it should be thoroughly eradicated as a similar tuberculous focus is treated. In addition, the subdural space should be irrigated with sublimate solution in order that one may secure the most direct treatment of the pachymeningitis which always surrounds a gumma cerebri, and also obtain a more immediate effect on the meningeal vessels which are affected with endarteritis. It is concluded on the basis of successful practical experience that in all syphilitic conditions of the nervous system the problem of rapid treatment is the same, namely, the local application of mercury by means of subdural irrigation.

THE INEXHAUSTIBLE TOPIC OF THE DAY.

To borrow a German expression, one might speak of "606 und kein End." The most influential German weeklies simply teem with articles on this subject. The current number of the *Deutsche medizinische Wochenschrift* (December 8), with no pretentions toward a symposium, contains no less than six elaborate articles, while the *Münchener medizinische Wochenschrift* (December 6) has three and the *Berliner klinische Wochenschrift* (December 5) two. We see here over half a score of articles published in a single week by three journals.

With the exception of the flood of commendatory articles after the announcement of the discovery of tuberculin, we cannot recall the parallel of this in the entire history of medical journalism. Michaelis covers the subject from the standpoint of the general practitioner. This article does not lend itself to abstraction, but the entire subject is exhaustively covered and the paper as such is worthy of a literal translation. Following Michaelis's article (in the *Deutsche medizinische Wochenschrift*) comes one by Oppenheim, which is wholly personal in character. This author's opinion as to the value of 606 in the neurological trinity of cerebrospinal syphilis, tabes dorsalis, and paresis is worthy of the most thoughtful attention. He cannot see that 606 does more for gummata of the central nervous system than mercury and potassium iodide. In regard to tabes dorsalis a few cases show notable improvement, but others again show injurious effects, while the majority are not influenced. The practitioner therefore assumes much responsibility in using 606 for tabes. In regard to paresis, Oppenheim has, however, seen one remarkable case of improvement among many indifferent results. This article is followed by a record of Rumpel's personal experience. The author in question is known for his monograph on lues of the nervous system published many years ago. He has, however, tested 606 in a great variety of non-syphilitic maladies, the microbic cause of which stands in some definite biological relationship with the *Treponema pallidum*. Rumpel appears to be an enthusiast. Not alone, according to him, is 606 a specific for syphilis, but it prevails over malaria and the Plaut-Vincent angina.

Next to Rumpel's article comes one from Carl Stern, well known for his work on the Wassermann reaction. Stern concludes that 606 is a remarkable specific, but not a cure-all. Stern is followed by Kromayer, a dermatologist, who gives valuable testimony. This writer decides that 606 does not evoke supersensitiveness when given in small doses. He would administer it in fractional doses.

In the *Berliner klinische Wochenschrift* (December 5) Touton of Wiesbaden begins a serial article, which, being unfinished, cannot be abstracted. Géronne, whose article follows the preceding, deals wholly with the intravenous method, which possesses little interest for the American practitioner.

Hirsch (*Münchener medizinische Wochenschrift*) sums up the general experience of ophthalmologists in the statement that 606 does not *per se* affect the optic nerve.

Has the Recognition of Bacilli Carriers Added to Our Prophylactic Resources?

The bacillus carrier is naturally most to be feared in institutions, especially in those which are overcrowded or poorly equipped and manned. The problems of this sort presented by insane asylums are clearly more difficult to deal with than those of institutions for the sane. Neisser (*Berliner klinische Wochenschrift*, Nov. 21) has recently discussed the experience of certain insane asylums from the carrier point of view and is forced to conclude from his limited and special experience that the discovery and isolation of the diphtheria carrier cannot prevent the recurrence of institutional epidemics. Lighting up of new epidemics and mere cumulation of cases in certain years are quite enigmatical in their causation. We must indeed continue to discover and isolate carriers, but the problem of sanitation must be equally considered, with special reference to the avoidance of overcrowding, and a sufficiency of intelligent nurses and keepers to offset the lack of cooperation by the irresponsible wards of the State. The special treatment of typhoid carriers is not difficult. The diphtheria carrier, on the contrary, sometimes requires months of isolation before he is free from disease. Preventive inoculation of diphtheria suspects may show up well in one institution, and may appear to cure the carriers. In other institutions it has been necessary to isolate the carriers until recovery. But the latter, as already stated, does not prevent renewed epidemics.

Injections of Cancer Residue.

In a paper read at the annual meeting of the Michigan State Medical Society at Bay City on September 28-29, 1910 (*Journal of the Michigan State Medical Society*), J. Walter Vaughan recounted his experience with the use of cancer residue. The object of injecting the non-toxic protein of the cancer cell, or cancer residue, was to find proof with regard to the formation of a specific ferment by means of a study of the various blood elements, particularly the leucocytes. Vaughan experimented on twelve persons suffering from malignant growths and drew the following conclusions: 1. The injections should always be small in amount, preferably 5 to 10 minims of a ½ to 1 per cent. solution. 2. Injections, according to present knowledge, should be controlled by daily differential leucocyte counts. 3. Injections should only be made when the percentage of mononuclear cells is on the increase. 4. A good blood reaction, by which is meant an increase of from 10 per cent. up of uninuclear cells following residue injection, tends toward a favorable prognosis. 5. If the blood count does not respond smaller doses should first be tried. If this fails to produce the desired change different residues should be used until one is found which will bring about this result. Vaughan's investigations are, at least, instructive and suggestive and it is possible that they point to a new method of treating cancer. If the principle of vaccine therapy is correct, then it would seem that Vaughan is working in the right direction, since the principle of his method and that of vaccine therapy are virtually the same. At any rate, according to those who have been in a position to pass opinions on the results of this treatment, the injection of cancer residue has had the effect of relieving the pain attendant on cancer. This alone would be an immense boon.

News of the Week.

Public Health Lectures.—During January and February a series of lectures on public health will be given at the Museum of Natural History, New York, under the auspices of the Board of Education, admission to which will be free. The program is as follows: January 7, "The Health of New York," by Dr. H. M. Biggs; January 14, "Communicable Diseases," by Dr. William H. Park; January 21, "The Relation of Flies to the Transmission of Disease," by Dr. H. D. Pease; January 28, "The City Milk Supply and Its Control," by Health Commissioner Lederle; February 4, "Tuberculosis," by Dr. Livingston Farrand; February 11, "Tuberculosis as a Social Problem," by Dr. James A. Miller; February 18, "Water Pollution and Water Purification," by Dr. C. E. A. Winslow; February 25, "Housing and Health," by Mr. Lawrence Veiller. The lectures are given at eight o'clock on Saturday evenings, and the course partially duplicates that given earlier in the year by Columbia University at the Horace Mann School.

Registration of Deaths.—In furthering its advocacy of a more careful and exact registration of deaths throughout the United States, the Bureau of the Census has issued a physician's pocket reference to the international list of causes of deaths. The bureau will upon application furnish copies of this leaflet, which has been prepared by Dr. C. L. Wilbur, together with specimen copies of the United States standard death certificate and of the model law governing registration.

Health Test for Hotel Employees.—In one of the large hotels of New York a system of supervising the health of the employees, in order that the guests may be protected, has recently been put into force.

Union of Hospital and Medical School.—Through the proposed agreement between the College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, which awaits only the formal action of the trustees of the former, it seems probable that New York will at last approach more nearly to the ideal in medical education. This union has been made possible by gifts to the hospital from Mr. Edward Harkness of a building to be used for a teaching and research pavilion, and from an anonymous donor, through Mr. Harkness, of a sum amounting to $1,300,000 as an endowment fund to be used solely in support of the educational and scientific work of the hospital. The condition of the gifts is that the hospital ally itself with an educational institution to which shall be given the right to make nominations to all the positions on the hospital staff, the ranking professors in medicine and surgery in the school to hold appropriate positions on the hospital staff, and not to be connected with any other hospital; the departments of pathology and bacteriology in the college to be allowed to conduct classes in the hospital, and a director of the surgical research laboratory to be appointed who shall be a member of the teaching staff of the college and shall be allowed to teach in the hospital. As a further condition, the College of Physicians and Surgeons is named as the medical school with which the hospital allies itself so long as the college is in a position to carry out its share of these conditions and complies therewith. In the event of its failing to comply with the conditions another medical school may be selected by the hospital. The Presbyterian Hospital not long ago acquired property on the east side of the city comprising the entire block between Sixty-seventh and Sixty-eighth streets, Avenue A and the East River, and adjacent to the grounds of the Rockefeller Institute. On this it is proposed to erect a new group of buildings which will afford ample ward and laboratory facilities.

Cost of Hospital Patients.—In its appeal for funds for the coming year the Hospital Saturday and Sunday Association includes a statement as to the increase in the expense of maintaining hospitals as compared to ten years ago. It has been found that in one institution, selected as typical, the daily cost per patient in 1900 was $1.17, while in 1910 it was $2.06. At the institutions represented by the Association over one million days of free treatment were given last year.

Von Leyden's Clinic.—Dr. H. Serena Mendes writes to deny the reports current in this country to the effect that Dr. von Leyden's clinic in Berlin has been closed since his death. On the contrary the clinic is being continued at 4a Corneliusstrasse, under the direction of Prof. Dr. Paul Lazarus, Dr. von Leyden's pupil and assistant.

Child Mortality in Detroit.—Following the publication of the mortality statistics for 1909, prepared by the Bureau of the Census, a protest was heard from the health authorities of Detroit, who claimed that the ratio of deaths under one year to the total deaths in that city was incorrectly given. The Detroit people asserted that this rate was only 20 per cent., while the Census Bureau gave it as 29 per cent. Dr. Wilbur, therefore, himself went to Detroit and with State representative made a careful inquiry into the records, with the result that the Detroit health officers have admitted the correctness of Dr. Wilbur's figures, and have decided to change the present system used in the registration office. In view of the criticisms from many parts of the country of the figures issued by the Bureau of the Census, the results of this careful investigation are of particular interest.

Civil Service Examination.—The United States Civil Service Commission announces an examination to be held on January 21, 1911, for the purpose of filling a vacancy in the position of physical director and assistant disciplinarian at the Haskell Institute, Kansas, at a salary of $800 a year. Applicants must be graduates of medicine, between the ages of twenty and fifty years, and should apply at once to the United States Civil Service Commission, Washington, for Form 1312. The application must be properly executed and filed with the Commission before the closing hour on January 21, eligibility for the position being determined solely by the evidence furnished by the application and examination form.

The Chattahoochee Valley Medical and Surgical Association will hold its ninth semi-annual session at Columbus, Ga., on January 10 and 11, 1911. An interesting and comprehensive program has been arranged. The president of the association is Dr. J. S. Horsley of West Point, Ga., and the secretary, Dr. W. L. Love of Opelika, Ala.

Colbert County (Alabama) Medical Society.—The annual meeting of the society was held in Tuscumbia, on December 14, officers being elected as follows: *President*, Dr. C. W. Williams, Chero-

kee; *Vice-President,* Dr. J. W. Maxwell, Sheffield; *Secretary-Treasurer,* Dr. J. T. Haney.

Insurance Company Hospital.—Notwithstanding the opposition of the residents of Saratoga Springs, the Metropolitan Life Insurance Company of New York has been granted permission to establish a hospital for the treatment of tuberculosis at Mount McGregor, the permit being issued by Dr. Porter, State Commissioner of Health, and Dr. J. S. White, Health Officer of Town of Moreau. The residents of Saratoga Springs who opposed the plan urged as an objection the possible damage to the mineral waters and to the property interests of the town; but the commissioners declare that the sewage of such an institution can be easily disposed of, and any possible contamination of the waters prevented. The site selected is about eight miles from Saratoga. The hospital will be maintained by the company for the benefit of its employees suffering from tuberculosis.

Straus Depot in Washington.—The authorities of the District of Columbia having failed to take over the pasteurization plant established in Washington by Mr. Nathan Straus of New York, the donor has announced that he has reconsidered his determination to withdraw his support on January 1, and will continue to operate the laboratory for the present. It is hoped that the Government will eventually decide to carry on the work itself, and that Congress may at this session take the necessary action.

Bridge for Charity.—The directors of the New York Throat, Nose, and Lung Hospital have received $2,050, to be used for their Tuberculosis Department and Night Camp, as the result of a bridge tournament held recently at the Plaza Hotel.

Head of Ambulance Board.—The New York Municipal Civil Service Commission has finally approved the appointment of Dr. Daniel C. Potter as Director of the new Board of Ambulance Service.

Epidemic of Mumps.—The bluejackets in the Naval Station at Norfolk, Va., are suffering from an epidemic of mumps, and one entire company of 136 men has been placed under strict quarantine.

More Centenarians.—At the age of 107 years, James Foster of Kansas City is reported as seeking work and refusing charity. Mrs. Rosanna Carroll, probably the oldest resident of Brooklyn, N. Y., died in that city, on December 18, aged 102 years.

New Brooklyn Hospital.—The Caledonian Hospital Society of Brooklyn, which was organized two years ago, has purchased an old mansion and the spacious grounds around it at the junction of Woodruff and St. Paul's avenue, Flatbush, on which it proposes to erect a modern hospital. The present house will probably be remodeled and equipped for use until funds can be obtained for a more suitable structure.

Operation on a Lion.—Surgery under somewhat difficult conditions was carried on at the Zoo in Central Park in New York recently when Headkeeper "Bill" Snyder operated on a fourteen-months-old lion cub, removing a fibrous tumor mass from its throat. After some strategy the animal was blindfolded and tightly lashed to the bars of its cage. Cocaine in liberal quantities was then injected into the neck in the region of the tumor and the mass removed. Unfortunately, although the operation was said to be an entire success, the patient died the next day—a result which, it must be confessed, sometimes attends operations done under far more favorable circumstances.

Charitable Gifts.—By the will of the late Mr. Michael Cudahy of Chicago, bequests of $2,500 each are made to St. Elizabeth's Hospital and St. Joseph's Hospital of that city.

Lebanon Hospital, New York, receives $2,500 under the will of the late Mrs. Charles W. Rockwell of Scranton, Pa., while in Scranton the West Side Hospital and the West Mountain Sanitarium each receive $10,000, the Hahnemann Hospital $5,000, and the Taylor Hospital and the Carbondale Hospital each $3,000.

The Flower Hospital, New York, receives a bequest of $5,000 for the endowment of a bed under the will of the late Miss Charlotte Dellinger of New York.

The Babies' Dispensary and Hospital Association of Cleveland, O., has received a gift of $100,000 from Mr. and Mrs. J. H. Wade, in memory of Mrs. Anna R. Wade, for the purpose of completing the dispensary building and milk laboratory.

Christmas gifts amounting in all to $1,500 were sent by the treasurer of the Friendly Sons of St. Patrick to various hospitals in New York as a recognition of their services to the Irish poor. This is a time-honored custom.

The Anna Jaques Hospital of Newburyport, Mass., receives a bequest of $200,000 by the will of the late Mrs. William O. Moseley of that city.

Phi Alpha Sigma.—The first chapter of this, the oldest medical fraternity in the country, to be organized in the West, was established in Chicago on December 17, when a class from the Northwestern University Medical Department was initiated. The initiation was in the charge of Dr. Thomas C. Chalmers and Dr. N. B. Van Etten of New York, and Dr. R. V. Patterson of Jefferson Medical College, Philadelphia.

Society of Hospital Internes.—The first regular clinical meeting of this newly organized society was held at St. Luke's Hospital on December 19, when an interesting program was presented by the members. Dr. N. B. Potter, the originator of the idea, also spoke on the purposes, scope, and advantages of the society. Representatives were present from St. Luke's, the Roosevelt, New York, City, Post-Graduate, Bellevue, and Mt. Sinai Hospitals. The next meeting will be held at the Roosevelt Hospital in January, the exact date to be announced later, at which the Committee on Constitution will report and the society will be permanently organized. Internes of all the New York hospitals are cordially invited to be present. Dr. H. W. Ernsheimer of Mt. Sinai Hospital is the chairman of the committee.

Obituary Notes.—Dr. David Sherwood Kellogg of Plattsburg, N. Y., a graduate of the University of Vermont College of Medicine in 1873, health officer of Plattsburg from 1878 to 1880, pension examiner from 1883 to 1900, and for several years acting assistant surgeon in the United States Army, a charter member of the Northern New York Medical Association, and a member of the New York State and Clinton County Medical Societies, died at his home, on December 19, aged 63 years.

Dr. Thomas J. Collier of Griffin, Ga., a graduate of the Tulane University of Louisiana in 1867, and a member of the Georgia State and Spalding County Medical Societies, died at St. Joseph's In-

firmary, Atlanta, on December 12, aged 69 years.

Dr. Charles E. Stone of Marysville, Cal., a member of the American Medical Association and of the California State and Yuba County Medical Societies, and superintendent of the County Hospital, died at his home on December 10, aged 82 years.

Dr. James Edgar White of Springfield, Ill., a graduate of the Rush Medical College of Chicago in 1883, and of the New York Post-Graduate Medical School and Hospital in 1894, a member of the Illinois State and Champaign County Medical Societies, and supreme medical director of the Court of Honor, died at his home on December 10, after a long illness, aged 55 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRADSHAW LECTURE AT R. C. S.—SIR A. P. GOULD ON CANCER—HEART STRAIN AND DILATATION—TWO EVENINGS' DISCUSSION AT THE MEDICAL SOCIETY OF LONDON.

London, December 9, 1910.

The Bradshaw lecture at the Royal College of Surgeons was delivered on Wednesday by Sir Alfred Pearce Gould, senior surgeon of the Middlesex Hospital. Cancer being his subject, he referred at the outset to the excellent work of the Imperial Research Fund directed by Dr. Bashford. Having remarked on the little influence of environment, though certain occupations were attended with special liability to the disease, Sir Alfred said it occurred in cell vertebrates, could be transferred from host to host, but the fact was far more important that it could not be transferred to an animal of another species. Passing to the work of the Middlesex Hospital Cancer Research Laboratories, he said the cancer cell was not an alien cell, but was under the same influence as its normal neighbors. Its life was disorderly, irregular, with a minimum of differentiation and function. Cancer was not a disease attacking the body from without, it was the result of some failure or breach of fundamental cell law, obedience to which resulted in perfect development, health, and length of days. Certain conditions had an influence on its causation, as age and sex, the effects of *x*-rays and alcohol. Mortality statistics showed its incidence in any occupation varied with the attendant habits as regards alcohol. Among the men insured in the Temperance and General Provident office the deaths from cancer in abstainers were 72 as against 100 in the moderate drinking section.

Sir A. P. Gould then expressed the opinion that clinical experience and experimental pathology threw a ray of hope across the dark sea of malignant disease. The primal laws of development held the cells of the tissues in true and loyal obedience to the very end in an almost infinite variety of conditions and the great majority of persons. The initial fact of the immunity of people from cancer was that 90 per cent. of men and women held the dread enemy at bay as they passed down the hill of life in spite of added years and other conditions which tended to wear down the obedience of cell life to its fundamental laws.

As to the disappearance of a cancerous growth, those who were studying the disease in mice reported that in them it was quite a frequent occurrence for a grafted growth, after attaining some size, to shrink slowly and completely away, and in some series of experiments a large proportion of the grafts which had "taken" had, after a period of growth, spontaneously vanished. Sir Alfred then referred to some cases he had treated in the Middlesex Hospital in which, though the disease was not cured, in the sense of being completely and permanently removed, yet there was reason to think that the word "cure" might be justified. He did not mention the treatments employed, as his purpose was not to vaunt a remedy but just to state a fact—that cancer, even where advanced and of long duration, might get better, might even get well. There was cure of cancer apart from removal. All therapeutical cures were obtained only by the working of physiological forces, and the first hope of therapeutic success came from observation of the efficiency of unaided nature to accomplish cure. In the darkness of night it is everything, he said, to know "there is a sun, and if we fix our eyes on the east we shall soon see the dawn and then the many colored heralds of the golden sun himself." It is much to the cancer-stricken to know there is a sun of healing. "When the biologist shall know the laws that govern cell growth, with a knowledge akin in its sweep and accuracy to that of the astronomer, he will have power—the power to prevent, to control, and to cure cancer."

Heart strain and dilatation was the subject of a discussion at the Medical Society of London, opened by Dr. Goodhart, and although he confessed at the outset that he had only undertaken the task on account of the president's kindly pressure, the fellows present could not but feel grateful to their president for having secured them this treat. Heart strain is common enough in the view of some practitioners, though others are inclined to pooh pooh it. But even the latter meet with cases difficult to account for which they cannot satisfy themselves amount to real injury, although the symptoms have come on, perhaps, after some unaccustomed exertion too insignificant in itself to satisfy the observer that it could have been the cause of the patient's distress. The doubts of the clinician were admirably expressed by Dr. Goodhart. He mentioned some cases in which unnatural sensations of illness, sighing, irregular pulse, with possibly nausea, and fainting and collapse gave rise to alarm. Pains over the region of the heart might follow with extreme lassitude. Then the impulse might be found somewhat outside the usually accepted normal limit, the beat variable, and some intermissions. No murmur or only a systolic bruit at the base, varying in extent and intensity with the posture. Prolonged rest is generally ordered on the strength of such symptoms, but is that the best treatment? Dr. Goodhart would hardly support it, for he held that true heart strain, by which he understood a state of the muscles that if not so dealt with would lead to dilatation, was a very rare condition. What, then, are the signs that dilatation has arrived? He thought the position of the impulse and the precordial dullness—so commonly relied on—were insufficient. The dullness was fairly reliable for enlargements of the right side, but of little value in the apical section. The impulse is a fairly constant landmark in relation to the chest wall, but what of the conditions that tend to alter its position, suspended as it is between the lungs and resting on the diaphragm? Then the tone and precision of the muscular contraction must be remembered. The ven-

tricular muscle twisted up into a tight spiral, but that was not a complete history of any living muscle. Considerable allowance must be made for contraction in the healthy play of any muscle and the distension or relaxation in a series of cavities linked together will cause variation in shape of the organ. Percussion could not then adequately gauge "the physiological play of the healthy heart." To what extent such variation reached Dr. Goodhart thought we had not any accurate knowledge. He instanced further the shape of the chest and said in the narrow chests too often met with the heart would occupy more of the front of the thoracic cavity.

Passing on to murmurs as evidence of dilatation, he said many are not valuable. Some often regarded as indicating valvular, or worse, muscular disease could not be explained except as functional, that is, excluding organic change in valves or muscle because the health remained good. It was said they disappeared with rest, but that was not his experience. Examination for life insurance revealed many. The subjects were nervous. It was unreasonable to expect a muscular organ with a throbbing vitality, nerve controlled, to be always in tone. There was a physiological up and down—hardly failure or imperfection—to which might be attributed many muscular rumbles, systolic souffles, and purely postural murmurs. He admitted many of the last-named might be mitral leaks, though not due to disease, and claimed they might be consistently spoken of as "valvular leakage without disease." A further argument against a too prodigal use of the term dilatation was that the symptoms which sent patients for advice were not those found when dilatation was beyond dispute. Fainting, one of the commonest in spurious cases, was rare in pronounced heart disease. The vascular mechanism prevented it and a dropped beat in the pump was not instantly noted in the capillaries. Faints were peripheral phenomena due to peripheral spasm, or relaxation, to nerve storm, etc. So an intermission of a beat, if unassociated with obvious disease, was one of the most unimportant of cardiac aberrations, and a weak pulse, "often made too much of, had seldom a sinister meaning *quâ heart.*" Another complaint, fatigue, is no indication of cardiac failure. So of pain in the region—there was no evidence that the heart showed more than a dull muscular sense, but plenty to show the surface area a neuralgic region. In over-distension of the right from excessive exertion, as in racing, there was little evidence of mischief on the left. A man might be played out by excitement or by physical expenditure and his nerve current cease for a moment to run. If it were possible to force it to continue the struggle damage would follow, but though the man looks so ill in most cases the heart will soon be working as well as ever. It might be asked whether true heart strains—however possible to locate them—might not be due to defective innervation, abortive messages, rather than to damaged muscle. It must be admitted that the heart has a magnificent power of resisting strain and dilatation seldom other than the result of real disease at a late stage. Early dilatation was not easy to determine, for it would share the signs of emotional and other disturbances of which the heart was the pastmaster of expression.

A discussion followed, extending over two evenings, being concluded on Monday.

Sir Douglas Powell admitted that many cases were imaginative and that the patients should be reassured. The chief point was careful diagnosis. In his experience many cases attributed to athletic exercises were really due to anemia. Patients who overdid muscular work often became anemic.

Sir Lauder Brunton compared heart-strain with joint-strain. If a joint were slightly strained it could bear gentle movements, but if severely strained absolute rest was best at first and when exercise was begun it should be very gentle. Cardiac dilatation might result from nervous causes, though he had seen a case in which it evidently originated in a great physical effort. In elderly patients the general state of nutrition was of course shared by the heart.

Dr. Henry Davy related two cases which he attributed to extensive decay of the teeth, the patients being brother and sister. The man had been a "blue" in football and cricket, but the lady could hardly be said to have undergone muscular fatigue once in her life.

Dr. Collier of Oxford, who has had great experience among undergraduates, said he had frequently had to consider whether athletes might continue their games. When there were definite signs of dilatation he generally advised discontinuance. Systolic murmurs running up the left side of the sternum, with abdominal epigastric pulsation, should prohibit athletic exercises. At the same time, patients with strains should not be frightened into thinking themselves "heart crocks." Rowing and competitions in races should be given up, and then they might be reassured that they might improve by living a quiet life, keeping seasonable hours, not smoking, continually limiting their exertion, and so forth.

Dr. S. West argued that supervised exercise was better for muscles than prolonged rest, under which wasting occurred.

Dr. W. Broadbent said in functional cases the jugular tracing was normal. In others there was a very large auricular wave, showing hypertrophy of auricle. Then violent exercises should be discontinued and relief to symptoms followed soon. But if the ventricular wave was higher, though rest reduced it, there was likelihood of relapses on exertion of any importance.

Dr. Alex. Morison thought hearts became inefficient without gross organic disease, but the condition was important and we must not be too optimistic.

Sir John Broadbent said percussion was overrated in the diagnosis. An athlete would have a bigger heart than a bookworm. It was not size that mattered so much as functional capacity.

Dr. L. Guthrie distrusted physical signs of strain or dilatation, though they might indicate a past strain or potential dilatation under stress, and so caution should be enjoined.

Dr. C. W. Chapman said in the young and strong a short rest would suffice. Past middle life it should be longer, depending on the state of the vascular system and the viscera.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

INTERNATIONAL CONGRESS FOR THE STUDY OF CANCER.—NEUROLOGY.

PARIS, November 30, 1910.

On October 5, at Paris, the International Conference for the Study of Cancer was held under the presidency of the Minister of Public Instruction. Twenty-three countries were represented by delegates and had answered the invitation trans-

mitted to them by the Minister of Foreign Affairs, and the President of the Republic had added his patronage to the conference. After the opening discourse, given by the Minister of Public Instruction, Professor Czerny, of Heidelberg, President of the Conference, gave an interesting address on the actual knowledge of cancer at the present day. The statistics of the past ten years seem to prove that cancer is increasing, and that it already has the second rank among the causes of mortality of adults. By injections of substances formed in the human body (indol, scatol), by the decomposition of albuminous bodies under the action of microbes, we have succeeded in producing on the ear of a rabbit, and once only on the skin of the human foot, atypical growths of the epithelium, whose histological appearance could not be distinguished from those of true epithelioma. In the beginning cancer is always a local disease and one perhaps generally curable easily by radical measures. Unfortunately cancer is not recognizable in the first phases of the disease; this is the explanation of the fact that cures are rarer as the disease advances.

Landouzy gave in a few words the history of the studies made of cancer, and represented the modern acquisitions in the etiology of this terrible affection. According to him we may actually be permitted to foresee the hour in which, by prophylaxis and serotherapy, medicine, repelling the spectre of cancer, will make of this fatal disease a malady curable and preventable.

Delbet believes that to-day the cure of cancer may be obtained by an operation done early and done well. Unfortunately the public puts off as far as possible that operation, and this is the reason why we must see a considerable number of victims of this terrible disease.

Dollinger of Budapest gave the result of cancer statistics. Sex has a certain influence. There are generally 40 men to 60 women. Cancer cases are more frequent in the cities than in the country. Cancers of the skin, lips, and breast, easy to operate on, furnish mortality figures lower than deep cancers. There surgical therapeutics is more difficult and less generally employed. In man 85 to 90 per cent. of cancers are located in the digestive tube. The value of fulguration in the treatment of cancer has been studied by Segond. He believes that the employment of fulguration is always indicated in presence of any neoplasm which it is possible to remove largely. The only application of fulguration is to be made in extended tumors in which the surgeon can take away the neoplastic mass that is visible to the eye, but cannot remove largely the healthy tissue.

Keating-Hart detailed all the benefits that may be expected from fulguration well applied.

Zimmern also thinks that fulguration is a good adjuvant to surgical action, for the electric spark has the property of exciting wounds to connective tissue proliferation, which modifies the neoplastic area and may form an obstacle to recurrence. He believes that whenever a neoplasm has been removed we should practise fulguration with the object of preventing local recurrence.

Vidal of Angers has studied the serotherapy of cancer. The injection in cancer subjects of the normal defibrinated blood of the pig or sheep has produced a temporary amelioration of cancers. But Vidal thinks that the best results have been obtained in anticancerous serotherapy by the employment of serum of immunized animals. We may make use of the sera of the patients themselves, of animals cured of cancer, of animals immunized by the aid of various supposedly cancer-producing agents, or by the aid of the cancer cells themselves.

Immunity to cancer has been studied by Georges Schöne of Marburg, who has shown that tumors do not take at all or do not take well in animals which are insufficiently nourished, in subjects of febrile infectious maladies, which had the pancreas removed, or are intoxicated by certain poisons. On the other hand, substances like chloride of sodium in large doses seem to favor the proliferation of neoplasms. Malignant tumors in the domestic animals have been studied by Gabriel Petit of Paris. He believes that cancer in domestic animals is identical with that of man. It strikes the carnivora and herbivora, the rodents and birds. The different categories of malignant tumors studied in man—epitheliomata, sarcomata—are also seen in animals. No carefully observed fact supports the theory of heredity and contagion of cancer.

Gaylord of Buffalo has observed epidemics of thyroid tumors in salmon. In a few months he saw 3,000 fish acquire tumors spontaneously. The malady followed the course of the river and attacked indiscriminately fish of various ages, as well those that were free as those that were captive. The inhabitants of the villages strewn along the banks of the contaminated river frequently had goiter.

True neoplasms of plants have been studied by Jensen. According to this author there exists a tumor of beets called commonly "beet goiter," which is very similar to the tumor in animals. The tumor proliferates indefinitely, bringing beet cachexia; it recurs after removal and is easily grafted. The seeds obtained from diseased beets produce healthy beets. This shows that in plants as well as animals there can not be recognized any hereditary influence for neoplasms.

The International Conference for the Study of Cancer was closed by Professor Czerny of Heidelberg, who announced that the third conference would take place in 1913 at Brussels. In the conference there were delegates from seventeen countries who took part in the discussion.

Dr. Lancereaux, former President of the Academy of Medicine, has just died at the age of 81 years, taken away quickly in a few days of pneumonia. Named Interne of the Hospitals in 1857, he became hospital physician in 1860, Agrégé in 1872, member of the Academy of Medicine in 1877. It was in the year 1908 that he occupied the chair of President of the Academy of Medicine. Lancereaux was especially known by his interesting investigations in the domain of pathological anatomy. The directing idea in these studies was to study the pathological alterations of the human body, taking for the basis of this study the changes which the tissues and organs undergo in the various phases of existence. It is to Lancereaux that we owe the description of the nosological types of epithelial nephritis in contradistinction from interstitial nephritis, of parenchymatous hepatitis from cirrhosis. If these divisions, so sharp and systematic, are not accepted to-day, still they have allowed of systematization which has been useful. Later, Lancereaux studied intoxications, and his writings on saturnism and alcoholism are extremely interesting. Among the discoveries of Lancereaux one should be men-

tioned; it is the frequency of lesions of the pancreas in diabetics which has led to the description of a special form, pancreatic diabetes. Lancereaux was an original man who by his fine qualities, his intelligence, and his works has a marked place in medical history of the later years.

Phylogenetic Association in Relation to Certain Medical Problems. G. W. Crile.
The Tuberculosis Problem as Applied to Children. J. B. Hawes, 2d.
The Therapeutics of Light. H. McIntosh.
Extraperitoneal Cesarean Section. J. L. Huntington.

Phylogenetic Association.—G. W. Crile states that the body has had implanted within it mechanisms of ancestral or phylogenetic origin whose purpose is the discharge of nervous energy for the good of the individual. In the skin are implanted many receptors for receiving specific stimuli which are transmitted to the brain. The receptors for pain have been designated noci-ceptors. The author coins a new word, "anoci-association," which designates the condition in which the nervous system is protected from stimuli from the noci-ceptors by means of a blocking of the nerve-paths with cocaine, and from fear, shock, and postoperative neuroses. In operations under inhalation anesthesia the nerve impulses from the trauma reach every part of the brain—the cerebrum that is apparently anesthetized as well as the medulla that is known to remain awake, the proof being the physiological exhaustion of and the pathological change in the nerve cells. Under ether anesthesia the damage is at least four times greater than under nitrous oxide. Inhalation anesthesia is, therefore, but a veneer, a mask that "covers the deep suffering of the patient." The cause of the exhaustion of the brain is the discharge of nervous energy in a futile effort to energize the paralyzed muscles in an effort at escape from the injury just as if no anesthetic had been given. The exhaustion is, therefore, of the same nature as that from overexertion. But if the nerve paths connecting the field of operation and the brain be blocked by means of cocaine then there is no discharge of nervous energy from the trauma, and consequently no exhaustion, however severe or prolonged the operation. Fear is a factor in many injuries and operations, and is born of the innumerable injuries in the course of evolution. Fear, like trauma, may cause physiological exhaustion of and morphological changes in the brain cells. The representation of injury, which is fear, being elicited by phylogenetic association, may be prevented by the exclusion of the noci-association or by the administration of drugs like morphine and scopolamine, which so impair the associational function of the brain cells that immunity to fear is established. Animals whose natural defense is muscular exertion, among which is man, may have their dischargeable nervous energy used up by fear alone, by trauma alone, but most effectively by the combination of both. What is the mechanism of this discharge of energy? It is the adequate stimulus of the noci-ceptors—the electric buttons—and the physiological response for the purpose of self-preservation. According to Sherrington, the nervous system responds in action as a whole and to but one stimulus at a time. The integration of the individual as a whole occurs not alone in injury and fear, but also, though not so strong, under other phylogenetic associations, such as the chase and procreation. When adequate stimuli are repeated in such a rhythm that the new stimulus is received before the effect of the previous one has worn off, a higher maximum is reached than is possible under a single stimulus, however powerful. What is the practical application of this? In operative surgery there is introduced a new principle, which removes from surgery much of the immediate risk from its trauma by establishing anoci-association; it places on a physical basis certain of the phenomena of fear; it explains the physical basis for the impairment of the entire individual under worry or misfortune; the daily noci-associations of the individual as a social unit; or a noci-influence of a part of the body. On the other hand, it explains the power of therapeutic suggestion and other influences which serve for the time to change the noci-integration, the physical basis for the difference between hope and despair; it explains some of the phenomena of Graves' disease, of sexual neurasthenia, possibly of hay fever, and the genesis of the common cold. The principle is probably equally applicable to the acute infections whose chemical noci-association gives rise to many of the phenomena of the disease and explains their cure by natural immunity and by vaccines; it should teach one to view his patients as a whole ;and especially should it teach the surgeon gentleness. It should teach one that there is something more in surgery than mechanics; and something more in medicine than physical diagnosis and drugs.

Tuberculosis and Children.—J. B. Hawes, 2d, states that every effort should be made to get the State and local authorities to provide adequate facilities for the care of children with pulmonary tuberculosis. One effective way of doing this is to make application for the admission of all such cases to the State sanatoria. The strongest argument which the board of trustees of the State sanatoria can use before the legislature is a long list of applications from children for whom there is no place, nor for whom, with the present appropriation, can a place be provided. There should be earnest and intelligent cooperation with the local school board to provide an outdoor school or fresh-air room for pretuberculous children; if such a school or room is established, the attention of the city legislature and Board of Health should be called to the good which it does. It should be insisted upon that tuberculosis and its prevention shall be taught in the public schools. This can best be done by means of tuberculosis exhibits prepared along the lines of those now loaned by the State, placed in all the public schools, and demonstrated wherever possible by doctors, nurses, or social workers.

Therapeutics of Light.—H. McIntosh concludes that light penetrates the tissues; that in so doing the chemical rays produce fluorescence of the blood and serum which is reduced or absent in pathological states, as, for example, in malaria; that the action of light upon the blood stream reduces oxyhemoglobin and thus stimulates the chemistry of the tissues, that is to say, improves metabolism. The most useful portion of the spectrum is not the heat or luminous portion, but the chemical portion. The physiological effects of light flow easily from the marked penetration of the light rays, particularly the chemical portion of the spectrum. The blue light has a peculiar field in the control which it has over pain and hyperemia. Red light by its exclusion of the chemical rays plays an important rôle in the treatment of smallpox.

Extraperitoneal Cesarean Section.—J. L. Huntington, after showing the advantages of the Solms flank cesarean operation, concludes that the experienced obstetrician should make himself familiar with the technique, so that in a case of contracted pelvis, moderate in degree, the patient should be allowed the test of labor with the possibility of a successful cesarean and a living child should the head fail to enter the superior strait.

Insufficientia Pylori. B. Frankel.
Magic and Medicine. A Study in the Borderland of Scientific Light and Darkness. J. Knott.

Rhinolaryngology and General Medicine.—H. Arrowsmith believes that one can state as an axiom that the non-specific acute inflammations of the nose and throat and the phenomena of "taking cold" are never due to exposure and never occur unless the patient is in a condition of perverted metabolism. The patients who consult one for these disturbances are almost invariably overclad, overfed, and under-exercised and under-aerated. In taking a stand against the indiscriminate enucleation of the faucial tonsils the author concludes as follows: 1. That pure hypertrophy of the faucial tonsil is essentially a phenomenon of early life; that, except in rare instances, it is rather protective than pathological, and that even a moderate number of attacks of acute amygdalitis rather substantiate than vitiate the presumption of this protective function. 2. That the cause of this hypertrophy is very often disease of the pharyngeal tonsil, ablation of which will frequently lead to retrogression of its faucial neighbor. 3. That up to the age of puberty, at least, a moderate, pure hypertrophy should be respected as an evidence of some important functional activity, probably protective in its nature. 4. That in case this hypertrophy, by reason of its excess and consequent mechanical interference with respiration or audition, demands action, the only justifiable operation is that of amygdalotomy, with preservation of the functionating tissue not in excess, and not of enucleation. 5. That if the disturbances in the tonsillar structure have been, beyond reasonable doubt, the source of neighboring glandular involvements, which in time may menace the general health, the only justifiable operation is not amygdalotomy, but complete enucleation. 6. That, after the age of puberty, when the tonsil, like the thymus, perhaps loses its physiological importance and should normally retrogress, pathological conditions in the way of cryptic, parenchymatous, or adjacent inflammations and infections, with their possible remote evil results, should be dealt with as thoroughly and as radically as our surgical resources enable one, the same, however, to be employed with a discrimination which sees beyond the obvious local phenomena and comprehends their general importance.

Etiology of Poliomyelitis.—F. Proescher describes a peculiar kind of microorganism that he has found in a fatal case of poliomyelitis. This was observed in smears of the spinal cord and closely resembled Negri bodies.

Epidemic Poliomyelitis.—W. S. Bryant calls attention to the prodromal nasopharyngitis, the numerous abortive cases with nasopharyngeal symptoms alone, and the spread of the disease by association with either simple nasopharyngitis or complicated paralytic cases. He is driven to the conclusion that in epidemic poliomyelitis, as in cerebrospinal meningitis, lobar pneumonia, true influenza, and diphtheria, the symptoms remote from the nasopharyngitis are not really pathological entities of the disease itself. They are to be considered in the light of compli cations. The disease proper, in contradistinction to the sequelæ, is amenable to local pharyngeal treatment. Prophylaxis is attained by nasopharyngeal hygiene. In times of epidemic poliomyelitis all cases of nasopharyngitis should be regarded with suspicion; they should be treated promptly.

Congenital Pyloric Stenosis.—R. Harrison reports a fatal case of this condition with the autopsy findings.

Sarcoma of Pituitary.—M. O'Malley reports a case in which the only symptoms manifested during the month the patient was under the author's care were mental confusion with the appearance later of stupor; occasional attacks of vomiting, which, with one exception, followed tube feeding and appeared to be due to irritation from this procedure. The double positive reaction of the blood serum to the Wassermann test, the great prevalence of syphilis in the negro race, together with the stated symptoms, led the author to make a provisional diagnosis of luetic disease of the brain.

Froehlich's Syndrome.—R. Ottenberg states that this syndrome occurs generally in cases in which the hypophysis is injured or destroyed. The symptoms are adiposity, loss of genital functions (atrophy), and loss of secondary sexual characters, particularly of hair on face, axillæ, and pubes.

Indigo Blue in Urine.—A. L. Benedict reports a case of this condition in which it is suggested that benzoic acid may have acted as an oxidizing agent.

Pyloric Insufficiency.—B. Frankel states that the diagnosis of this condition is completely at variance with the clinical experience of gastrologists.

Magic and Medicine.—J. Knott believes that it might not be inopportune to call a momentary halt in the self-satisfied appreciation of one's present attainments, while taking a bird's eye view of the tortuous passage of human opinion during the past ages through one of the domains of thought and discussion most nearly outlying the borderland of medicine. The result, as presented to the reader, is an expansion, with connecting and collateral comment, of some notes and observations which the author published five years ago.

Metabolism in Diabetes.—G. Lusk states that while authorities whom he respects have claimed that fat may be converted into sugar in the metabolism of diabetes, he can only say that he has never seen any evidence of it. The sugar certainly does not come from any pre-existing sugar in the protein molecule, but must be a derivative of the lactic acid. The intensity of diabetes should not be determined by the percentage of sugar in the urine, but by the relationship between the intake of sugar plus the possible maximum of sugar production from protein as compared with the total sugar output. In diabetes one is dealing with an organism which has no carbohydrate metabolism, with a high protein metabolism, and a more or less pathological fat metabolism, requiring sodium bicarbonate and abnormal quantities of water in order to dissolve the unoxidized products formed. The heat production is not diminished in diabetes as compared with the normal man. The diabetic obtains his calorific energy from fat instead of from carbohydrates, and if fat is not given him in sufficient quantity to maintain his requirements, he uses his own body fat. Benedict and Joslin have declared that the heat production of the diabetic may be 15 per cent. above the normal. This rise in metabolism is attributed by Zuntz to increased renal activity. One must take to heart these lessons. The physician can be sure that he is treating his

patient properly only when he knows that he is giving him at least the 35 calories per kilogram required normally, and these must be contained in materials which the patient can oxidize. Protein will not give more than 10 or 15 per cent. of this requirement of energy. To give fat in sufficient quantity requires all the arts of cookery. Here, as always, when the appetite is no longer a proper guide, the physician's knowledge of the patient's requirement is the only possible resource. When instinct fails science must be invoked.

Treatment of Diabetes Mellitus.—G. B. Wallace states that in diabetes certain principles may be laid down for practically all cases. First, the tolerance for sugar is determined by gradually increasing the bread in the test diet until glycosuria reappears. The patient is then placed on a carbohydrate-free diet for at least two weeks. The sugar tolerance will gradually increase, the hyperglycemia disappear, and it is rarely that acidosis to any dangerous extent occurs during this period. A mixed diet is now given and the new degree of sugar tolerance is determined as before. In many cases it will be found that it approaches the normal. In others it may show only a slight increase. In all cases, however, the subsequent diet should be such that the urine remains sugar-free and a carbohydrate-free diet should be given for a week or two at least once in three months. This may not seem necessary to some patients, but it must be enforced. In severe cases the qualitative management of the diet is of greater importance. The fact is now well established that high protein feeding is not desirable in severe cases. The proteins of eggs and vegetables are to be preferred to those of meat. As regards carbohydrates, in severe cases most patients do better with one kind of starch alone than with several kinds. This is the basis for the rice, potato, and oatmeal treatments. Of these, the last is of the greatest importance, and it is sometimes remarkably beneficial. Though it may decrease glycosuria, its chief value is in lessening acidosis. It is to be given alone as gruel, with no other carbohydrate, to the amount of 250 grams a day. As regards fat feeding, the amount of fat in the diet does not increase the acetone bodies unless it is taken in enormous quantities. Our knowledge concerning acidosis is incomplete and the latter is not always in proportion with the sugar intolerance. It may be slight when the other is great, and *vice versa*. Allard has pointed out that in dogs the acidosis is not due to a non-utilization of carbohydrates, but probably to a pathological state of the liver. It seems determined that the condition is not strictly an acidosis, but rather an intoxication by specific poisons. One of these we know—oxybutyric acid—and its salts are also poisonous. One should try to prevent the formation of these substances and hasten their excretion. A strictly protein diet increases the acetonuria, but, if it can be persisted in, an ultimate decrease can often be obtained. The addition of carbohydrates lessens the acidosis but increases the glycosuria, but in threatening coma the latter is of less importance. The periods of vegetable or oatmeal feeding exclusively are especially useful in persistent acidosis. Sodium bicarbonate aids the excretion of oxybutyric acid, and to get the best effects it should be given in large doses. The author lays out a general line of treatment of severe diabetes, avoiding a strict diet for any length of time or alternating it with vegetable diet. Each case, however, must be studied individually. Thus only can it be learned what is best for each individual.

Antiketogenesis.—R. T. Woodyatt found that though a diabetic cannot oxidize glucose, he may be able to oxidize other substances chemically allied to it, and which, having the power to lower acidosis, are known as antiketogenetic substances. A study of antiketogenesis may justify a hope that, among the many substances possessing antiketogenetic properties, there may be some which will not have the injurious by-effects of the antiketogens now known. He has, therefore, studied two substances which produce the phenomenon in the laboratory experiments. The first of these is glycol aldehyde or diose, the simplest possible sugar. This was fed in a single 20-gram dose to a patient with severe diabetes who was kept in bed, and all necessary precautions taken with regard to diet and the collection of excretions, to insure a consistent metabolism experiment. There was no increase in the urinary-reducing substances, no appearance of glycol aldehyde in the urine, and no significant change in the general acetone bodies or ammonium. The patient, however, had some nausea and loosening of the bowels. In view of the fact that P. Meyer saw toxic effects in animals from this substance, and the other fact that some of its oxidation products are toxic, it seemed likely that the gastrointestinal symptoms produced were not merely incidental to the existing acidosis. No further use was therefore made of this product in diabetes, though animal experiments show that it can act as an antiketogenic body. The next substance that the author experimented with was glycerin aldehyde, which is formed, among other changes, when glucose is placed in an alkaline solution. When given to a healthy individual large doses are tolerated without any apparent effect, and in diabetes as high as 50 grams have been given without causing glycosuria or the appearance of any reducing substance in the urine. The effects of continuous doses, however, have not been reported. But in four separate experiments, single large doses given to severe diabetic cases, the results were identical, namely, an increase in the urinary glucose and a marked reduction of acidosis. There was no gastric disturbance more than can occur from an equal dose of sugar and the substance is not toxic. The author offers an explanation of antiketogenesis as follows: This process appears to be the expression of a simultaneous oxidation and reduction reaction in which the acetoacetic acid, by virtue of its ketone group, acts as the oxidizing agent, and hence undergoes reduction, while any substance containing alcohol groups, notably sugar, acts as a reducing agent, and hence becomes oxidized. The process is stated in further detail in his article.

The Pancreas and Diabetes.—J. H. Pratt concludes that the total removel of the pancreas always leads to a fatal diabetes. Atrophy of the pancreas produced by excluding all the pancreatic juice from the intestine is associated with a marked decrease in the limit of assimilation for sugar. Transplantation of a portion of the pancreas prevents the development of diabetes when the rest of the gland is extirpated. Lesions of the islands of Langerhans are found in most cases of diabetes. They are usually associated with changes in the acini. In the progressive atrophy which follows the occlusion of all the pancreatic ducts in dogs and cats both islands and acini are gradually destroyed. All the islands may disappear without diabetes resulting. The conclusion is justified that the pancreas has an internal function concerned with the metabolism of sugar. The nature of this function, the relation of the islands of Langerhans to the acini, the significance of histological changes in both structures, these and other problems still await solution.

Hairy Tongue.—M. L. Heidingsfeld concludes that hairy tongue may be conveniently divided into two general classes: (1) true, idiopathic, or genuine cases, characterized by well-defined, stable, black-brown or yellow-brown thick, soft, fur-like patches covered with densely intertwined hair-like filaments; and (2) false, pseudo, or spurious cases characterized by thickish yellow-brown or greenish discolorations of evanescent character, covered with a soft mushy detritus occasionally containing short filaments, shorter than in the other form. The true cases originate in some developmental anomaly, developing from germinal products present at birth, but showing themselves

in early adolescence or later. The pseudo cases probably owe their origin to general or local irritation or disease and are not uncommon in the early stages of syphilis. A parasitic nature has not been demonstrated.

Pathology of Ethmoiditis.—R. H. Skillern in discussing the comparative pathology of hyperplastic and suppurative ethmoiditis, presents the microscopic pathology of these two conditions which shows that the ethmoidal structures and their components are, under certain conditions, dissimilarly affected, and often in diametrically opposite ways.

Tuberculosis of Ankle-Joint.—J. W. Sever concludes that tuberculosis of the ankle-joint and bones of the foot in children is insidious in its onset, chronic in its course, and attacks usually young children. The expectant or conservative method of treatment is preferable to the operative one. Time is saved and deformity less under the conservative plan than by the operative method. There is also less danger of secondary joint involvement and general tuberculosis by pursuing the non-operative plan. The disease may be associated with bone and joint tuberculosis in other parts of the body. The prognosis is fairly good for life, but poor for a good ankle-joint in which there is no disability. A certain number get a good functional ankle, with but slight deformity. In regard to the smaller metatarsal bones the results are good for joint motion.

Experimental Diabetes.—J. J. R. Macleod concludes that in the utilization of carbohydrates in the animal body the glycogenic function of the liver is at least as important as the glycolytic action in the tissues, and, since there is plenty of evidence that this glycogenic function is easily deranged so as to cause diabetes, it should be more carefully investigated as to its participation in the cause of those forms of diabetes which, at first sight, may seem to be quite independent of it.

Dehydration by Dietetic Measures.—A. Magnus-Levy states that the essential feature of the Karell treatment is the exclusive use of milk in relatively small quantities at definitely stated intervals. The idea underlying Oertel's method is a great reduction in the quantity of food ingested, while the Widal treatment, on the other hand, consists in excluding sodium chloride as much as possible from the food. The restriction of the ingestion of fluid must be subordinated to the task of reducing the sodium chloride and, when this is cut down, thirst becomes less and the amount of water taken is decreased in the natural course of events. A salt-free diet is rarely carried out in its full extent, as it requires persistence and patience more than are usually possessed. In a large number of cases the desired effect can be produced by stimulating renal activity with drugs, which are resorted to instead. This reduction of sodium chloride is especially indicated in the edema of parenchymatous nephritis, but it is also useful in combating some of the symptoms of contracted kidney, such as headache, uremic asthma, angina pectoris. It is wrong to allow patients who have been relieved of dropsy and other chief symptoms to return to their ordinary salty diet, and especially patients with diabetes insipidus must permanently refrain from such diet, as it is impossible to make a diseased kidney do the work required for excreting concentrated urine. A diet poor in proteins probably acts favorably, besides its effect on the compensation, in other directions. It is particularly to be recommended also in cardiac patients who have been also previously high livers, and in the later stages of interstitial nephritis when more or less severe uremic manifestations appear. The author thinks it is better to allow a certain reduction of weight by a scanty protein diet than to allow such symptoms to continue. As regards treatment of individual cases, in proper cases one may attempt to carry out each one of the three treatments mentioned according to the directions of their originators. In the Karell milk treatment he thinks it specially important to adhere to the four-hour intervals between the separate portions allowed the patient. The salt-free diet of Widal is theoretically easy to administer, but one is apt to encounter the opposition or lack of comprehension of the cook. No article of food need necessarily be forbidden if given without any artificial addition of salt, either before or after cooking it. Milk also can be permitted only in small amounts, as it contains about two grams of sodium chloride to the liter. If a patient, after having been on a salt-free diet, is to be allowed any amount of salt, the directions should not be general, but should prescribe the exact amount he should use. The author manages by ordering a salt-free diet, to which the patient adds a small, accurately measured amount, as he pleases, during the twenty-four hours. These dietetic measures are just as important in the treatment of circulatory and renal disorders as in the treatment of the glycosurias.

House Quarantine.—H. Cohen insists on the importance of house quarantine in safeguarding the public from the dangers of existing foci of infection.

Treatment of Wounds.—A. Carrel states that with asepsis we have not the right to believe that we have reached the last step in the treatment of wounds. He asks if it would not be feasible to act on the processes of repair themselves and expedite them. One might thus greatly improve the therapeutics of wounds and fractures, and one must therefore analyze the mechanisms which are instrumental in cicatrization of wounds, the factors which modify their functions, the stimuli by which they are started, and the causes of their reciprocal action in the common work.

Vapor Anesthesia Apparatus.—J. T. Gwathmey describes his improved three-bottle apparatus for the administration of ether and chloroform.

Eye-Strain and Exophthalmic Goiter.—G. M. Gould and A. C. Durand believe that eye-strain may cause exophthalmic goiter, and report a case which seems to them a proof of this. The eye-strain of ametropia often causes tachycardia or tremor, and frequently both combined. How exophthalmos is produced by eye-strain is not so readily understood and still less the cause of the goiter. The conclusion is suggested that as multitudes of goiterous patients have no tachycardia or exophthalmos the goiter symptom is somewhat independent or secondary. Probably the tachycardia is the first of the ocular reflexes instituted, followed by the exophthalmos as chiefly a secondary vascular phenomenon. In the case reported the exophthalmos disappeared during mydriasis and returned with its disappearance.

Elephantiasis of Scrotum and Penis.—R. Russ reports a case of this condition successfully operated upon.

Chronic Appendicitis.—W. H. Boese reports a case of this condition simulating neoplasm. There was an unusually large circumscribed development of inflammatory tissue.

Results of Bronchial Obstruction.—G. N. Pitt states that the results of compression of a bronchus may be the following: The lung may be slightly reduced in size with definite diminution in the entry of air; the chest may be

hyperresonant, the lung overdistended, and the diaphragm displaced down abnormally. The lung may be reduced in size, airless and solid from collapse, and the chest dull on percussion, when the obstruction to the tube is complete, or when respiration is feeble. The bronchi become filled with retained secretions. A retention pneumonia ensues, with a resulting pyrexia. These changes may all pass away; but if the obstruction persist there occur a general fibrosis of the lung beyond the obstruction and a bronchiectasis. Dilatation of the tubes occurs. Fibroid thickening of the lung results from the retention of the secretions, the prolonged collapse of the alveoli, the bronchopneumonia, the peribronchial changes following on the destruction of the bronchial epithelium, and the interference with the pulmonary and lymphatic circulation. Secondary infections may produce a septic pneumonia, gangrene may occur, especially with malignant disease and when the pulmonary artery is occluded. There may be putrefactive changes, and as a secondary result of the bronchiectasis there may be a pleurisy or an empyema. The causes of bronchial obstruction may arise from without or within the bronchus. Usually only one bronchus is affected, but in some cases the trachea is involved, as well as one or both bronchi. The external causes producing compression are: 1. Aneurysm of the aorta. 2. Malignant disease of: (*a*) Esophagus, epithelioma; (*b*) Bronchial glands—(1) primary, usually sarcoma (2) secondary to growth at a distance. 3. Enlarged caseous or suppurating glands. 4. Gummata. 5. Abscess. 6. Dilated left auricle. The internal causes are: 1. Bronchiolitis. 2. Syphilitic ulceration with scarring. 3. Primary malignant disease of a bronchus (usually columnar celled carcinoma). 4. Foreign bodies in the bronchus. The most important evidence suggesting a foreign body in a bronchus is (1) the history of swallowing something, immediately before the onset of an acute attack of severe dyspnea and cough. (2) Not infrequently a whistling or wheezing sound which the patient can localize to one side, varying in quality if the object is not fixed in the bronchus. (3) Great distress, with not infrequently a constricting pain behind the sternum, made worse by movement. (4) Dyspnea, with varying exacerbations, often intense and made worse by cough, but it may be elicited only by exertion. After a time there may be no distress. (5) Absent or, rarely, very noisy breath sounds, with some slight diminution of voice and tactile vocal fremitus limited to one side of the chest. (6) At first resonance on the affected side, soon consolidation with dullness, and, after a time, the signs of cavities, and the simulation of phthisis; query occasionally hyperresonance. The physical signs sometimes vary from time to time. (7) With *x*-rays, the defective movement of the diaphragm and of the thorax, the alteration in the density of the lung, and not infrequently the outline of the foreign body itself, may be clearly made out. (8) Delay in the commencement of inspiration as compared with that on the other side. (9) Defective movement with consequent diminution in the size of the affected side. (10) Violent, paroxysmal, persistent cough, which is apparently most marked when the object is at the bifurcation, as the sensibility of the mucous membrane is greatest here, as can be noticed when passing a bronchoscope. (11) Early pyrexia, which later becomes hectic, associated with chills. (12) After a short time an expectoration more or less profuse, purulent, often bloody, and later often fetid. (13) In some there are nausea and vomiting, which may be very troublesome. (14) Pneumonia often develops in forty-eight hours: this may be septic and may be followed by gangrene.

Ehrlich-Hata Preparation.—J. McIntosh and P. Fildes report favorable results following the use of this remedy in sixteen cases. They believe that the importance of 606 as a destroyer of spirochetes cannot be overestimated, even apart from the beneficial effect upon the patient. In those cases in which spirochetes were demonstrable in very large numbers before inoculation, none were found in less than twenty-four hours, even after prolonged search. This fact has already been fully established. The importance of the observation lies in the probability that cases of syphilis can be rendered practically noninfective in a day or two. If this be true, Ehrlich will have swept away the scourge of 2,000 years and given into the hands of any State which will avail itself of it a weapon for the forcible suppression of syphilis.

Biparental Inheritance of Webbed Toes.—H. P. Newsholme reports a case of webbed toes in which inquiry elicited the fact that this deformity occurred through three generations and involved twenty-two members of a family of twenty-nine. Three members of this family had diabetes.

An Obscure Case of Peritonitis.—R. H. Norman reports a fatal case of peritonitis in which post-mortem examination revealed the following: A mass of inflamed tissue was found behind the stomach, in which were several broken-down caseous glands. There was a cavity in this mass, and from it one sinus led into the stomach. The ulcer in the stomach was not a recent one. Another sinus led to a caseous mesenteric gland, and two others led into the peritoneum. The openings into the peritoneum were apparently recent. There were a number of caseous mesenteric glands, and acute peritonitis was present. The right lung was bound down by old adhesions.

Uterine Cervical Polypus.—H. Macnaughton-Jones reports a case and presents a drawing of the sagittal section of an entire uterus, the cervix of which was destroyed by a carcinomatous crater, and in the fundus, growing from its summit, a mucous polypus. Section of the latter showed a solid carcinoma. There was no connection whatever between the polypus and the carcinoma of the cervix, the mucosa of the fundus and body being quite free from carcinoma. The patient was a woman aged fifty-seven years.

Surgical Versus the Expectant Treatment of Intracranial Tumor. Sir Victor Horsley.
Cancer. Sir Alfred P. Gould.
The Results of Bronchial Obstruction. G. N. Pitt.

Treatment of Intracranial Tumor.—See page 1190.

Cancer.—Sir Alfred P. Gould enumerates the latest results of cancer research in the effort to unravel what has hitherto been a tangled skein. Cancer occurs in all races of men, but they are not all equally liable to cancer. It is a disease that occurs in all vertebrate animals. It can be transferred from host to host but cannot be transferred to an animal of another species. The essential part of every cancerous growth is the living cancer cell. This possesses a great power of continuous multiplication. It retains the inherited limitations to type of the cells among which it first appears. Cancer cells develop and differentiate but little and irregularly. The development of the cancer cell is neither purposeful nor effective. Cancer cells exhibit periodicity in their growth. The study of the form of cancer cells and the attempt to find in it some index of their nature has yielded but little that is positive. One knows but little of the intracellular metabolism of the cancer cell. It seems to beget no toxin, to generate no new substance, and to depart but little from the chemistry of health. Regarding the cancer cells as members of a community and in relation to neighboring cells, one notes first the disproportionate growth of the cancer cells. The multiplication of the cancer cells causes not only complicated infoldings of the cancer itself but flattening and distortion of the adjacent soft tissues. The cancer cells not only compress but also invade the adjacent tissues, and

compel them to form a supporting and vascular stroma of a type governed by the cancer cell and not by the stroma-yielding mesoblastic cells. The facts about cancer may be summarized in the disproportionate multiplication of certain cells, their imperfect, irregular, and useless differentiation, their failure to form Altmann's granules, their excessive affinity for and need for potassium, their insistent intrusion into surrounding tissues, their imperfect cooperation with the other cells, and, finally, their selfish greed which enables them to live when other cells are failing and perishing for lack of nourishment—what is it all but a failure of, or a revolt against, that great cytological law or impulse which first manifests itself in the primary division of the ovum, and lasts on till the death of the organism? Cancer is not a disease attacking the body from without, it is the result of a breach or failure of fundamental cell law—a law of which one knows only the results; a law so majestic that obedience to it results in perfect development, perfect health, the full measure of days, and disobedience to it may slowly spell out all the inscrutable woes of cancer. The various etiological factors that are known to exert an influence on cancer lend support to this view of its nature. Cancer arises in cells that are growing or have grown old. It is because of the fact that the breast and the uterus are specially prone to cancer as they get old, before the rest of the woman ages, that cancer is more frequent in women than men, and that its age incidence differs in the two sexes. Chronic irritation, by adding to the frequency of cell division, is producing the special condition of cellular old age; it is equivalent to the ageing of a tissue. The *x*-rays and alcohol have a similar effect. One must not look for immunity from this disease along the lines in which it is found for infections. Cancer immunity might be evidenced in one or more of the following ways: 1. The power of living cells to conform to the law of normal development and to avoid that increased multiplication, defective differentiation, and tendency to intrude themselves into, and grow in, neighboring cell territories, which together connote cancer. 2. Opposition to the intrusion of cancer cells into, and their development in heterologous tissue. 3. Inhibition of the growth of cancer or destruction of living cancer cells. When the biologist shall know the laws that govern cell-growth, with a knowledge akin in its sweep and accuracy to that of the astronomer, he will have the power to prevent, to control, and to cure cancer.

Results of Bronchial Obstruction.—See abstracts of articles in *The Lancet*.

Berliner klinische Wochenschrift.

December 5, 1910.

Indications for Artificial Termination of Pregnancy.—Hammerschlag gives in detail six indications for interrupting gestation. These do not exhaust the subject, but are discussed from the standpoint of extensive personal experience. Hyperemesis gravidarum is first mentioned, and the author appears to regard this as a mere hysteroneurosis of reflex origin, which is largely controllable by treatment. Only in exceptional cases does the condition proceed to a stage of intoxication, as shown by elevation of temperature and pulse, albuminuria, etc. The pregnancy should be terminated as soon as such symptoms appear. Out of nineteen personal cases but two required interruption of gestation and one patient was lost. Second in order come cardiac lesions. Naturally the indication for interruption occurs in broken compensation. Of forty patients with valvular lesion, eighteen had satisfactory compensation. Of the remaining twenty-two cases in which compensation had been compromised, six were sufficiently grave for interruption of pregnancy and three patients died despite the treatment. Interruption should, if possible, be performed early in gestation. The worst prognosis is in cases of associated myocarditis. Third in order is tuberculosis—pulmonary and laryngeal. The latter is an indication for immediate interruption. Pulmonary tuberculosis occurring alone is seldom an indication for interruption and never in very advanced cases. If, during the first or second stage, pregnancy lights up a severe exacerbation such as to threaten death if patient is allowed to go to term abortion should be performed. The fourth condition is nephritis, including the kidney of pregnancy. In cases of the latter which threaten loss of vision or other permanent damage, the pregnancy may be interrupted if other measures fail, although one should seek to save the child by deferring the intervention as long as advisable. Ordinary acute nephritis is not an indication for termination of pregnancy, while chronic nephritis does indicate the latter, as does, exceptionally, pyelitis. The author has personal records of 112 cases of nephritis in pregnancy, chiefly of the ordinary kidney of pregnancy. Gestation was interrupted but ten times, seven of which were for chronic nephritis. In seventeen cases of pyelitis he intervened in one only. The fifth condition for possible interruption is diabetes. This is considered chiefly from the academic standpoint, little personal experience being quoted. Gestation should be interrupted whenever acetonemia develops to ward off coma. Of three cases of the author's one died of coma despite intervention. The sixth and last condition considered is chorea. If this is severe enough to threaten death by exhaustion, acute heart disease, or other complication, the failure of customary remedies constitutes an indication for interruption.

Pathological Ferment Action.—Wohlgemuth concludes his serial article, referring to the part played by enzymes in the production of pigment in malignant growths and in the condition known as ochronosis. Of more practical interest are the results of enzyme action in pancreatic disease. The author was the first to show that amino acids can activate the pancreatic enzymes. Hence, entrance of intestinal matter into the pancreatic duct may be responsible for some cases of autolysis without reference to the presence of activating germs. If isolated foci of necrosis occur we may explain these by the presence of small inflammatory lesions which set up autolysis with formation of low products of proteid cleavage. The part played by enzymes in these pancreatic lesions is not clear from the author's description. One would naturally call to mind the action of the pancreatic digestive enzymes, including the special erepsin of the pancreas, etc. It may be, however, that he refers to the common, intracellular autolytic enzyme which he has assumed to occur in all functionally active organs. That enzymes play a certain rôle in some forms of fatty degeneration—naturally those which are aseptic—seems probable; and phosphorus liver is discussed as a concrete example. This condition is accompanied by total disappearance of the hepatic glycogen, such as might occur from activation of the hepatic diastase. The same phenomenon is seen in obstructive jaundice, and is readily explained by the known property possessed by bile of activation of diastase. The rest of the article deals only with certain post-mortem changes ascribable to enzymes.

Münchener medizinische Wochenschrift.

December 6, 1910.

Treatment of Dysentery Bacilli Carriers.—Mayer states that previous attempts to dispossess these bacilli by internal medication have failed. The only resource left is isolation until the germs disappear from the stools. This has been found to require from three to seven months at the outside. In the present paper the author has reference chiefly to cases in troops where sanitary measures are more available than in civil practice, and where the danger of lighting up new epidemics is much more marked. In ad-

dition to isolation the stools require immediate disinfection. It has been found that if the period of isolation is too short bacilli which have disappeared from the feces *pro tem.* may reappear. In the meantime every effort should be made to prevent acute dysentery from becoming chronic.

Sequelæ and Repeated Attacks of Diphtheria.—Kayser emphasizes several practical points in this paper. Postdiphtheritic paralysis is hardly a family malady. Only a single case of family incidence was known to the writer before the one reported below. The evidence is still in favor of the view that serum is unable to prevent paralysis, which the author might have termed metadiphtheritic lesions from certain analogies with other diseases. These paralyses are usually treated in dispensaries, as they do not develop during the hospital period. The author saw apparently diphtheritic paralysis in three children of one father, but thinks this may have become possible through a history of paternal alcoholism, coupled with the fact that the children also used alcohol. This was not prescribed at the dispensary, but the father, who was an innkeeper, was responsible, the physician concurring for a time. In cases of this sort paralysis from alcoholic neuritis is not always easy to exclude. These cases were treated in the dispensary and a history of frank diphtheria was not obtainable for the patients, although the disease had been epidemic in the vicinity. Another patient with intraocular paralysis of apparently diphtheritic origin was the son of a wine merchant and accustomed to the use of wine. In none of the patients were bacilli found. The last named patient had three successive attacks of paralysis of accommodation. A history of diphtheria for each attack was imperfect, and even for the primary attack was doubtful. Repeated attacks of diphtheria are now known to be so infrequent that a single attack must be regarded as conferring at least as high a degree of immunity as holds in the case of other infectious diseases. In prebacillary days repeated attacks of the malady must have been largely streptococcic. A certain distinction must be made between reinfection and relapse. The latter should occur in carriers only, and is naturally very rare, as the mere presence of the bacilli without disease implies immunity. True reinfection would, in theory, occur most likely during severe epidemics, and only after years of immunity. A supersensitiveness to diphtheria toxin is doubtless the explanation of postdiphtheritic lesions, and to recurrence of diphtheria under any conditions.

Toxic Action of Milk-Sugar in Infant Feeding.—Braunmüller refers to Finkelstein's claim as to the toxicity of milk-sugar in infants with a tendency to pedatrophy and the use of whey-free milk in this connection. In a series of infants treated with the latter it appeared that babies developed sugar intolerance in the course of treatment. The symptoms were not toxic but merely those of mild indigestion, sufficient, however, to influence the nutrition very unfavorably. Such infants could utilize only a definite amount of sugar. It occurred to the author to substitute carbohydrates (barley water) for sugar, beginning with small quantities and gradually increasing, and this promises well. The author appears to give full credit to whey-free milk as a form of alimentotherapy, but does not regard the cutting down of carbohydrates as salutary. If sugar intolerance is present he would advocate the substitution of barley as already stated.

Deutsche medizinische Wochenschrift.

December 8, 1910.

Surgery of Brain Tumors.—Hildebrand, in a brief article—chiefly conclusions from a case history—emphasizes certain points as follows: We are seldom able to make a diagnosis as to the nature of a tumor or even to say whether it is benign or malignant. The latter occurs with much greater frequency. He has heretofore been very pessimistic as to ultimate recovery from the malignant form. But he believes that in certain cases of exact localization operative removal is attended with a better prognosis. This is even more the case with benign tumors. A serous meningitis may be indistinguishable clinically from a tumor. Diagnostic and operative technique have been improved so greatly in recent years that it is now a reproach to fail to operate for benign tumor (always supposing, of course, that it is operable). Operation may not prevent choked disk and optic atrophy; hence, when such symptoms appear a palliative trepanation should be done, as a first stage, extirpation to follow if indicated.

Atoxyl and Its Derivatives.—From Blumenthal's article on this subject we may quote his optimistic belief that atoxyl will continue to be a source of new therapeutic synthetics produced by further additions to, and mutations in, its molecule. He believes that incorporation of iodine and bromine into the latter will accentuate the organotropic properties of atoxyl. In addition to 606 there is a new substance, a benzosulfo atoxyl known for short as hectin, which is said to be far superior to atoxyl when the latter is indicated. It has been used chiefly in France. Uhlenhuth has introduced Hg. into the atoxyl molecule, and Lesser has used this derivative with remarkable results in syphilis maligna. Silver incorporated in the atoxyl molecule appears to give a substance which intensifies its therapeutic value. Jacoby appears to believe that atoxyl derivatives may furnish in time an anticancerous remedy. In regard to the selective action of atoxyl on the optic nerve the author believes that this will be eliminated in its derivatives, and by special technique in regard to size and frequency of dosage. The good results of atoxyl in trypanosomiasis have been obtained largely by pushing the remedy. It is desirable to find derivatives which will act in small, perhaps single, doses.

Operative Treatment of Hay Fever.—Blos, who has already written on this subject, publishes a brief résumé of the latter. Other authorities are barely mentioned by the writer, so that we may understand that his intervention, which consists of resection of the anterior ethmoidal nerve, originated with him as far as its application to hay fever is concerned. The technique of the operation is not new, as it appears in Kocher's Operative Surgery, (fifth edition). Killian has recently alluded to the operation in connection with reflex neuroses of nasal origin, chiefly such as proceed from sinus disease. The nerve is exposed through the inner wall of the orbit and while the operation is practicable under local anesthesia the intervention is relatively severe in character, as the surgeon is obliged to work behind the lacrymal structures, and there is danger of compromising these. The orbital periosteum must be removed, whereupon the nerve is rendered visible as it emerges from the anterior ethmoidal foramen. The present article was written in response to numerous queries in reference to technique and permanence of results. The author seems to have operated but three times. The cases were of unusual severity and chronicity and the recovery or near-recovery seems to have been permanent.

Chills Following Adrenalin and Saline Infusion.—C. Haeberlin reports a case of peritonitis following perforative appendicitis. Three days after the operation, owing to the bad condition of the patient, the latter received an intravenous infusion of saline solution containing adrenalin. One hour later he had a severe chill, followed by a rise of temperature and increase of pulse rate. Death occurred the next day. The author explains the chill as analogous to that which occurs in puerperal fever as the result of a sudden increase of absorption of toxins by the blood. The injection of adrenalin causes a rapid rise of blood pressure, which is similarly followed by an increased absorption of toxins.—*Zentralblatt für Chirurgie.*

Book Reviews.

THE PRINCIPLES OF PATHOLOGY. By J. GEORGE ADAMI, M.A., M.D., LL.D., F.R.S., Professor of Pathology in McGill University, and Pathologist-in-Chief to the Royal Victoria Hospital, Montreal; late Fellow of Jesus College, Cambridge, England. Volume I: General Pathology. Second edition, revised and enlarged, with 329 engravings and 18 plates. Philadelphia and New York: Lea & Febiger, 1910.

IT is a pleasure to welcome again this unique volume of Adami's on General Pathology, and to note that the scientific events of the past two years have necessitated an hyperplasia of seventy-nine pages. Even the preface has been remodeled, and from it, to the reviewer's regret, certain pleasant personalities have been omitted. It seems a pity to alter one of the best prefaces in any book; most of them are so formal, if not bombastic.

The table of contents has been remodeled so as to give more detailed information of the chapter contents. The index has been altered, some heads being omitted and others added, the omissions evidently being necessary to save space since the subjects referred to have not been deleted from the text. The excellent system of employing heavy-faced type for the chief page reference has been adopted in the index.

To turn to less mechanical matters, it is not possible in the limited space at command to discuss all of the new substance which has been introduced. The first part of the volume seems to be largely rewritten. New matter is introduced in the chapters on the physiology of the cell, on the chemistry of the phosphorized fats, and on Mendelean heredity. The section on the methods and diagnostic results of complement fixation has been remodeled to include the later views on the relationships between the lipoids and the fixation of complement, it being very properly pointed out that we are dealing with a non-specific Bordet-Gengou phenomenon. Slight additions have been made to the section on tumors. It is to be regretted that the borrowed cuts could not have been redrawn in this edition, the mechanical reproduction in many being quite unsatisfactory. Yet despite this defect the volume still remains, in the opinion of the reviewer, one of the best presentations of general pathology in any language.

PULMONARY TUBERCULOSIS AND SANATORIUM TREATMENT. A Record of Ten Years' Observation and Work in Open-air Sanatoria. By C. MUTHU, M.D., M.R.C.S., L.R.C.P., Associate of King's College, London; Physician Mendip Hills Sanatorium, Wells, Somerset; late Physician, Inglewood Sanatorium, Isle of Wight; author of "Some Results of Sanatorium Treatment of Phthisis," "The Inhalation of Formic Aldehyde in the Treatment of Pulmonary Tuberculosis," "The Diagnostic Value of Tubercle Bacilli in the Treatment of Phthisis," "A Short Account of the Aryan System of Medicine," etc. New York: William Wood & Company, 1910.

THIS admirable book of 200 pages differs from all of the other recent works on the same subject, in this respect, namely, while presenting the current accepted views as to the nature and management of tuberculosis, it also embodies the author's original conceptions of the etiology and treatment of this disease. The work is divided into three parts: the first, dealing with the scientific aspect; the second, the sanatorium; and the third, the social aspect of tuberculosis. In the introduction the author shows how the best results in this disease are obtained by closely following Nature's own method of cure. He speculates that the tubercle bacilli may originally have been innocuous organisms, and that some of their types may be so still; and that they have become, and may still become, pathogenic by a change of environment and nutrition. He concludes that predisposing factors alone cannot produce tuberculosis, that the unknown personal factor predominates, and that this, which is outside the pale of environment or microorganisms, determines whether or not infection should occur. This view is certainly an original one and suggestive of much thought. The author emphasizes the value of clinical experience as more reliable than either statistical or experimental evidence. The discussion of early diagnosis is masterly. In the section on the principles of open-air treatment are given in detail all the measures and routine adopted in a modern sanatorium, including rest, diet, breathing and singing exercises, manual work, inhalations, and recreations. There are special chapters on the treatment of hemoptysis, on the treatment of laryngeal tuberculosis chiefly with the aid of vocal rest and medicated inhalations, on the use of formaldehyde inhalations, and of static electricity in the treatment of pulmonary tuberculosis. The section on the social and economic factors of tuberculosis presents this subject concisely and fully, and includes an elaborate plan of remedial and preventive measures by means of which the nation may hope to overcome the disease.

THE EAR AND ITS DISEASES. By ALBERT A. GRAY, M.D., Laureate of the Lenval Prize in Otology, International Medical Congress, 1909; Fellow of the Royal Society of Edinburgh; Surgeon for Diseases of the Ear, Victoria Infirmary, Glasgow; Surgeon for Diseases of the Ear and Throat, Glasgow Cancer Hospital; Author of "The Labyrinth of Animals." With Steoroscope and 123 Illustrations, of which 37 are Steoroscopic. New York: William Wood & Company, 1910.

THE author in preparing this work has tried to keep in view the interests of the student, the practitioner, and the aurist. The first chapter is devoted to the subject of acoustics. The difficult subject of the anatomy of the ear is treated in considerable detail. By means of stereoscopic illustrations and special methods of preparation, the mastering of this subject is greatly facilitated. The inclusion of a small but accurate stereoscope with this book furnishes the ready means of studying these illustrations. One notes the admirable manner in which the author associates the clinical phenomena with the pathological conditions present. The work is an eminently practical one for both specialist and general practitioner, and in its clearness and freedom from controversial details, it is well adapted to the needs of the student. The illustrations leave nothing to be desired on this point. They are of exceptional beauty and clearness, and add an incalculable value to the work. The series of eighteen illustrations representing the appearances of the tympanic membrane in normal and pathological conditions cannot be improved upon. The author is to be congratulated upon the general accuracy, completeness and at the same time compactness of his work, which represents the best in modern otology. As an example of consummate book making, bringing all the resources of perfect typography and illustration, together with the happy mechanical aid of stereoscopy, within the compact limits of a manual at moderate cost, this work may be said to be unique.

L'HOMOSEXUALITÉ ET LES TYPES HOMOSEXUELS. Par le Docteur LAUPTS (G. Saint-Paul). Nouvelle Edition de "Perversion et Perversité Sexuelles." Preface d' Émile Zola. Paris: Vigot Frères, 1910.

To those who are interested in the literature of sexual perversion for which the demand abroad has been much greater than in this country, the mere statement of the title of this book is sufficient to describe its purport. To the psychiatrist this subject presents problems connected with phases of his daily work, but the general practitioner can find but little of value in a topic that has already been exploited to the point of nausea.

A MANUAL OF TOXICOLOGY. A concise presentation of the principal facts relating to poisons, with detailed directions for the treatment of poisoning. Also a table of doses of the principal and many new remedies. By ALBERT H. BRUNDAGE, A.M., M.D., Phar.D., M.S., Professor of Toxicology and Physiology in the Departments of Medicine, Dentistry, and Pharmacy of Marquette University; formerly President of the Board of Pharmacy of the State of New York and Examiner in Toxicology in same: etc.; Honorary member of the Brooklyn (N.Y.) Medical Society; Life Member of the New York State Pharmaceutical Association; Member of the American Medical Association, the American Pharmaceutical Association, the American Microscopical Society, the American Association for the Advancement of Science, etc. Seventh edition revised and profusely illustrated. New York: The Henry Harrison Co.; London: Ballière, Tindall & Cox, 1910.

THE seventh edition of this useful work contains two new sections: (1) on simulation of poisoning by disease, autointoxication and disease, action and elimination of poisons; and (2) on pharmacological toxicology. The book contains an immense amount of information on a most important topic; and, as a rule, the author has been successful in eliminating the non-essentials of the subject. A book on toxicology should be of easy reference, for if it is wanted at all it is apt to be wanted in a hurry. Under the heading Morphine in the index we find 14 entries, but it is the sixth one that gives the main information. Similarly under Aconite there are 12 entries; under Arsenic 15; under Mercury 9; under Strychnine 12; and in no case is there any indication as to which entry gives the desired information, and in no case is it the first entry. We would suggest that in the next edition thick type or black figures be used to indicate the page upon which the subject is chiefly considered.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

North Carolina Board of Medical Examiners.

June, 1910.

ANATOMY AND HISTOLOGY.

1. Name the bones of the foot, and describe the inferior extremity of the tibia.
2. Name and describe the salivary glands.
3. Locate and describe the gall-bladder.
4. (*a*) With what bones does the radius articulate? (*b*) Name the ligaments of wrist-joint.
5. Give origin, insertion, function and nerve supply of the following muscles: Sartorius, sternocleidomastoid and the sphincter ani externus.
6. What constitutes the brachial plexus? and describe the musculospiral nerve.
7. (*a*) Name arteries which supply the heart with blood and where they originate; (*b*) name branches of subclavian artery.
8. (*a*) Name the abdominal viscera wholly covered with peritoneum; (*b*) those partially covered.
9. Describe the broad ligaments of the uterus and their anatomic relations.
10. Describe the structure of the prostate gland and give its anatomic relations.
11. Describe the medulla oblongata.
12. Describe the portal system.

PHYSIOLOGY AND HYGIENE.

1. Enumerate the changes, degenerative and regenerative, that take place in a neuron whose nerve fiber has been severed from its cell.
2. Define metabolism, and mention the manifestations of cell life.
3. Discuss the hydrochloric acid of the gastric juice—(*a*) its functions, (*b*) the probable histological elements concerned in its secretion, (*c*) its origin, or probable nature of the chemical reaction or reactions by which it is produced.
4. What facts are suggested by clinical observation and animal experimentation as to the importance to health of the thyroids and parathyroids?
5. Discuss the phenomena of heart action—(*a*) as to the cause or causes of its beat, (*b*) as to the probable nature of its *inner stimulus* to automatic rhythmical contractions, (*c*) as to the control of the rate and force of its beat.
6. What means of defence is afforded by the constituents of the blood against invasion of the organism by pathogenic germs?
7. What is uric acid, what its properties, and what its origin?
8. Define and state the significance or use, as the case may be, of (*a*) indican, (*b*) creatin, (*c*) glycogen, (*d*) collagen, (*e*) lipase.
9. Define or describe diffusion, dialysis, and osmosis, and suggest certain physiological phenomena due more or less to these processes.
10. Of what food value are commercial meat extracts?
11. Suggest the prophylaxis of gastroenteric toxemias of bottle-fed infants.
12. Point out the measures necessary to prevent the spread of infection from a case of typhoid fever, a case of scarlet fever, a case of diphtheria, a case of yellow fever.

CHEMISTRY.

1. Define (*a*) chemical affinity; (*b*) the difference between an atom and a molecule; (*c*) an element and a compound.
2. Give the chemical names of the following formulæ: (1) HCl; (2) H_2SO_4; (3) HNO_3; (4) H_2O; (5) H_2O_2; (6) $AgNO_3$; (7) NH_3; (8) HgCl; (9) $HgCl_2$; (10) Na_2SO_4; (11) NaCl; (12) HgO.
3. Describe hydrogen, giving symbol, atomic weight, chemical properties, and express by a chemical equation the reaction which takes place when zinc is acted upon by hydrochloric acid, hydrogen being liberated.
4. Name the chief four elements which enter into the formation of organic compounds.
5. Describe in detail (*a*) the "coagulation by heat" test for albumin in the urine, (*b*) the "nitric acid" test, (*c*) Fehling's test for sugar, (*d*) Boetger's bismuth test for sugar.

DISEASES OF CHILDREN.

1. Describe symptoms and sequelæ of acute atrophic (infantile) paralysis, and designate location of the pathological lesion.
2. Describe treatment (with prescription) of a case of acute gastroenteritis, child two years of age.
3. Treat a case of acute catarrhal croup in a child of three years (with prescription).
4. Give differential diagnosis between measles and scarlet fever.
5. Give the dose of the following drugs for an infant three months old: Tinct. aconite, phenacetin, tinct. opii camphorata, quinine, syrup of ipecac, ammonium chloride, spiritus etheris nitrosi, comp. spts. of ether, sodium bromide.

MATERIA MEDICA AND THERAPEUTICS.

1. What is meant by an official drug?
2. Define a fluid extract, a spirit, an infusion, a decoction.
3. Select four of the following drugs and give their official, botanical and common names, the parts used, their chief official preparations and alkaloids (official alkaloids only), and state very briefly their physiological actions and therapeutic indications—aconite, belladonna, digitalis, ergot, nux vomica, opium. (Answers should not exceed one page of written matter to the drug.)
4. Give the dose of apomorphinæ hydrochloridum, hydrargyri iodidum flavum, cocaina, phosphorus, pilocarpinæ hydrochloridum, resina podophylli, santoninum, tinctura aconiti, tinctura gelsemii.
5. Give official names (Latin or English) of Basham's mixture, carron oil (chief use), Dover's powder (amount of each ingredient), Gray powder, Hoffman's anodyne, Lugol's solution, Monsel's solution, spirit of Mindererus, tartar emetic, Donovan's solution.
6. How would you treat a case of poisoning when the toxic agent was unknown?
7. Name four drugs that are specifics, and the diseases they will cure.
8. State what remedies you would use to relieve pain; give indication and contraindications of each.
9. State what drugs you would use to produce sleep; give indications and contraindications of each.
10. Write a prescription for each of the common complications of typhoid fever.

PRACTICE OF MEDICINE.

1. Differentiate between vesicular and bronchial breathing. What does bronchial breathing denote?
2. What is meant by cardiac compensation? Give symptoms of ruptured or broken compensation.
3. Give differential diagnosis between peptic ulcer and gastralgia.
4. What approximately is the normal amount of urine in twenty-four hours and specific gravity? How affected by acute nephritis, chronic interstitial nephritis, chronic parenchymatous nephritis, diabetes mellitus?
5. In unilateral facial paralysis how would you differentiate a central from a peripheral origin? Give causes. In which does reaction of degeneration follow?
6. Differentiate between follicular tonsillitis and diphtheria.
7. Give etiology and symptoms of arteriosclerosis and state what conditions of heart, brain and kidney are produced by it.
8. Give symptoms of acute intestinal obstruction.
9. Give leading symptoms in leukemia (splenomedullary) and the blood picture.
10. Write one prescription in pill form for anemia, using three or four drugs.

OBSTETRICS AND GYNECOLOGY.

1. Define version. Give the indications and dangers of version.
2. Describe the changes in position the uterus undergoes during pregnancy.
3. Into what stages is labor divided. Give a description of each stage.
4. What are the dangers of ergot in obstetrics? And when should it be given?
5. Define and classify ectopic pregnancy. What are the symptoms of rupture of an ectopic pregnancy? Give the treatment.
6. Give the physical signs of an acute peritonitis.
7. What are the symptoms of cancer of the uterus?
8. What are the relative advantages and disadvantages of the abdominal and vaginal routes in pelvic surgery?

SURGERY.

1. (*a*) What is pyothorax? (*b*) What particular infection is its most frequent cause, and (*c*) what is its treatment? (*d*) If operation, describe it.
2. (*a*) Discuss ascites, and (*b*) give some of the causes and treatment for same.

3. Describe operation for internal strabismus.
4. Describe amputation of lower leg one inch below tubercle of tibia.
5. (*a*) Define hemorrhoids, (*b*) discuss their palliative treatment, and (*c*) describe the ligature operation.
6. Describe operation for resection of six inches of middle of ileum. (This includes preparation of abdomen.)
7. Discuss shock and its treatment. Differentiate between symptoms of shock and hemorrhage.
8. (*a*) Give prominent symptoms of carcinoma of the cervix uteri, (*b*) discuss its treatment (if operative, do not describe operation, simply name it), and (*c*) give the most frequent predisposing cause.
9. What are the causes, symptoms and treatment of intestinal perforation?
10. Discuss briefly the uses of the Röntgen ray in surgery and in the treatment of superficial epithelioma.
11. Mention two kinds of suture material and describe the preparation of each for surgical use.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NORTH CAROLINA BOARD OF MEDICAL EXAMINERS.

June, 1910.

ANATOMY AND HISTOLOGY.

1. *Bones of foot:* Os calcis, astragalus, cuboid, scaphoid, internal cuneiform, middle cuneiform, external cuneiform, five metatarsals, and fourteen phalanges.

For inferior extremity of tibia see Cunningham's "Anatomy" (1909), page 233; or Gray's "Anatomy" (1908), page 238.

2. Parotid, submaxillary, and sublingual glands. See Cunningham's "Anatomy" (1909), page 1009; or Gray's "Anatomy" (1908), page 1224.

3. See Cunningham's "Anatomy" (1909), page 1118; or Gray's "Anatomy" (1908), page 1350.

4. (*a*) *The radius articulates with:* Humerus, ulna, scaphoid, and semilunar.

(*b*) *Ligaments of wrist joint:* Anterior, posterior, external lateral, and internal lateral.

5. SARTORIUS. *Origin:* Anterior superior spine of ilium, and part of notch below. *Insertion:* Inner side of tibia near tubercle. *Function:* Flexes and crosses legs. *Nerve supply:* Middle cutaneous, or branch from anterior crural.

STERNO-CLEIDO-MASTOID. *Origin:* Upper end of sternum and upper and inner end of clavicle. *Insertion:* Mastoid process of temporal bone and outer half of superior curved line of occipital bone. *Function:* Flexes head on neck and rotates the head. *Nerve supply:* Spinal accessory and cervical plexus.

SPHINCTER ANI EXTERNUS. *Origin:* Tip of coccyx. *Insertion:* Central tendinous raphe of perineum. *Function:* To keep the anal orifice closed. *Nerve supply:* Fourth sacral and internal pudic.

6. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius.

For musculospiral nerve see Cunningham's "Anatomy" (1909), page 632; or Gray's "Anatomy" (1908), page 1007.

7. (*a*) The right and left coronary arteries from the aorta. (*b*) Vertebral, thyroid axis, internal mammary, and superior intercostal arteries.

8. (*a*) *Viscera wholly covered with peritoneum:* Liver, stomach, spleen, jejunum, ileum, transverse colon, sigmoid flexure, upper part of rectum, uterus, and ovaries.

(*b*) *Viscera partially covered with peritoneum:* Duodenum, ascending and descending colon, middle part of rectum, and bladder.

9. See Cunningham's "Anatomy" (1909), page 1189; or Gray's "Anatomy" (1908), page 1502.

10. For *structure* of prostate see Cunningham's "Anatomy" (1909), page 1175; or Gray's "Anatomy" (1908), page 1462.

RELATIONS OF PROSTATE. *Anteriorly:* Symphysis pubis, anterior ligaments of bladder, branches of dorsal vein of penis. *Posteriorly:* Rectum. *Laterally:* Levator ani. *Base:* Surrounds neck of bladder, seminal vesicles, and vasa deferentia. The *apex* rests on triangular ligament.

11. See Cunningham's "Anatomy" (1909), page 481; or Gray's "Anatomy" (1908), page 874.

12. See Cunningham's "Anatomy" (1909), page 901; or Gray's "Anatomy" (1908), page 768.

PHYSIOLOGY AND HYGIENE.

1. A nerve fiber cut off from the cell from which it comes undergoes degeneration along the whole peripheral cut end at one and the same time. The changes are as follows: (1) The axon dies and withers away; (2) the medullary sheath breaks up into fine fatty drops; (3) the nuclei under the neurilemma proliferate. This change also takes place in the proximal portion of the nerves up to the nearest node of Ranvier. The cell from which the axon comes shows a degeneration which is as follows: (1) Nissl granules become few and smaller, and eventually disappear entirely; (2) the whole cell eventually degenerates and dies, and therefore the whole proximal portion of the nerve fibers now shows Wallerian degeneration. If after section the cut ends be sutured together the axons in the central end will in time grow down the degenerated peripheral end to the parts originally supplied by the cut nerve.

2. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative or constructive (anabolism), and (2) destructive (katabolism).

The *manifestations of cell life* are: Movement, ingestion, assimilation, excretion, growth, irritability, and reproduction.

3. HYDROCHLORIC ACID. (*a*) *Functions:* (1) To aid in digestion of proteids; (2) protective influence in destroying pathogenic bacteria. (*b*) It is produced by the oxyntic or parietal cells in the mucous coat of the stomach. (*c*) (1) $NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl$; or (2) $2Na_2HPO_4 + 3CaCl_2 = 3Ca_3(PO_4)_2 + 4NaCl + 2HCl$.

4. The *function of the thyroid* is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

Removal of the thyroid gland causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out and the patient becomes unwieldy and clumsy in both body and mind. The complete removal causes death in most animals, and it is not considered justifiable in man. It has been claimed that the parathyroids can to some extent perform the function of the thyroids after extirpation of the latter.

5. (*a*) The cause of the heart beat is unknown. There are two theories: (1) That it originates in the nerve ganglia in the heart (neurogenic theory); (2) that it originates in the muscle cells of the heart (myogenic theory). (*b*) The probable nature of the inner stimulus to automatic rhythmical contractions is *nervous*. (*c*) The control of the rate and force of the heart beat is by: (1) The sympathetic nerve, which quickens it; (2) the pneumogastric nerve, which inhibits or slows it.

6. The white corpuscles, by their phagocytic action; the plasma, by its alkalinity; and the agglutinating action of the blood all serve as a means of defence against bacterial invasion.

7. Uric acid is a dibasic acid, with the formula $C_5H_4N_4O_3$. It occurs chiefly in the urine, as urates of sodium and ammonium. It crystallizes as lozenge-shaped plates or prisms, arranged in bundles; it is without odor or taste, is slightly soluble in water, and is insoluble in alcohol or ether. In man it has a twofold origin, one portion coming from the breaking down of the nuclein containing tissues or cell elements of the body, and the other from the purin compounds in the food.

8. (*a*) *Indican* is indoxyl potassium sulphate; it is found (in excess) in the urine in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc.—(From Witthaus' *Essentials of Chemistry.*)

(*b*) *Creatin* is a complex amido acid; it is found in muscle tissue, brain, urine, etc.; very little is formed in the body, and it is excreted in the urine as creatinin.

(*c*) *Glycogen* is animal starch, found chiefly in the liver and muscles. It is converted into sugar as it is needed in the body.

(*d*) *Collagen* is a constituent of connective tissues, cartilage, and bone; gelatin can be obtained from it.

(*e*) *Lipase* is an enzyme whose function is to split fats; it is found in the pancreatic juice.

9. "The term *diffusion* has long been applied to the regular mixing of the molecules of two gases when brought into contact in a confined space. More recently it has been applied to the mixing of the molecules of two solutions when brought into contact. If, however, the two solutions are separated by a membrane, permeable to the solutions, diffusion will still occur. To this form of diffusion the term *Osmosis* has been applied in the case of water, and *Dialysis* in the case of diffusible substances. All bodies can be divided into two groups, *crystalloids* and *colloids*. To the former group belong bodies having a crystalline form, which readily go into solution in water. All such bodies are diffusible (dialyzable), their power of dialysis, however, varying considerably. To the second group belong such bodies as have no crystalline form (amorphous). These are generally bodies with a large molecule, which form colloidal suspensions in water, and are only slightly or not at all diffusible. An exception to this second group is hemoglobin, which has a very large molecule but is crystalline and is diffusible."—(Kirkes' *Physiology*.)

Physiological applications: "In the animal body the fluids are separated by delicate membranes across which the constituents of the fluids, inorganic and organic, are continually passing. Thus prepared foods in the intestine pass across the intestinal wall into the blood- and lymph-vessels; the constituents of the blood pass across the wall of the capillary vessel into the tissue spaces, from which they pass (*a*) through the walls of various glands to take part in the formation of their secretion; (*b*) across the sarcolemma into the interior of the muscle fiber; (*c*) across the limiting surface of and into the interior of all tissue cells. The waste products, the results of tissue and food metabolism, pass from the interior of cells across their limiting membranes or surfaces into the tissue spaces; thence across the wall of the capillary vessel and the epithelium of the lung, the kidney, the liver, etc., to take part in the formation of the excretions. These and other processes are believed to be accomplished by the factors, diffusion, osmosis, and filtration."—(Brubaker's *Physiology*.)

10. The food value of commercial meat extracts is very slight; they have a feeble stimulant action, and serve to flavor the water with which they are mixed.

11. See French's "Practice of Medicine" (1907), pages 780 and 781; or Osler's "Practice of Medicine" (1909), page 508.

12. See French's "Practice of Medicine" (1907), pages 107, 324, 194, and 275; or Osler's "Practice of Medicine" (1909), pages 96, 138, 207 and 238.

CHEMISTRY.

1. (*a*) *Chemical affinity* is that force which attracts atoms to each other and causes them to unite to form a molecule. (*b*) An *atom* is the smallest portion of an element which can enter into chemical reaction. A *molecule* is the smallest portion of a substance (element or compound) which can exist free. (*c*) An *element* is a substance out of which we cannot, by any known means, get dissimilar substances. A *compound* is a substance made up of two or more elements, chemically united, in definite proportions.

2. HCl is hydrochloric acid; H_2SO_4 is sulphuric acid; HNO_3 is nitric acid; H_2O is hydrogen monoxide; H_2O_2 is hydrogen dioxide; $AgNO_3$ is silver nitrate; NH_3 is ammonia; HgCl is mercurous chloride; $HgCl_2$ is mercuric chloride; Na_2SO_4 is disodic sulphate; NaCl is sodium chloride; HgO is mercuric oxide.

3. *Hydrogen:* Symbol, H; atomic weight, 1; valence, 1; is a colorless, odorless, tasteless gas, the lightest substance known, the unit of atomic and molecular weights, does not support combustion, but when lit burns with a pale blue flame which gives very little light but intense heat, combines explosively with chlorine in sunlight, is a necessary ingredient in all acids.

$$Zn + 2HCl = ZnCl_2 + H_2$$

4. Carbon, hydrogen, oxygen, and nitrogen.

5. (*a*) *Coagulation test:* The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

(*b*) *Nitric acid test:* Pour into a clean test tube a layer of HNO_3 about half an inch deep; then with a pipette carefully float on to the surface of this acid a layer of urine, taking care that the liquids do not mix. If albumin is present a cloudy ring, with sharply defined borders, will appear at the point of junction of the two layers.

(*c*) *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 bms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(*d*) *Boettger's test:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.—(From Witthaus' *Essentials of Chemistry*.)

DISEASES OF CHILDREN.

1. See French's "Practice of Medicine" (1907), page 1083; or Osler's "Practice of Medicine" (1909), page 915.

2. See French's "Practice of Medicine" (1907), page 781; or Osler's "Practice of Medicine" (1909), page 509.

3. See French's "Practice of Medicine" (1907), page 645; or Osler's "Practice of Medicine" (1909), page 597.

4. *Measles:* Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

Scarlet fever: Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctuate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

5. Tinct. aconite, ♏⅛; phenacetin, gr. ¼; tinct. opii camphorata, ♏j; quinine (sulphate), gr. ½; syrup of ipecac, ♏½; ammonium chloride, gr. ⅛; spiritus etheris nitrosi, ♏j; comp. spts. of ether, ♏j; sodium bromide, gr. ½.

MATERIA MEDICA AND THERAPEUTICS

1. An *official drug* is one that is listed in the Pharmacopœia.

2. A *fluidextract* is a solution of a vegetable drug of such strength that 1 c.c. of the fluidextract represents 1 gram of the drug.

A *spirit* is an alcoholic solution of a volatile substance.

An *infusion* is a fluid preparation made by steeping a vegetable substance in boiling water.

A *decoction* is a fluid preparation made by boiling a vegetable substance in water.

3. ACONITE. *Official name.* Aconitum; *botanical name,* Aconitum Napellus; *common name,* Monk's-Hood; *part used,* the root; *official preparations,* fluidextract and tincture; *official alkaloid,* aconitine; *physiological action,* first stimulates and then paralyzes heart and also sensory nerves, lowers blood pressure, dilates peripheral blood-vessels, is a respiratory sedative, reduces body temperature, is a diuretic and diaphoretic.

Therapeutic indications: For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritis, herpes, chilblains, etc.

BELLADONNA. *Official name:* Belladonna; *botonical name:* Atropa Belladonna; *common name:* Deadly nightshade;

parts used. leaves and root; *official preparations:* tincture, extract, plaster, and ointment (of the leaves); and fluid-extract and liniment (of the root); *official alkaloid:* atropine; *physiological action:* anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Therapeutic indications: To relieve pain, relax spasm, check sweating, as a mydriatic for night sweats, to check griping of purgatives; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, spasmodic cough.

DIGITALIS. *Official name:* Digitalis; *botanical name:* Digitalis purpurea; *common name:* Purple foxglove; *parts used:* dried leaves; *official preparations:* extract, fluid-extract, tincture, and infusion; *official alkaloids,* none; *physiological action:* it is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels and causes a rise in blood pressure, it also acts as a diuretic.

Therapeutic indications: In heart diseases (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in non-valvular cardiac affections; (4) in irritable heart, due to nerve exhaustion; also cardiac palpitation, irritable heart from nerve exhaustion, cardiac and renal dropsy, and exophthalmic goiter.

ERGOT. *Official name:* Ergota; *botanical name:* Claviceps purpurea; *common name:* Spurred rye; *parts used:* the sclerotium; *official preparations:* extract, fluidextract, and wine; *official alkaloids:* none. *Physiological action:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

Therapeutic indications: To promote uterine contractions during third stage of labor; fibroids, menorrhagia, post-partum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headache, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

NUX VOMICA. *Official name:* Nux vomica; *botanical name:* Strychnos nux vomica; *common name:* Quaker button, or poison nut; *parts used:* seeds; *official preparations:* extract, fluidextract, tincture, strychnine (with its sulphate and nitrate); *official alkaloid:* strychnin; *physiological action:* It excites the digestive secretions, increases the appetite, increases peristalsis, and improves the digestion; it is a vasoconstrictor, it raises blood pressure, and is a cardiac stimulant; it is also a respiratory stimulant; hearing and sight are rendered more acute.

Therapeutic indications: As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, alcoholism, and urinary incontinence.

OPIUM. *Official name:* Opium; *botanical name:* papaver somniferum; *common name:* white poppy; *parts used:* capsule; *official preparations:* powdered, granulated, and deodorized opium; extract, tincture, camphorated tincture, tincture of deodorized opium, tincture of ipecac and opium, pills, wine, vinegar plaster, and powder of ipecac and opium: *official alkaloids:* morphine, codeine. *Physiological action:* It is analgesic, hypnotic, diaphoretic, narcotic, a respiratory and cardiac stimulant (later a depressant), it checks most secretions (not perspiration), it stimulates the brain, and contracts the pupil.

Therapeutic uses: As an anodyne, a hemostatic, in inflammations, as an expectorant, in diarrhea, in alcoholism, manias and diabetes, as an antispasmodic, in insomnia, and as a diaphoretic.

4. *Dose of:* Apomorphinæ hydrochloridum, gr. 1/30 (expectorant), gr. 1/10 (emetic); hydrargyri iodidum flavum, gr. 1/5; cocaina, gr. ss; phosphorus, gr. 1/125; pilocarpinæ hydrochloridum, gr. 1/5; resina podophylli, gr. 1/6; santoninum, gr. j; tinctura aconiti, ♏x; tinctura gelsemii, ♏viij.

5.

	OFFICIAL NAMES.
Basham's mixture...	Liquor ferri et ammonii acetatis; solution of iron and ammonium acetate.
Carron oil.....	Linimentum calcis; lime liniment.
Dover's powder.....	Pulvis ipecacuanhœ et opii; powder of ipecac and opium.
Gray powder.....	Hydrargyrum cum creta; mercury with chalk.
Hoffman's anodyne.	Spiritus ætheris compositus; compound spirit of ether.
Lugol's solution....	Liquor iodi compositus; compound solution of iodine.
Monsel's solution...	Liquor ferri subsulphatis; solution of ferric subsulphate.
Spirit of Mindererus.	Liquor ammonii acetatis; solution of ammonium acetate.
Tartar emetic.....	Antimonii et potassii tartras; antimony and potassium tartrate.
Donovan's solution..	Liquor arseni et hydargyri iodidi; solution of arsenic and mercuric iodide.

Carron oil is chiefly used for burns; Dover's powder contains 10 per cent. each of ipecac and opium.

6. *"General antidotes* have been devised for use when the nature of a poison is unknown, with the object of a 'shot-gun prescription,' intended to hit something. One of the best is *Jeaunel's,* composed as follows: Liquor ferri sulphatis, ʒijss; magnesia calcinat., ʒij; carbo animalis, ʒj; aqua, ʒxx. These ingredients should be kept separate—the solution of the sulphate in one vessel, the others together. When needed, the former should be added to the latter and violently agitated. Dose, ʒiss to ʒiij. This is a perfect antidote for arsenic, zinc, digitalin, etc. It delays the action of the salts of copper, morphine and strychnine, and slightly influences compounds of mercury. It is valueless for cyanide of mercury, tartar emetic, hydrocyanic acid, phosphorus, or the caustic alkalies. If the nature of the poison is entirely unknown, a harmless yet effectual antidote in most cases is one composed of equal parts of magnesia, wood charcoal, and the hydrated ferric oxide, given freely in plenty of water."—(Potter's *Materia Medica,* etc.)

7. *Four specifics:* Quinine, for malaria; diphtheria antitoxin, for diphtheria; mercury, for syphilis; colchicum, for gout.

8. *Opium* has the power of relieving pain arising from almost any cause, it is especially useful in pain occasioned by gross lesions—inflammation, traumatism, and morbid growths. In the various so-called functional pains, such as headache and neuralgia, the coal-tar derivatives—*antipyrin, phenacetin,* and *acetanilid*—are more serviceable analgesics. *Cannabis indica* somewhat resembles opium in its action as an analgesic, but it is far less powerful. It is especially useful in neuralgia and migraine. The *bromids,* by depressing the cerebral cortex, often afford relief in headache, but in other forms of pain they usually fail. Some drugs seem to have an affinity for certain nerves; thus *gelsemium* and *butyl chloral hydrate* are often distinctly valuable in trifacial neuralgia."—(Stevens' *Materia Medica.*)

9. CHLORAL, SULPHONAL, and TRIONAL: *Chloral hydrate* produces a natural sleep, acts promptly, but is of no service if pain is present; it also lowers the body temperature. It can be given for a long time without deleterious effect, but it may irritate the tissues and weaken the heart. *Sulphonal* produces a natural sleep, but is of slow action, requiring three or four hours to take effect; it is of no use if pain is present, does not irritate the tissues and weaken the heart, but is probably not so good for continuous use as chloral hydrate, though the two may replace each other for a time. *Trional* is very similar to sulphonal, but is more soluble, and acts quicker. Both sulphonal and trional are supposed to be safer than chloral.

PRACTICE OF MEDICINE.

1. *Vesicular breathing* is that which is heard normally over the air vesicles of the lungs; *bronchial breathing* is that which is heard normally over the trachea and bronchi. Bronchial breathing, elsewhere, denotes consolidation of the lung, phthisis, pneumonia, pleuritic effusion, hemorrhagic infarction or syphilis of lung.

2. By *cardiac compensation* is meant the changes in the heart muscle (hypertrophy, etc.), due to effort on the part of the heart to meet the increased work thrown upon it in case of valvular lesions. *Symptoms of broken compensation* are: Dyspnea cyanosis, edema, cough, hemoptysis, and disturbances of stomach, liver, or kidney.

3. See French's "Practice of Medicine" (1907), page 750.

4.

	AMOUNT IN 24 HOURS.	SPECIFIC GRAVITY.
Normal	About 40 to 50 ounces.	About 1015 to 1025.
Acute nephritis.	Diminished.	About 1025 to 1030+.
Chronic interstitial nephritis	Greatly increased.	1010, 1005, or less.
Chronic parenchymatous nephritis.....	Diminished.	High or low.
Diabetes mellitus.....	Greatly increased.	1030 to 1045.

5. See French's "Practice of Medicine" (1907), page 1008; or Osler's "Practice of Medicine" (1909), page 1020.

6. In *diphtheria* the onset is more gradual; the temperature rises to about 101° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.

8. The relative advantages and disadvantages of the abdominal and vaginal routes in pelvic surgery are thus summarized by Dudley (*Diseases of Women*):

Advantages of the abdominal route: (1) A large field is open for operation; (2) the operator may see what he is doing instead of depending largely on touch; (3) diagnosis of unsuspected conditions and complications is much easier; (4) the abdominal section is adapted to large tumors and pus sacs, and to conditions high in the pelvis; (5) the appendages may be removed with better chance of avoiding rupture of a pus sac; (6) there is less danger of wounding intestines, bladder, or ureters and greater facility in the control of hemorrhage; (7) the frequent concurrence of appendicitis and other abdominal lesions with pelvic disease and the impossibility of reaching them by the vagina; (8) it gives more light and more space for conservative work.

Advantages of the vaginal route: (1) It gives better drainage, and is therefore specially adapted to cases of vesical or intestinal fistulæ; (2) it avoids abdominal scar and risk of ventral hernia; (3) it is suitable for cases of small tumors without high adhesions; (4) when properly performed it lessens the danger from shock, and is therefore suitable to cases of extreme pelvic infiltration which are inoperable, because too dangerous, by the abdominal route; (5) it involves less handling of the intestines, and therefore less consequent danger of intestinal adhesions; (6) recovery is less complicated and more rapid.

Unfortunately, the vaginal route is, for at least a very large proportion of cases, impracticable. The long, narrow virgin vagina or the vagina which has become contracted from senile atrophy may render the field of operation almost inaccessible. A very large uterus with exceptionally short, thick, broad ligaments and greatly enlarged appendages, with adhesions extending beyond the reach of the finger, may also be difficult or impossible to manipulate through the vagina. Under such conditions the abdominal route is much safer.

SURGERY.

1. Pyothorax is empyema. See Rose and Carless' "Surgery" (1908), page 926; or Da Costa's "Surgery" (1908), page 773.

2. See Rose and Carless' "Surgery" (1908), page 983.

3. *Tenotomy of internal rectus:* "The speculum is introduced and the eyeball drawn outward, if necessary, by an assistant. The conjunctiva over the lowest portion of the insertion of the muscle, together with the subconjunctival tissue and Tenon's capsule, is seized with a pair of fixation forceps, raised and divided with scissors; the first cut divides the conjunctiva, the second Tenon's capsule. Keeping the fold raised with the forceps, a strabismus hook is introduced through the opening, passed beneath the tendon, and pushed upward until its point is seen through the conjunctiva at the upper border of the muscle. The hook is transferred to the left hand and raised so as to lift the tendon. The scissors are taken in the right hand and introduced, one branch between the tendon and conjuctiva, and the other between the tendon and sclera; the tendon is divided close to the sclera by two or more small cuts. The hook is reintroduced to make sure that no portion of the tendon has been left undivided. If the tendon has been completely divided, the hook can be advanced to the cornea without resistance; if not, the undivided fibers must be cut with scissors. The hook is again introduced and swept from behind forward, above, and below, to ascertain whether there are any uncut fibers of attachment to the sclera which, if found, must be severed. The conjunctival wound is closed with one or two vertical sutures."—(May's *Diseases of the Eye.*)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 1, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Surgery, and was devoted to a symposium on hyperthyroidism.

The Therapeutic Application of a Theory for the Pathological Physiology Involved in Disease of the Thyroid Gland.—Dr. JOHN ROGERS described a theory to account for the normal and pathological physiology of the thyroid gland and its application to the management of cases showing disease of this organ. He first presented several cases as follows: The *first*, a typical and rather severe myxedema of fifteen years' duration. Commercial thyroid at first was beneficial and later failed entirely by causing hyperthyroidism; a substitution of 1/10 gr. of the pure thyroid proteids proved helpful, but the dose had to be steadily increased until thyroidism again appeared. Then a combination of the thyroid pure proteids with the pancreas nucleoproteid relieved all symptoms. The pancreatic enzymes were injurious. The *second* case, also one of myxedema, but with a goiter and with high blood-pressure and severe gastroenteric disturbance, was relieved entirely by feeding with the adrenal nucleoproteid. The *third* case, again one of myxedema, could be relieved only by a combination of the thyroid pure proteids and enterokinase. The *fourth* case, one of severe typical exophthalmic goiter, was at first made worse by the antithyroid serum, but cured entirely within three months by the subcutaneous administration of thyroid globulin. The *fifth* case, likewise one of severe typical exophthalmic goiter, after improving under the antithyroid serum developed glycosuria. Partial thyroidectomy was then performed, with complete cure of both the thyroidism and the glycosuria. The glycosuria and hypertrophy of the left lobe did not disappear entirely until trypsin was given by rectum. The *sixth* case, one of severe exophthalmic goiter, was improved at first by the antithyroid serum, but this finally became ineffective. All four of the different thyroid vessels were then tied at intervals of two or three weeks, but no appreciable gain resulted until adrenal nucleoproteid feeding was begun. This had resulted in an almost perfect cure.

Dr. Rogers next proceeded to his theory of thyroid disease, based upon the chemistry of the gland, and the above clinical observations which had many times been repeated. The thyroid of untreated Graves' disease contained less iodine per gram of gland substance than the normal organ, and the quantity seemed to diminish in proportion to the severity of the disease. Two active substances could be isolated, one a nucleoproteid, the other a globulin. The globulin product decreased in abundance and the nucleoproteid increased in direct proportion to the cellular hyperplasia and disintegration characteristic of the thyroid changes in a typical Graves' disease. In primary acute toxemic Graves' disease the thyroid contained little or no colloid (the equivalent of the globulin constituent) and a great abundance of nucleoproteid; and in cases which had not previously been given iodine this element was much less than normal in each gram of gland substance. The reverse was true of the normal thyroid. From experiments and from clinical observation, it was probable that the thyroid nucleoproteid was limited in its effects to stimulation of the chromaffin or sympathetic-adrenal system, and so by stimulation of the cardioaccelerator nerve produced tachycardia. The thyroid globulin, or colloid, on the other hand, was assumed to have a universally activating effect upon every organ and tissue in the body. As the thyroid, adrenals, pancreas, liver, and duodenum seemed closely allied in diseased states of the thyroid, these organs were singled out for a diagrammatic representation of thyroid physiology. The thyroid globulin was thus supposed to activate the adrenals, pancreas, duodenum, and liver directly, and aid in the production of an "internal" secretion from the adrenals and pancreas, which, with the thyroid globulin and the absorbed intestinal enzymes, in turn passed through the circulation to the liver and were thus a necessity for its normal chemical processes. In Graves' disease there was a deficiency of thyroid globulin (qualitative at first more than quantitative) and an excess of nucleoproteid, and this excess unduly stimulated the chromaffin system which, through the adrenal portion of the system, inhibited the pancreatic and duodenal chemistry, while it stimulated the heart. The deficiency of thyroid globulin, on the other hand, led directly to an imperfect liver activation, and indirectly added to the damage to the liver by an imperfect or deficient internal secretion from the adrenals and pancreas, which also were necessary in the liver chemistry.

The primary cause of all thyroid disease seemed to be glandular fatigue, and the thyroid with its assumed universally activating properties, was, of course, exposed to excessive demands upon its product. In myxedema, the fatigue led to atrophy of the thyroid epithelium. In Graves' disease, a compensatory hypertrophy took place in response to the demands upon the thyroid, but the fatigued epithelium was unable to perform its biochemical duties and multiplied so rapidly in its attempt to metabolize iodine, that it disintegrated and thus formed an imperfect or actually deficient amount of colloid or globulin, and an undue excess of nucleoproteid. As the thyroid globulin was supposed to be universally activating, it must, when in excess, activate the thyroid itself; and as the gland was supplied by the sympathetic nervous system, and excess of thyroid nucleoproteid in its stimulation of these nerves, must likewise stimulate the activity of the thyroid epithelium. Hence, in the activation of the thyroid by its own globulin and nucleoproteid products, there arose, in overactivity of the gland, a double vicious circle and a self-perpetuation of a fatigue phenomenon which involved not only the thyroid, but also the liver, duodenum, pancreas, and adrenals. The latter were part of another apparently autoactivated system, as their only known product, adrenalin, seemed to be limited in effect to the terminal filaments of the sympathetic nervous system; and if the adrenals were capable of functional overactivity like the thyroid, the sympathetic might unduly stimulate the thyroid and so cause a hyperthyroidism, which was a secondary and not a primary disease of the gland.

The therapeutic problem was first to rest the thyroid and allow the epithelium time to regain its ability properly to metabolize iodine; and next to cut off the superabundant thyroid nucleoproteid (and also the globulin)

which possessed the power, through the sympathetic or chromaffin system, of stimulating the thyroid and the heart, and of inhibiting the pancreas and duodenum. The primary, acute toxemic cases could be cured by the antithyroid serum, which, by its cytotoxic and antitoxic components, neutralized the thyroid products, but after the subsidence of the acute symptoms rest was necessary. The chronic cases required a preliminary ligation of the thyroid vessels always under local anesthesia, to obtain rest for the gland. Afterwards the antiserum or supporting organ therapy should be employed. In the toxemic exacerbations of chronic thyroidism, the antiserum must be used with great caution. Partial thyroidectomy was of advantage in cases showing constitutional symptoms, but having only a circumscribed or unilateral enlargement of the gland. The portion of the gland allowed to remain should be in reasonably good condition and of better character than the part removed, or relapse would follow. But the possibility of a primary cause for the disease in a chromaffin system or adrenal disorder must always be borne in mind. The thyroid was only one of several glands which seemed closely associated in the maintenance of a normal nutritional chemistry. A functional disturbance in any one of these organs, among which the pituitary must be included, seemed often to cause a compensatory hypertrophy, and frequently overactivity of the thyroid and therefore radical operation upon the thyroid should be undertaken only after due consideration of the associated conditions.

A Consideration of Surgical Methods of Treating Hyperthyroidism.—Dr. Charles H. Mayo of Rochester, Minnesota, read this paper. (See page 1173.)

Dr. Arpad G. Gerster said it was like carrying coals to Newcastle for one to attempt to add anything. He thought he voiced the sentiments of all present in saying that they should be congratulated in having such an intricate and difficult subject presented to them in such a clear way. Nothing was left untold either chemical, physiological, or surgical, and yet the subject had been treated purely from the medical standpoint and by two well-known surgeons. They had heard in the presentation of their colleague from the West the matter treated in its pathological and in its histological aspect, and also some of the essential facts which brought forth the disease.

Dr. Howard Lilienthal said he had operated upon a few of these cases of exophthalmic goiter, but he did not believe he had any right to an opinion in the face of what they had heard. They should remember that the thyroid gland was something more than just a gland in the neck, for they heard of its enormous influence on remote parts of the body; in it they looked for causes of disorders hitherto obscure. In New York the medical men were not yet in a position to send these cases to the surgeon. All the cases he had operated upon had been such as Dr. Mayo called the advanced cases; the result had been an improvement as a rule in most of the symptoms. They were assuming an attitude toward the thyroid gland that they formerly assumed toward the prostate; they formerly were afraid to touch this organ, whereas now they operated upon it often.

Dr. S. P. Beebe said that in exophthalmic goiter the thyroid gland was not alone involved; there were other glands which showed pathological changes. In the cases that died from so-called medical death, as well as those that died after operation, the autopsy would reveal the thymus gland in a large percentage of the cases hypertrophied. He doubted whether they were in a position to formulate any theory to explain the interrelation of the ductless glands with this disease. With regard to the treatment Dr. Beebe thought there was a very distinct field for it; the disease as it occurred in young women responded to medical treatment. These young women got well and they remained well as though they had been subjected to surgical treatment. He was referring to the mild cases.

Dr. John Rogers said he regarded this disease as a serious one and with a large mortality; he saw but very few get well spontaneously. He urged his hearers to consider this disease as one of fatigue, one of overstrain. Fatigue was at the bottom of this malady and much he believed could be done in the way of prevention.

Dr. Mayo said that they must consider among the causes of this disease septic tonsils, measles, diphtheria, scarlet fever, etc. A great many of the cases of exophthalmic goiter experienced some shock, usually mental.

Election of officers: *President,* Dr. William M. Polk; *Vice-President,* Dr. Glentworth R. Butler; *Trustee,* Dr. A. Alexander Smith; *Committee on Admission* (for 3 years), Dr. H. Seymour Houghton; *Committee on Admission* (for 5 years), Dr. William Kelly Simpson; *Committee on Library,* Dr. Thomas L. Stedman; *Corresponding Secretary,* Dr. Egbert Le Fevre.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 25, 1910.

Dr. S. M. Brickner in the Chair.

Specimen of Primary Ovarian Pregnancy.—Dr. I. C. Rubin said that the first genuine case of primary ovarian pregnancy was demonstrated in 1899; since then there had been eighteen or nineteen authentic cases reported in the literature. The majority of the authentic cases had been early cases, the gestation having proceeded to the sixth or eighth week. The specimen he presented was removed from a patient during July, 1910. She was twenty-four years old. She had been married three years, had one child who was two years old, and she had never had any abortions or miscarriages. Her marital relations were unhappy. her last menstrual period was seven weeks before admission to the hospital. Two months before her admission she had sharp pain in the lower abdomen, especially on the right side, radiating to the back and down the thighs; she then first noticed a profuse yellowish vaginal discharge which was associated with frequent and burning urination. This had since subsided. She came to the hospital because of sharp radiating pains, especially on the right side, chilly sensations and fever, weakness and leucorrhea. Her abdomen was found to be greatly tympanitic, and no palpable masses or rigidity were present. Tenderness was present over the lower half of the abdomen, more marked on the left side. The uterus was found to be somewhat enlarged and in good position. On the left side, close to the uterus, was a mass about the size of an average sized ovary; this was exceedingly tender to the touch. This mass seemed to be fixed and was regarded as an enlarged ovary without, however, having the usual hardness of an ovary. The tubes could not be palpated. On July 28, 1910, an exploratory laparotomy was performed for a possible ectopic gestation. The uterus was found to be the size of the non-pregnant organ. The left tube was bent upon itself and attached to an enlarged ovarian mass. This mass was fixed by soft adhesions to the broad ligament close to the uterus. The left ovary looked edematous and presented at one portion a dark chocolate brown irregular protruding surface; this was thought to be a degenerated corpus luteum verum. On trying to deliver the left adnexa a small plum-colored mass, about the size of a hazel nut, was brought into view. This had apparently been free in the pelvis and suggested a ruptured ectopic pregnancy. The tube on either side was neither macroscopically enlarged nor ruptured. The left ovary still attached to the uterus by its proper ligaments

was, therefore, regarded as the probable seat of the pregnancy. After describing what appeared in the pathological and microscopical examinations of the specimen, Dr. Rubin said that this case satisfied all the requirements of a primary ovarian pregnancy. 1. There were positive evidences of pregnancy. 2. These evidences were within ovarian stroma. 3. The tube on the same side was separate, distinct and showed no gross microscopical signs of pregnancy. 4. The ovary was connected to the uterus by its proper ligament. To be more specific he said that the case really presented an ovarian abortion. The mole could not be shown because it was lost. The uterus was not the seat of pregnancy, nor was there any evidence of a decidual formation within the uterine cavity.

Dr. Robert Tilden Frank said that he had had an opportunity to examine the specimen presented by Dr. Rubin and there was no doubt but that the findings were quite unmistakable, both macroscopically and microscopically. He thought it possible that the cells thought to be decidual cells might be interpreted as stroma cells, the result of the hemorrhagic condition. That was the only point on which there might appear a difference of opinion.

Dr. Knipe referred to the monograph of Bryson and Teacher on ovarian pregnancy in which was brought out the rarity of this condition.

Pubiotomy for Dystocia.—Dr. Frederick C. Holden reported this case. The patient was thirty-eight years old, brought to the hospital in labor at term. Prior to admission the repeated application of the forceps to bring the head into the pelvis failed. On admission the fetal pulse was to the left and below the umbilicus. There was a longitudinal presentation, with the vertex above the brim of the pelvis, dorsum anterior position. The uterus was tense. It was decided to do a pubiotomy operation rather than an abdominal section. This was done by the method of Döderlein. The bone was sawn through, moderate pressure was made upon the fundus, and the child glided into the pelvis. An easy delivery was accomplished by means of forceps. The child weighed seven pounds and eleven ounces. The occipitomental diameter was 13 cm.; the occipitofrontal was 11 cm.; the suboccipitobregmatic was 10 cm. and the biparietal 10 cm. Fowler's posture was at once instituted after the operation and ergot was given. She was discharged from the hospital on the thirty-third day in good condition. Her walking gait was almost normal. She remained in good health and attended to her household duties since her return home.

Cesarean Section for Contraction Ring.—Dr. Frederick C. Holden reported this case. The patient was a primipara, twenty-two years old. When admitted to the hospital she had been in labor twenty hours, with the membranes ruptured and with complete dilatation for hours. The labor pains were strong and regular. The examination showed a full term uterus with a live child. The fetus was found to be in left mental posterior position. There was a firm contraction ring around the child's neck and shoulders, completely preventing flexion of the head. Twenty-two hours after the onset of labor, seven and a half after the membranes had ruptured, and six hours after the collar was found, a cesarean section was performed. There was delivered a normal child weighing six pounds and ten ounces. An uninterrupted convalescence followed.

Dr. John O. Polak referred to the ease with which the child's head fell into the pelvis after the bone had been severed in the first case reported by Dr. Holden. In those trying cases of prolonged labor he did not consider pubiotomy an elective procedure; in such cases he favored section. With regard to the second case reported by Dr. Holden, it was a very interesting one. He recalled one case in which the contraction ring had been pulled so tightly that there was practically nothing but membrane over the head of the child, thus preventing the head from engaging. After making an incision through the ring the child was readily delivered.

Dr. Sidney D. Jacobson, in discussing the pubiotomy case, recommended the open method, the hemorrhage being his objection to the closed method. In four of the seven cases he had had, there practically had been no hemorrhage by the open method. Seven mothers and six babies recovered.

Dr. Holden just sawed through the bone and was careful not to go beyond it. If care was used he saw no reason why one should be bothered with hemorrhage.

Multiple Puerperal Abscesses of the Uterus.—Dr. William H. W. Knipe reported this case. Besides multiple abscesses in the uterus, several foci of pus were found in the broad ligament. He stated that a detailed report of this interesting case would be given later.

When Shall We Operate in Puerperal Septic Infection?—Dr. John Osborn Polak read this paper and offered the following summary: (1) Each case of postpartum or post-abortal infection must be studied individually and an accurate diagnosis made on the clinical, bacteriological, and blood findings before any treatment was instituted. (2) Nature was competent in the majority of instances to localize and circumscribe the infection. (3) Curettage, douches, and examinations during the acute stage broke down barriers, and opened avenues for the further dissemination of sepsis to the endometrium, parametrium, and adjacent tissues; the danger from curettage increased with each month of pregnancy. (4) Enormous pelvic and abdominal exudates might disappear without operation, and in time enlarged ovaries, tubes, etc., might assume their proper size and function; further, as long as the patient's general condition improved, no surgery was advisable. (5) All operations were attended with less risk after the acute stage of the infection had subsided, and an exact diagnosis was more easily made at this time. (6) After the uterus was thoroughly emptied, the pelvis should be left absolutely alone, and they should make every effort to support the patient and increase her natural blood resistance. (7) Vaccine therapy had a definite but limited field in the treatment of puerperal septic infection. Inoculating with the autogenous vaccines would promise prompt results in staphylococcus and colon bacillus infections, but in streptococcus poisoning the vacine treatment was unreliable. This was of value only when the virulence of the germ was attenuated, or when Nature had already developed a phagocytic defence. (8) Extraperitoneal drainage of local foci should be selected when possible, either by incision just above Poupart's ligament, or by posterior vaginal section; when this was impossible, because of an inability to determine the exact antomical relations of the local foci, an exploratory laparotomy was justifiable in order to make an exact diagnosis and determine upon the safest route for drainage. (9) Operative interference in the acute stage of sepsis was only indicated in general purulent peritonitis, post-abortal peritonitis, infected tumors in or near the genital tract, and uterine rupture when said rupture had occurred in the course of labor, and had been handled outside of a well managed maternity. (10) Thrombophlebitis was a conservative process on the part of Nature to limit the infection, and any form of pelvic manipulation only tended to break down and separate parts of these thrombi, extending the infection to the more remote parts, thus jeopardizing the patient's life.

Dr. Herman J. Boldt was unable to find any flaw in Dr. Polak's paper. Too much emphasis could not be laid upon the injurious effects of the traumatism these women received in the early stages of labor and before they were brought to the hospital.

Dr. Joseph Brettauer said he made the statement ten or fifteen years ago, which could not be repeated too often, that the curette killed more women in the puerperium than any disease or complication of childbirth. These local affections should be left alone, for they could care for themselves; when the curette was used the endometrium became infected by the germs from the localized infection.

Dr. F. C. Holden said that young men should be properly qualified before they attempted the use of the curette and that it was up to the teachers in the medical schools to speak against the frequent use of this instrument.

Dr. William H. W. Knipe believed that the less they attempted to do for these cases of puerperal sepsis the better; leave them alone.

Dr. Ross McPherson said that the majority of these patients were very much run down; their resisting powers should be raised, and this could be accomplished, at least in a measure, by treating them more in the open and fresh air, by attention to their diet, etc. The curette had killed more people than any instrument used in surgery.

Dr. George G. Ward, Jr., said that the dangers attending the use of the curette should be emphasized more by all teachers in medical schools, not only in the puerperal cases, but in the gonorrheal as well.

Dr. William S. Stone said he had never seen a case of puerperal sepsis unless a physician had been in attendance and the curette used. He also said that he had not seen a single case that had been attended by a midwife; if the case ended fatally it was because of what the doctor who was called in had done. These statements he considered to be nearly true.

Dr. Samuel W. Bandler emphasized the importance of the diagnosis of these cases of puerperal sepsis, especially during the early days where there was practically no discharge, but a rapid pulse, etc. These cases were best diagnosed by bimanual examination. On several occasions he had evacuated the cellular exudate, which looked like beef extract, and with good results.

Dr. Herman M. Collyer believed that the abscesses should be opened and iodine injections employed.

Dr. John O. Polak said that he had very definite ideas regarding thrombophlebitis. They had not seen many typical cases, with the chills, temperature, foci, etc. Only one case they had got well without interference. It was, in fact, a case of true pyemia. Subsequently she developed an abscess in the lungs, a staphylococcus infection. The other cases, eighteen in all, involved the femoral veins and the pelvic veins; all were self-limited and all recovered. Incising the exudates was a very unsatisfactory procedure in his hands. In those instances in which there were no localized foci of pus, he thought it was better to leave them alone, especially if the Fowler position was maintained.

Dr. C. Clarence Sichel asked why Dr. Polak left gauze in the cavity eight days.

Dr. Polak replied that six or eight rolls of gauze were used. On the fourth day the central roll was withdrawn, another on the fifth day, and so on, thus allowing the cavity gradually to come down. They never had been called upon to reopen a cavity thus treated.

Election of Officers.—*Chairman*, Dr. H. D. Furniss; *Secretary*, Dr. Frank A. Dorman.

Symptom Complex of Scarlatina Vaccination.—G. Vladimiroff describes the effects of prophylactic injections of Gabritschewsky's scarlatina vaccine (a streptococcus bouillon culture heated to 60° C. and preserved with carbolic acid), administered hypodermically in three doses of 0.3 to 1 c.c., at eight-day intervals. There results a rash strikingly resembling that of scarlet fever, lasting from three to four days, and spreading over the entire body in twelve hours. The strawberry tongue appears on the second day. Desquamation frequently succeeds the attack. —*Archiv für Kinderheilkunde.*

Medicolegal Notes.

Exclamations of Pain and Suffering Do Not Bar Testimony of Physician's Examination, Though Not for Treatment.—In an action for personal injuries the evidence of physicians who examined the plaintiff for purposes of testimony and not for treatment was objected to because exclamations and complaints of pain and suffering and the flinching and wincing of the plaintiff are inadmissible in evidence and because these things occurred in the examination. His regular attending physician, whose testimony was also objected to, testified that when he pressed the plaintiff's spine at particular points he evinced points of tenderness about the spine, and would call out "Quit!" or "Stop!" and would wince. He explained that at the point of soreness, when pressed, there was a convulsive action of the muscles, simultaneous with the exclamations and wincing. The testimony of the other two physicians as to their examination of the plaintiff by pressing along the spine was practically the same. "When I came to a place where he would flinch or jump quickly as if in pain I marked that point with a pencil, and at every point where he would flinch I would mark it. I would go along on different parts of the body, and whenever I would find such places I would mark them. Again, I would go over them a second or third time to prove or to find out whether the pain occurred at the same point or not. When the pain occurs at the same point after several examinations we infer from that there is a point of pain there. A man flinches or makes an outcry. * * * I ran a cambric needle, I guess, three-fourths of an inch deep in and around the back part of the thigh and over the back where it joins the frame. It did not make any impression on him, and he did not jump, and if it hurt he did not say so or make any movement. During this examination he would complain of pain; that is, he didn't say anything, but he would jump when I would stick him where it hurt him. He would wince or flinch." They also testified that from their experience the plaintiff could not have located the exact spot of pain if he did not in fact feel the pain. It was held that the evidence was admissible.—Ft. Worth & D. C. Ry. Co. v. Hays, Texas Court of Civil Appeals, 131 S. W. 416.

Opinions of Witnesses as to Value of Physician's Services Not Conclusive.—In an action by a physician for professional services the opinions of witnesses as to the value thereof are not conclusive. The jury may exercise its own judgment, and it is error to direct them to return a verdict in accordance with such opinions.—Marsh v. Richer, Onondaga County Court, New York, 125 N. Y. Supp. 245.

Physician Cannot Give Expert Opinion on Matter Outside of Medical Science.—In an action for damages for personal injuries to a railroad passenger it was held that a physician was not competent to express his opinion on the question whether the passenger sustained an injury to his arm while it was inside or outside an open car window. This was a matter of mechanics rather than of medical science, and the rule is that opinions of experts are inadmissable except as to those matters of which they have knowledge not acquired by ordinary persons. —Kuttner v. Central Railroad of New Jersey, New Jersey Supreme Court, 77 Atl. 470.

Evidence of Symptoms of Fracture of Skull Erroneously Excluded.—In an action for personal injuries it was held that the evidence of a physician who had attended the plaintiff immediately after the injury and for about three weeks after as to whether the symptoms present would show that the plaintiff had sustained a fracture of the skull was erroneously excluded. The evidence was excluded apparently on the ground that whether or not the skull was fractured was a matter of fact which a physical examination would show.—Charron v. Northwestern Fuel Co., Wisconsin Supreme Court, 1128 N. W. 75.

Right to License to Practise in Washington—Necessity for Diploma.—A number of cases were decided together in the Washington Supreme Court involving the construction of chapter 192, Wash. Laws 1909, relating to the practice of medicine. Each of several applicants filed with the board of medical examiners an application for a license to practise, claiming the right to a license under the provision of this law relating to the licensing of persons who were engaged in practice prior to its passage. The board refused to issue licenses. The applicants appealed to the superior court, which reversed the decisions of the board and directed licenses to be issued. The superior court's decision was, on appeal by the board,

affirmed by the supreme court. The statute provides (Section 4) that any person who treats the sick or affected may register his or her diploma with the board of medical examiners, and receive a license to practise by paying a specified fee, provided that he or she shows the board that he or she has been legally engaged in such practice prior to the passage of the act within the State, and is a graduate of a legally incorporated school or college, or by having been in continuous practice in one locality in the State for the past two years. Each of the applicants had been for more than two years prior to the date of approval of the act in such continuous practice. It was contended on behalf of the board that an applicant must, in addition to showing two years' practice in one locality, have a diploma and register the same with the board before he is entitled to a license under the provisions of the last clause of section 4. The applicants, who did not have, and never had, diplomas, contended that a diploma was not a prerequisite to their right to licenses under that clause. The court said that it must be conceded that the provisions of the law are somewhat involved, and that the question of its meaning is not free from doubt. It was, however, of the opinion that one who had been in continuous practice in one locality in the State for two years prior to the enactment of the law is not required to furnish further evidence of his qualifications by a diploma, and that such a person would be entitled to a license, regardless of the fact of his ever having a diploma. In some of the cases it appeared that the applicants were engaged in the practice of medicine and surgery for the two years prior to the passage of the act without having a license required by the law as then existing, Laws 1901, p. 50. This, it was contended, excluded such a person from the right to a license, because it was argued that such a person was not legally engaged in practise and therefore was not engaged in practise at all within the meaning of the section. The court held, however, that the clause of the section referred to two classes who may receive licenses: those who have been "legally engaged in such practice prior to the passage of this act" and those who have been in "continuous practice" in one locality for two years. The use of the word "legally" in referring to one class and omitting it in referring to the other clearly indicated the legislative intent to give the license privilege to the second class, even though they had violated a previously existing license law.—*In re* Christensen, Washington Supreme Court, 109 Pac. 1040.

Practising Without License Is Not Being "Legally Engaged in Practice."—In another case under the same statute it appeared that the applicant became a resident of the State January 1, 1909, and since then until after the enactment of the law, March 18, 1909, was engaged in the practice of medicine and surgery in the State without the license required by the then existing law. (Laws 1901, p. 50, c. 42.) It was held that he was not "legally engaged in such practice prior to the passage of this act" as required by section 4, and that a license was properly denied by the board.—*In re* Harold, Washington Supreme Court, 109 Pac. 1043.

Member of County Board Cannot Bind County for Physician's Services.—One member of a board of county commissioners cannot bind the county to pay for the services of a physician in attending upon the poor without first having been authorized thereto by a majority of said board while in session.—Mahr v. Board of County Comrs. of Pottawatomie County, Supreme Court of Oklahoma, 110 Pac. 751.

Release from Damages for Injuries by Poison in Drug Not Invalidated by Inability to Read.—A young woman who had sustained injuries from taking a quantity of belladonna which had become mixed with licorice powder sold by a wholesale druggist to the retail druggist from whom she purchased sued the wholesale druggists for damages. A release of her claim of damages presented to her for her signature in the presence of her father, mother, and sister was signed by her unread. She claimed that she was unable to read it on account of the effect of the belladonna on her eyes, and because she was hurried by her father and signed it under the impression that it was merely a receipt to the druggist for her loss of time sustained by the poisoning. It was held that this did not invalidate the release, since her mother was present when it was signed and was able to read it to her. The evidence showed that the plaintiff when she signed the release was not in such a stupid condition that she could not understand it if it had been read to her. When it was shown that the release was not obtained by fraud, mere inadequacy of consideration was not ground for annulling it. —St. Louis Court of Appeals, Missouri, 130 S. W. 829.

INDEX.

A.

Aaron, C. D., report of a case of carcinoma of the colon treated with the neoformans vaccine, 572.

Abbe, Robert, custodianship of the watch and Bible of Dr. Benjamin Rush, 805.

Abbe, Truman, a fracture of the pubic bone, 676.

Abdomen, diagnosis of chronic surgical lesions of upper, 730; gunshot wound of, 1118; pain in, diseases of, 641; palpation of, simplified, 30.

Abortion, tubal (see pregnancy).

Abrams, A., asthma and lung reflexes of Abrams, 813.

Abscess, alveolar, 730; cold, enzyme treatment of, 416; internal medication in, 285; retropharyngeal, report of three unusual cases, 529; treatment of localized appendicular, 285.

Academy of Medicine, library of, 453.

Accidents, the year's, 869; treatment of desperate illness following, 883.

Achlorhydria hæmorrhagica gastrica, 1018; in chronic gastritis, 462.

Achylia gastrica, new theory of, 417.

Acidosis, pathogenesis, prophylaxis, and treatment of, 292; primary, with recovery, 973.

Acne vulgaris, treatment of, 790.

Acroasphyxia in childhood, 539.

Acromegaly, 1013.

Actinomycosis, 730; experimental production of, 246; two cases of, 363.

Adenitis, relation of tonsil to tuberculous, 515; treated with streptococcus vaccine, 492; treatment of tuberculous cervical, 514, 515.

Adenoids and tonsils, excision of, 410; failures in removal of, 503; influence on mental condition, 213.

Adenomata, multiple, of rectum, 323.

Adenopathy, early diagnosis of tuberculous bronchial, 963; radiography in, 1189.

Adhesions, prevention of, 247.

Adiposis dolorosa in mother and daughter, 780.

Adolescence, corpulence in, 452.

Adrenal gland (see suprarenal capsule).

Adrenalin, and saline infusion, chills following, 1203; in treatment of cancer, 411.

Aerophagia, treatment of, 416.

Aerotherapy, 278.

Ainhum complicating uncinariasis, 492.

Albuminuria lordotic, 922.

Albumin, in urine of normal children, 1075; milk, in diarrhea, 196.

Alcohol, and legal medicine, 729; as cause of hepatic cirrhosis, 505; effect on nerves, 415; effect on unanesthetized animal, 286; effects on mind and nervous system, 427; effects upon circulatory system, 429; in acute infections, 1161; injections in treatment of facial neuralgia, 1044; in nephritis, 247; relation to gastritis, 275; wood, blindness from, 831.

Alcoholism, in women, 427; treatment of, 790.

Alexia, traumatic, 1070.

Alimentary canal, relationship of cancer and ulcer of, 540.

Alopecia and seborrhea, 633; exposure to sun as cause of, 694, 695.

Amberg, E., guide for the lateral sinus line, 721.

Am Ende, C., unboiled condensed milk as a source of summer diarrhea, 113.

Am Ende, C. G., poison ivy rash, 243.

American Laryngological Association, President's address, 340.

American Public Health Association, President's address, 552.

American Electrotherapeutic Association, 20th anniversary, 758.

American Neurological Association, President's address, 251.

Amnesia, alcoholic, 503.

Amputation, in childhood, 969.

Amyloidosis in Japan, 636.

Analgesia, spinal (see anesthesia, spinal).

Anaphylaxis, 780; and idiosyncrasy, 678; clinical, 449; estimation of, 539; in hay fever, 878, 879; in meningitis, 769; reaction of, contraindicating administration of antitoxin, 457; serum, 1021; serum and drug, 910; toward cow's milk, 986.

Anarthria, and lenticular zone, 384.

Anders, J. M., street dust as a factor in spreading disease; methods of removal, 563.

Anesthesia, alternating, 1105; and Trendelenburg position as influencing excretion of urine, 124; combined spinal and general, 1164; dangers of, 1017; deaths under, 74, 364; death under gas and oxygen, 866; electric, 836, 1035; in head surgery, 730; in nose and throat work, 635; insufflation, 688; in the aged, 285; local, 884, 1017; local, strengthening of, 734; nitrous oxide; nitrous oxide-oxygen, 642, 925; recent progress, 616; relation to general practitioners, 59; spinal, 168, 334, 968; spinal, dose of stovaine in, 1017; spinal, with stovaine and strychnine, 635.

Anemia, pathogeny and hypodermic treatment of, 409; pernicious, 751, 780; pernicious, extreme blood picture in, 874; pernicious, treated by blood injections, 78; pernicious, treatment of, 372, 649.

Aneurysm, aortic, 601, 983; of common carotid, 836; *x*-ray appearance, 1068.

Angina pectoris, 825; compared with gastrocirculatory seizure, 77.

Angioma, treatment with hot air, 75.

Anthracosis, pulmonary and intestinal absorption, 297.

Antiformin, sources of fallacy of, 410.

Antiketogenesis, 1199.

Antitoxin, diphtheria, quick rash after, 686.

Antigonococcic serum, and bacterins, 600; report of other cases treated with, 674.

Antivivisection, exhibition of, 538; literature of, 1168.

Anthrax, treatment of, 420.

Antrum, dentigerous cysts of, 422; of Highmore, suppuration of, 756; maxillary, radical operations on, 343; surgery of, 648.

Anuria, postscarlatinal, 706.

Anus, absence of, 237; dangers of forcible dilatation of, 689.

Aorta, aneurysm of, 601; compression of, 637; peritoneal patching of, 21; regurgitation of, 1020; regurgitation of in an infant, 594.

Aphonia, faradism in, 974; hysterical, treatment of, 333.

Apoplexy, operative treatment of cerebral, 374.

Appendicitis, causes of death after operation for, 505; diminution of mortality, 248; early operation in, 163; studied by radiography, 248; treatment of localized abscess in, 285; useless operations for, 501; verminous, 635.

Appendix, inflammatory pseudocarcinoma of, 205; intussusception of, 1087; lesions produced by oxyuria, 639; residual, 619.

Arabinosuria, 288.

Ardati, N., observation on dengue, 408.

Army, report of Surgeon-General of, 1055.

Arsenic, in syphilis, 1107.

Arsenobenzol (see Ehrlich-Hata preparation).

Arteriosclerosis, clinical aspects, 370; high blood pressure in, 1111; iodine cachexia in, 976; transient cerebral crises in, 787; treatment by high-frequency currents, 113, 166.

Artery, recurring hypertonus of, 1162.

Arthritis, acute, of doubtful origin, 827; chronic gonorrheal, 603; deformans, metabolism in, 639; gastrointestinal, 1066; gonorrheal, treated with vaccine, 984; rheumatic, followed by streptococcus invasion, 457; rheumatoid, thyroid extract in, 1164.

Arthrodesis in infantile paralysis, 76.

Arthropoda, germ carriers, 1069.

Arthrotomy, technique of, 823, 874, 969, 1016, 1065.

Arteries, hypertension of and relation to eye diseases, 831.

Arteritis, syphilitic, 593.

Arylarsonate poisoning, recovery from, 548.

Ascaridiasis, chenopodium oil in, 420; intoxication from, 689.

Ascites and subcutaneous drainage, 921; intraperitoneal injections of adrenalin in, 888.

Ascitic fluid, therapeutic use of, 417.

Association, phylogenetic, 1197.

Asphyxia, from tuberculous gland,

425; neonatorum, oxygen in, 39.
Asthenia, congenita coincident with diabetes mellitus, 205; universalis congenita, 167.
Asthma, and lung reflexes of Abrams, 813; bronchial, bronchoscopic treatment of, 546.
Asymbolia, 985.
Ataxia, Friedrich's, 397.
Atcherley, J., a theory as to the origin of leprosy, 231.
Athletics, the value of, 20.
Atoxyl and its derivatives, 1203.
Autointoxication, and allied intestinal troubles, 371.
Automobile, influence on upper air passages, 305.

B.

Babinsky sign in diphtheria, 724.
Bacillus, coli, as pathogenic germ and saprophyte, 596; coli infections, 974; coli infections in children, 455; infection of operative wound, 876; coli, outside of body, 977; coli, rôle in disease, 465; lactic acid, nature and action, 456; of Friedlander causing acute suppurative nephritis, 297; typhoid, fermentation properties of, 1112.

danger when dealing with plague, 18.
Cyst, chylous of mesentery, 464; sebaceous, simple method of removal, 458.
Cystitis, after rectal operations, 548; postoperative, 81.
Cystocele and procidentia, operation for, 81; pelvic fascia in operation for, 794.
Cystotomy, postprostatic, 701.
Cystourethroscopy, 1107.

D.

Dairymen, problems of.
Deaf child, duty of general practitioner to, 594.
Deaf-mutism, 146.
Deafness, Beethoven's.
Deal, F. A., tuberculin treatment in advanced stages of tuberculosis; a report of seventeen cases treated with tuberculin serum in hospital practice, 952.
Death, of fetus, and salt-free diet, 193; rate for 1909, 587; registration of, 1192.
De Beeck, F. Op., a suppurative adenitis under the sterno-cleidomastoid muscle treated with streptococcus vaccine, 492.
Deeks, W. E., a hitherto undescribed syphilitic sign, 544; the carbohydrate diathesis, 607.
Degeneracy, a study in, 359.
Dehydration, by diet, 1200.
Delavan, D. B., the influence of the automobile upon the upper air passages, 305.
Delinquents, juvenile, and juvenile courts, 450.
Dementia præcox, and depressed states, blood-tests in, 383; mental mechanisms in, 382; nature of, 382; pupillary disturbances in, 782; thyroidectomy in, 686.
Dengue, observation in, 408.
Depression, clinical significance of, 371.
Dermatitis, bullous, fatal case of, 697; factitia, 1120; primula, 417.
Dermatology as a specialty, 114.
Dermatomyositis, recovery in, 286.
Desiccation, oscillatory, in treatment of cancer, 836.
Development, exceptional, hereditary and congenital causes, 48.
Diabetes, as an infectious disease, 166; bronze, 637; chemical problems in, 889, 944, 991; coma in, treated with bicarbonate of soda, 639; experimental, 1200; mellitus, alimentotherapy, 1070; mellitus, coincident with asthenia congenita, 205; mellitus, results in treatment, 611; mellitus, treatment of, 1199; metabolism in, 1198; modifications in, 165; of kidney origin, 30; pancreas and, 1199; relations of blood diastase to, 248.
Diarrhea, albumin-milk in, 106; summer, caused by condensed milk, 113; caused by gas bacillus, test for, 777.
Diaschisis, theory of, in relation to cerebral localization, 251.
Dickinson, G. K., anemia, with some remarks as to its pathogeny and hypodermic treatment, 407.
Diet, before operations, 975; fish as, 584; for dehydration, 1200; in training, 194; of school children, 1067; rational, 825.
Dietetics, 834.
Disinfection, alcohol in hand, 549; of hands with alcohol and without soap, 78; of operative field by tincture of iodine, 549.
Dislocation of neck during sleep, 287.
Dispensary, preliminary examination of children at, 956.
Dioxydiamidoarsenobenzol, see Ehrlich-Hata preparation.
Diphtheria, Babinsky sign in, 724; cutaneous, 969; nasal, 673; nasal, diagnosis in young children, 975; nasal, in infants, 926; primary streptococcus, 276; results of serum treatment of, 287; sequelæ and repeated attacks of, 1203; statistical analysis, 65.
Diplegia, treatment of spastic, 195.
Dlugasch, L., exophthalmic goitre simulating typhoid fever, 769.
Doctor, modern, 646.
Dose, determination of, below one year, 825.
Dowd, C. N., tendon transfer for correction of spastic hand deformity, 175.
Dreams, interpretation of, 1129.
Drennan, J. G., the abstraction of calcium salts from the mother's blood by the fetus a cause of large white kidney in the former, 17.
Dropsy, renal, 734.
Drowning, partial, treatment of, 77.
Drueck, C. J., the enema; its place in the treatment of gastrointestinal diseases, 63.
Drug addictions, present status of, 169.
Duodenum, diagnosis of ulcer of, 793; Einhorn bucket of, 463; examination of contents of, 864; experiences with contents of, 114; feeding by, 92, 548; regurgitation from, 592; ulcer of in infant, 297; ulcer of, diagnosis, 288; ulcer of, treatment, 334.
Dust of streets in spreading disease, 563.
Dwyer, J. G., the use of vaccines, serums, and the Hiss extract of leucocytes in the treatment of eye, ear, nose, and throat infections, 178.
Dysentery, with fermenting organisms, 331.
Dysmenorrhea, causes and treatment, 293.
Dyspepsia, belladonna in, 1154; gallbladder, 787.
Dystocia, treatment of, in pelvic contraction, 340.
Dystrophy, progressive muscular, 783.

E.

Ear, acute inflammations of middle, 442; injury of by a batpin, 203; internal complications of middle ear diseases, 731; ossiculectomy in chronic suppuration of middle, 547; vaccines in suppurations of, 778.
Eccles, R. G., immunity reactions as products of natural selection, 1135.
Echinococcus disease, serodiagnosis of, 542.
Eclampsia, a new theory of, 966; bad prognostic signs of, 975; cesarean section in, 594; continuous sugar instillations in, 698; etiology, 38; puerperal, 745; subcutaneous infusion in, 1022; surgical treatment, 39; treatment of, with comparative dangers of chloroform and ether in, 38; vaginal cesarean section in, 38.
Eckridge, F. L., anthum complicating mucinariasis Americana in an American white girl, 492.
Eczema, etiology and treatment of, 835; secondary, 696; treatment by colonic lavage, 333.
Edema, significance of mineral salts in.
Education of student of medicine, 826.
Ehrlich-Hata preparation, 54, 325, 458, 517, 547, 682, 795, 826, 921, 930, 969, 1079, 1159, 1161, 1201; action on psoriasis and lichen ruber, 636; action on spirochetes in mouth, 1070; action on the eye, 1113; and filariasis, 977; clinical value, 416; control of trials of, by Noguchi test, 590; danger of intravenous injection, 506; experiences with, 878, 1174; fate of, 326; in leprosy, 1165; in malaria, 783; in non-syphilitic affections, 420; in recurrent fever in rats, 547; in suspension, 373; in complicated syphilis, 459; in syphilis, 284, 325, 517, 547, 589, 1110; in tabes and paralysis, 1070; in yaws, 1106; optic neuritis following use of, 1112; personal observations on, 672; supersensitiveness to, 1112; symposium on, 817; technique of injection, 374, 549; topic of the day, 1191; unexpected good results from, 595; Wassermann reaction with, 636.
Ehrlich's biochemical theory, 1109.
Einhorn, M., duodenal alimentation, 92.
Elastic traction and pressure in surgery, 1111.
Electricity, death from shock by, 896; direct continuous current of, 834; high frequency currents of, 835.
Electrocardiogram in diagnosis, 779.
Elements, search for new, 821.
Elephantiasis, etiology, 968; of scrotum and penis, 1200.
Ellis, R., poison ivy rash, 161.
Ely, L. W., further observations on the pathology of joint tuberculosis and practical deductions therefrom, 147.
Embolism, air, due to labor, 295.
Employers' liability law, 683.
Empyema, 208, 776; treatment by aspiration and drainage, 165.
Endometritis, chronic, 1105.
Enterocolitis, prophylaxis of, 970.
Entomology in medical research, 914.
Enuresis, from thyroid insufficiency, 789; epidural injections in treatment of, 769.
Epidemics, relation of public and physician to, 212.
Epilepsy, and idiocy, prevention of, 1021; Brown-Séquard's in guinea-pig, 1158; cause of, 1017; digestive troubles in, 1077; Jacksonian, surgical treatment, 961; senile, 168; treatment with rattlesnake venom, 502.
Epistaxis, relation to constitutional disease, 632.
Epithelioma, electrolytic arrest of, 412; of lip, 458.
Erdmann, J. F., a case of stab wound of the heart, 1095.
Ergot, physiological experiments with, 113.
Erysipelas, treatment of, by hot air, 29.
Eshner, A. A., a possible second attack of acute anterior poliomyelitis in the same patient, 526.
Esophagus, diverticula of, 10, 424, 836; gastrostomy in nonmalignant strictures of, 644; stenosis from alkalies, 1066; stricture of, 837; treatment of cancer of upper third, 1022; treatment of idiopathic dilatation of, 461.
Esophoria, non-refractive, 921.
Ether, administration of, 1017; practical administration of, 633.
Ethmoiditis, pathology of, 1200.
Evans, W. A., library ventilation, 531; ventilation in schools, 173; ventilation of cars, 1000.
Exophthalmic goiter; see Graves' disease.
Exophthalmos in brain tumor, 1108.
Eye, affections of, caused by intranasal or accessory sinus disease, 422; diseases of and arterial hypertension, 831; diseases of, prevalent, 592; dominance of, anomalies, 138; injuries to, 879; malarial manifestations in, 1116; method of preserving, 832; nervous affections in relation to, 778; nervous affections in relation to adjustments, 1016; radium therapy in disease of, 1021; removal of

foreign bodies from by giant magnet, 345; spontaneous rupture of glaucomatous, 1096; strain, and Graves' disease, 1200; strain, peculiar results of, 861.
Examinations and prizes, 677.
Excreta, apparatus for collection of, in infants, 639.
Exercises, functional, in nervous diseases, 546.
Expert testimony, 330; ethical aspects of, in relation to plea of insanity, 133; given without stating facts, 1034; physician not competent to give, outside of medical science, 1231.
Experimentation, animal, 1167.
Extremities, septic infections of, 886.
Exudates, postoperative, 1066.

F.

Face and skull, distortion of, during infancy, 591.
Fallopian tubes, absence of, 733.
Fatigue, 885.
Faulkner, R. B., tonsil research, 56.
Fauntleroy, A. M., a simplified method for the transfusion of blood, 403.
Feces, examination, 202.
Fedde, N., a pith-ball manometer, 105.
Feeblemindedness, prevention of, 551; care of, 283.
Femur, congenital absence of, 200.
Ferments, pathological action of, 1164, 1202.
Fermentation, gastrointestinal, 626.
Fernandez, J. S., the simple extraction of cataract, 357.
Ferris, A. W., first aid to the insane and psychopathic wards, 309.
Fever, sand-fly, 379.
Fibroids, see uterus; of broad ligament, 80.
Fibroma molluscum, 694; nasopharyngeal, 921.
Fish, as food, 544; diet of, 584.
Fistula, anal, treated by excision and suture, 105; vesicovaginal, 594; vesicovaginal, repair of, 124.
Fleming, A., and Clemenger, F. J., a simple complement fixation technique in syphilis, 187.
Fluids, silent, in the thoracic cavity and their clinical significance, 27.
Fly larva infection, 1110.
Foot, flat, 513; treatment of club, 513; weak, 19, 790; weak, caused by relaxation of annular ligament, 511.
Forceps, abuse of in primiparæ, 410.
Fordyce, J. A., 606, in syphilis, 589.
Foreign bodies in superior mesenteric veins, 1069; toothpicks as, 973.
Forensic medicine, history of, 707.
Foster, N. B., further observations in alcoholic gastritis and its relation to experimental gastritis in animals, 275.
Fox, C. D., a case of tetanus successfully treated with magnesium sulphate, 720; report of five cases of tetanus and remarks on the treatment of the disease, 262.
Fracture, acetabular, 643.
Fracture, and dislocation of atlas and axis, 644; justaepiphyseal of hip and shoulder, 511; near joints, 1068; of femur, and results of, 791; of pubic bone, 676; of skull, 1049; of skull, evidence of, wrongly excluded, 1213; of vertebræ, causing injury of spinal cord, 256; operative treatment, 1017, 1117; operative treatment of simple, 205; tetanus in compound, 1068; treatment by parathyroid medication, 69; treatment of, 33; treatment of, by means of internal aluminum splints, 54.
Freudenthal, W., in what way can laryngology aid in making the diagnosis of incipient pulmonary tuberculosis? 190.
Friedenwald, J., important events in the development of gastroenterology, 270.
Fluoroscope, aid of, in removing foreign bodies from bronchi, 505.
Fuller, E., postprostatic cystotomy, 701.
Furunculosis, treatment of, 202.

G.

Gallstones, during pregnancy and puerperium, 82; etiology of, 916; results of, 793.
Gangrene, Nösske's procedure in threatened, 548.
Gangs, psychological study of, 477.
Gardner, C. H., treatment of rhus poisoning, 330; treatment of barber's itch, 1064.
Gastrectomy, partial, 793.
Gastric juice, psychic, in man, 495; variability of, 463, 875.
Gastritis, alcoholic, 275.
Gastroenterology, development of, 270; for non-malignant diseases, 1018.
Gastrointestinal diseases, treatment of, by enema, 63.
Generative organs, internal secretions of, 1021, 1069, 1112.
Genital, canal, bacteriology of, 294; crisis in the newborn, 116.
Geriatrics, plea for study of, 536.
Germicides, common, 920.
Gibson, C. L., external urethrotomy without a guide, 226.
Gillman, G., the bedside Widal test, 768.
Glioma, extramedullary of spinal cord, 1016.
Goiter, carbolic acid injections in, 1051; vocal cords in, 504; exophthalmic, see Graves' disease.
Goldman, A., another case of pyloric obstruction, 1147.
Gonococcus and granulation tissue, 288; and the trachoma bodies, 109; and trachoma bodies in mutation, 452; infection of the kidney, 568; vaccine and serum, 600.
Gonorrhea, abortive treatment of, 830; and syphilis, education of public as to prevention of, 553; diagnosis and treatment of chronic, 830; in male children, 766; prophylaxis of, 830; marriage following, 830; treatment of acute, 830; treatment of in women, 201; vaccines in, 830.
Goodman, E. H., an historical note in the so-called Ludwig's angle, or the angle of Louis, 152.
Gordon, Alfred, superficial and deep sensory disturbances, in their relation to astereognosis and asymbolia, 5; mental disturbances following traumatism; medicolegal considerations, 1179.
Gottheil, W. S., experiences with arsenobenzol, 1174.
Gould, G. M., and Durand, A. C., the anomalies of ocular dominance, 138.
Gout, electricity in, 835.
Granulation tissue and gonococcus, 288.
Granuloma, ulcerating of pudenda, 827.
Graves' disease, 1115, 1162; and eyestrain, 1200; diarrhea of, 595; in relation to pregnancy, 165; lymphocytosis in, 1066; new principle in treatment, 647; paroxysmal tachycardia in, 374; present status of treatment, 591; simulating typhoid fever, 769; surgical treatment, 336, 451, 591; types of, 728; versus cardiac neuroses, 405.
Grawitz, E., pernicious anemia, its definition and treatment, 751.
Greeley, H., the king's evil, 719.
Griffith, F., case of congenital fusion of toes, with note on previous generations, 67.
Gross, M., Oefele, F. V., and Rosenberg, M., technique of examination of duodenal contents, 864.
Guntzer, J. H., nasal osteoma; report of a case, operation, 12.
Gutta-percha tissue for dressing wounds, 548.
Gwathmey, J. T., recent progress in anesthesia, 616.
Gynecology, American, 83; local treatment in, 1025; modern malpractice in, 836; progress in, 741.

H.

Hagner, F. R., gonococcus infection of the kidney, with reports of cases, 568.
Hahn, M., hemophilia treated by transfusion.
Haig, A., the circulation as a factor which determines the effects of microbic invasion, 392.
Hair, sudden blanching of, 459.
Hand, spastic deformity of, treated by tendon transfer, 175.
Hassin, G. B., and Hershfield, A. M., the treatment of chorea minor with large doses of arsenic (method of Comby-Filatov), 15.
Hay fever, anaphylaxis in, 878, 879; in children, 799; operative treatment of, 1203.
Hart, T. S., results in the treatment of diabetes mellitus, 611.
Head, mechanical injuries of, in children, 931.
Health, caravan crusade, 727; test for hotel employees, 1192.
Heart and renal disease, treatment of, 1120; block, central origin of some cases, 594; blood pressure in hypertrophy of, 788; child's, anatomically and diagnostically, 1074; congenital disease of without cyanosis, 930; dilatation of, differentiated from pericarditis with effusion, 457; disease of, carbonic acid baths in, 1120; disease of, in acute psychoses, 331; disease of, marriage of girls with, 1113; high-pressure hypertrophy of, 888; neuroses of, versus conditions simulating Graves' disease, 495; posttraumatic disease of, 880; puncture of, 372; reaction to digitalis, 1111; stimulants, comparative study of, 1097; strain and dilatation, 1162, 1194; surgery of, 325; syphilis of the, 26; stab wound of, 1095.
Heat, artificial application of, 826.
Hebosteotomy, as an aid to delivery, 37.
Helminthiasis, eosinophilia in, 333; in children, 42.
Hematemesis, 920.
Hematoma, of broad ligament, 80.
Hematoporphyrinuria, toxic, 1024.
Hemiplegia, following acute infections, 730; from middle meningeal hemorrhage, 730.
Hemophilia, fatal case, 287; neonatorum, treatment of, 108; treated by transfusion, 624.
Hemorrhage, following tonsillectomy, 246.
Hemorrhagic, diathesis, treatment, 165; disease, relation of blood platelets to, 685; disease of newborn, direct transfusion in, 502; of newborn, serum treatment of, 286.
Hemorrhoids, bloodless operation for, 780; radical cure of, 687.
Hemospermia, essential, 686.
Herpes, primary febrile, 449; zoster ophthalmicus, 833.
Heredity, 592; and nervous diseases, 780; biparental, of webbed toes, 1201; in relation to mind, 878; laws of, 1106.
Hernia, cases of inguinal, 837; diaphragmatic, 974, 1112; inguinal, 1116; femoral, 745; inguinal, fol-

lowing appendectomy; ligation of sac in, 118; silver filigree in ventral, 837; silver wire and linen thread for cure of, 837; strangulated omental, 975; strangulated umbilical, 877.
Hexamethylenamine, elimination of, by the ear and nose, 113; in meningitis, 825.
Hip, congenital dislocation of, 826; spontaneous dislocation of, 917.
Hoffman, J. J., and Jackson, J. A., report of a case of sarcoma of the adrenal gland, 360.
Hollis, A. W., report of the treatment of typhoid fever with vaccine, 622.
Homesthesia, 782.
Hookworm, non-oviparous female, 780.
Hospital, abuse of, 727; accommodations for infectious diseases, 466; cost of patients, 1192; criticism of, 868; medical college, 243; noise, 444; public and private, 743; public in New York, 467; of Rockefeller Institute, 723; public, establishment and management of, 108; reform in relation to budget reform, 467; reorganization, 465; union of and medical school, 1192; what constitutes an ideal? 466.
Huber, J. B., the anti-tuberculosis propaganda, 440.
Humorism, ancient and modern, 733.
Hunt, E. L., the hereditary and congenital causes of exceptional development, 48.
Humerus, benign cyst of, 878.
Hughes, C. H., medical college hospitals, 243.
Hydatid, serum diagnosis of, 372; symptom-complex in ruptured abdominal, 732; toxicity of, 157.
Hydrotherapy and thermotherapy, 835.
Hymen, imperforate in sisters, 28.
Hyoscyamus niger, extensive poisoning by, 1113.
Hyperchlorhydria, caused by prisms, 778; in abdominal and pelvic surgery, 318.
Hyperemia in treatment of infections of breast, 114.
Hypernephroma, 1107.
Hypersomnia or pathological sleep, 678.
Hypertension, arterial, 584; recurring, 1162; treatment of, 1163.
Hyperthyroidism, surgical treatment of, 1173, 1211.
Hypophysis, 334; and castration, 1172; intranasal route for growths of, 422; sarcoma of, 1198; tumors of, 257, 594, 790, 827; tumors of, Froehlich's syndrome in, 1198.
Hypnotics, synthetic, 112.
Hypopituitarism, 778.
Hypothyroidism, 456.
Hysteria, in childhood, genesis of, 234; under psychoanalysis, 219; with autopsy, 728.
Hysterectomy, in sepsis following abortion, 698.
Hysterosalpingectomies, complicated, 698.

I.

Ichthyol, irritating effect of, 503.
Icterus neonatorum, 205.
Idiots, Wassermann reaction in, 286.
Ileocolitis and acidosis, 503.
Immunity and vaccine therapy, 728; in non-bacterial diseases, 971; reactions as products of natural selection, 1135.
Indians, epidemics among Alaska, 729.
Indicanuria, 919.
Indigestion, periodic attacks in children, 34.
Indigo blue in urine, 1198.
Inebriates, 918.
Infancy, mortality of, 326, 542; feeding, 1120; feeding, practical indications for, 389; feeding, toxic action of milk sugar in, 1203; nutrition of feeble, 826.
Infantilism, malarial, 961.
Infections, coincident, and immunization, 363; wound, 824; *x*-ray and light in, 836.
Inflammation, treatment of non-infective, 835.
Influenza of nose and throat, 342.
Insane, care of, 786; first aid to, 309; psychopathic wards for, 309; state and county care of, 786.
Insanity, fat over-feeding in, 331; laboratory for study of, 786; occupation as therapeutic agent in, 996; mania-depressive and dementia præcox, 704; postoperative, 1077; syphilis in, 202.
Insurance, sick, 635; state, 635.
Intestines, infections of, in children, 85; malignant obstruction of, treatment, 738; putrefactions of, treated by rectal instillations of autogenous bacteria, 519; reflex of, 1164; surgery of, 650; treatment of fermentative states of, 787; obstruction, caused by foreign body, 592; obstruction, due to round worms, 826.
Insufflation, intratracheal and strychnine poisoning, 733.
Intussusception in infants, 744.
Iodine, caution in use of internally, 1113; in surgery, 1107.
Iris, heterochromia of, 165.
Isaacs, A. E., drainage and dressing of wounds in minor surgery, 101.
Itch, straw, 68.

J.

Jaundice, chronic family, 34; family hemolytic, 116; interpretation of, 647.
Jones, H., two cases of actinomycosis, 363.

K.

Kakels, M. S., a preliminary report on Ehrlich-Hata preparation for the cure of syphilis, 517; concerning the Ehrlich-Hata preparation 606, 1079; control of trials of 606 by the Noguchi test, 500.
Kakels, S. W., on preliminary examination of children at the dispensary as a means of protection against contagious diseases, 956.
Kaplan, D. M., concerning the restoration of inhibitory qualities in liver extracts, 904; the approximate estimation of protein (globulin?) contained in the cerebrospinal fluid, 1187.
Kala-azar, blood in, 583.
Kearney, H. W., anesthesia in its relation to the general practitioner, 59.
Kidney, accessory arteries of, 780; adenocarcinoma of, 740; anchoring for dislocation of, 362; and ureter, calculi of, 970; calculus of, 458; complete subparietal rupture of, 807; cystic, 826; cystic and renal cysts, 203; cystadenoma of, 779; diagnosis of surgical lesions of, 645; gonococcus infection of, 568; hemorrhage from, 162; large white, due to abstraction of calcium salts by fetus, 17; methods for determination of sufficiency of, 793; migration of calculi of, 822; movable, 592; study of functional activity of, 598; surgery of, 210; tests for adequacy of, 251; transplantation of, 280.

Meiostagmin reaction in tuberculosis differentiation, 459.
Mendel, L. B., on the adaptation of the human saliva to diet, 349.
Meningism, relation to lumbar puncture, 363.
Meningitis, coccidioidal, 973; epidemic and carriers, 420; influenzal, 77; pneumococcus, 204; serotherapy and anaphylaxis in, 769; typhoid, 238, 760.
Menopause, delayed, 27, 169; premature treated by lutein extract, 201.
Menstruation and ovarian grafting, 115; causes of, 295.
Mercury, in pulmonary tuberculosis, 311, 1188.
Mesenteric vessel, embolism and thrombosis of, 979.
Metabolism and mouth disease, 684; in skin diseases, 697; laboratory findings in diseases of, 835; nitrogen, in artificially fed infants, 932.
Metatarsalgia anterior, operation for, 511.
Metritis, treatment of chronic, 835.
Microplasia, 379.
Migraine, caused by chlorine retention, 457.
Mind, disease of, error in diagnosis of, 382; disturbances following traumatism, 789, 1179; influence of, 733; prevention of defects and diseases of, 551.
Mineral waters as artificial sera, 826.
Miners' consumption, 1067; nystagmus, 1068.
Milk, 213; charities in the United States, 770; condensed, causing summer diarrhea, 113; influence of colloidal protection in, 686; problems of the dairyman, 468; raw, 469; supply of Copenhagen, 468; supply, practical methods of supervising, 551.
Mitchell, J. R., a new theory of eclampsia, 906.
Momburg's method, influence on heart and circulation, 637.
Monstrosity, recurrent, 287.
Morphinism, treatment of, 922.
Mortality, infant, 326, 542, 785, 823; infant, in Detroit, 1192; infant, in Toronto, 1014; infant, national importance of, 591.
Moschcowitz, A. V., intussusception of the appendix, 1087.
Mosquito, campaign in Manila, 823.
Mouth prophylaxis, 456.
Murmurs, pseudoapical, 458.
Muscle, substitution functioning, 1113.
Museum, Hunterian, 455.
Mycosis fungoides, 693.
Myelitis, acute, caused by thrombotic softening, 1110; pressure, a new type of, 254.
Myeloma, multiple, 1020.
Myiasis, intestinal, 419.
Myocarditis, purulent with Adams-Stokes syndrome, 634.
Myomata, *x*-ray treatment, 1922.
Myositis fibrosa, 258; ossificans progressiva, 646.
Myxofibrosarcoma, 1107.

N.

Narcosis, insufflation, 688; new theory of, 288.
Narcotics, addition to, 918.
Nascher, I. L., a plea for the study of geriatrics, 536.
Nasopharynx and tonsils, lymphosarcoma of, 423.
National Health Department proposed, 592.
Navy, medical service in, 878; report of Surgeon-General of, 1149.
Neck, preservation of submaxillary branch of facial nerve in operations on, 515.
Neff, M. L., occupation as a therapeutic agent in insanity, 996.
Negro, as a health problem, 730.
Nephrectomy, and ureterectomy, 1169; results, 1063.
Nephritis, alcohol in, 247; chronic, blood pressure and uranalysis in, 417; chronic, treatment, 164; following tonsillitis, 971; hemoglobinuric, in pneumonia, 29; without albumin, 284.
Nerve, suture of circumflex, 338.
Nerves, effect of alcohol on, 414.
Nervous diseases, hospital treatment of, 711; organic, early recognition and diagnosis, 208.
Nervousness, clinical significance of urine in, 383.
Neuralgia, facial treated by alcohol injections, 1044; trifacial, 649; trigeminal treated with alcohol injection, 29.
Neurasthenia associated with visceral ptoses, and surgical relief, 121; chronic, due to operations, 594; nasal phenomena in, 340; the discard heap, 824.
Neuritis, 579.
Neurology, and preventive medicine, 779; in Zurich, 1129.
Neuropathic states, cause, 1069.
Neuroses, functional etiology of, 648; of infants, 781; prevention of, 551; reflex, 783; traumatic, 973; traumatic, physician's responsibility in, 645.
Neustaedter, M., why the exceptional child is entitled to receive training suited to its needs at public expense, 273.
Newton, R. C., a brief study of the contribution of Ignaz Philip Semmelweis to modern medicine, 432.
Niles, Geo. M., some remarks on the treatment of pellagra, 448.
Noma, epidemic of, 193.
Northrup, W. P., postscarlatinal anuria for five days in a boy of three and a half years, recovery, 706.
Nose, accessory sinuses of and diagnosis of their suppurative disease, 95; and throat, influenza of, 342; deformity of treated by transplantation of rib cartilage, 422; instruments in surgery of septum of, 762; malignant disease of, 731; phenomena of, in neurasthenia, 340; osteoma of, 12; scab formation in, 372; submucous resection of septum, 202, 826, 975, 1018; vascular communications of with dura and orbit, 341.
Nostrums, restraining vendors of, 817.
Nuisance, automobile smoke, 1057.
Nystagmus, miners', 1068.

O.

Obesity, electrical treatment, 961; metabolism in, 783; relation to other diseases and prophylaxis, 150.

Osteochondritis dissecans, 511.
Osteopathy, ruling against, 413.
Osteophytes, of os calcis, 511.
Ostheimer, M., measles and German measles, characteristics of the present outbreak in Philadelphia, 410.
Otology, relation to preventive medicine, 332.
Ovary and tubes, plastic surgery of, 683; cancer of, 1013; cysts of, 592; fibroma of, 1023; grafting of and menstruation, 115; non-malignant, 1160; removal of cyst of and leaving other ovary, 377; surgery of, 1119.
Oxidizing and reducing substances, 205.
Oxygen, in asphyxia neonatorum, 39; use of combined with alcohol vapor, 415.
Ozena and respiratory gymnastics, 426.
Pachymeningitis and meningismus, 689.
Palate, soft, edema of, 546; widening of arch, 1066.
Pancreas, aberrant, 1077; functional tests, 922; internal secretion of, 538; intoxication, 459; necrosis of, 1164.
Pancreatitis, acute, 743, 921; acute hemorrhagic, 74, 743.
Panophthalmitis, enucleation in, 27.
Papilledema, bilateral, 686.
Papilloma, causing hydronephrosis in a horseshoe kidney, 28.
Paralysis, agitans, parathyroid gland in treatment of, 1146; facial, and Busch's cosmetic operation, 116; muscle-group isolation and nerve-anastomosis in, 510; musculospiral, surgery of, 648; operative treatment of deltoid, 510; operative treatment of talipes calcaneus, 510; printer's, 540; spastic, operative treatment, 419; traumatic facial, 826.
Paraplegia, from spinal compression, 825.
Parasyphilis, modern treatment of, 169.
Parathyroids, and sudden deaths, 782; in treatment of fractures, 69; in treatment of paralysis agitans, 1146; relation to the thyroid, 107.
Paratyphoid fever, 824; in the nursling, 115; osteoperiostitis, 1113.
Paresis, general, atypical, 824; bacteriology of, 824; juvenile form of, 404; modern treatment of, 169; ocular changes in, 384.
Paget's disease, extramammary, 691.
Parker, G. M., hysteria under psychoanalysis, 210.
Parturition, causing air embolism, 205.
Pellagra, climatic treatment of, 547; in Illinois, 191; in Ohio, 695; nature of, 1100; parasitic origin of, 21; treatment, 448.
Pelton, H. H., the diagnosis of incipient pulmonary tuberculosis, 573.
Pelvis, infections of in women, new method of cure, 883; postoperative treatment of disease of, 124.
Pennsylvania State Department of Health, organization of, 552.
Percussion, dorsal, of thorax and stomach, 1140.
Perineum, secondary repair of complete lacerations, 744.
Peritoneum, Mikulicz's method of increasing resistance of, 1016.
Peritonitis, diffuse and general, 793; gonorrheal in man, 637; obscure case of, 1201; treatment of, 633; pneumococcus, 1169; tuberculous, 26.
Persson, G. A., culture of lactic acid bacillus in the treatment of chronic specific urethritis, 534.
Pertussis, diagnostic sign in, 501; treatment of, 455; ulceration of frenum linguæ in, 549.
Peters, L. S., mercury succinamid in the treatment of tuberculosis, 1188.
Phagocytosis, influence of quinine and morphine upon, 974; of erythrocytes, 921.
Pharmacopeia, of 1910 and its construction, 169; relation to food and drugs act, 170; revision of, 170; useful drugs, in, 170.
Pharmacy, council on, 971.
Pharyngoscope, improved, 493.
Philippines, cholera in, 245; health problems of, 867; obstetrics in, 245; tuberculosis in, 241.
Phimosis in childhood, bloodless treatment, 1165.
Phlegmasia alba dolens, 974.
Phobias, treatment of, 459.
Photography, medical, 729.
Phototherapy, 834.
Physical treatment, reactions in, 836.
Physician, rewards of the obscure, 981; the young, 1017; services of, member of county board cannot bind county for, 1214; value of services of, 1213; vanishing income of, 1009.
Piles, carbolic acid injections in, 1051.
Pill, brown-bread, 684.
Pilots, Pennsylvania State, 832.
Pituitary body (see hypophysis); extract, in post-partum hemorrhage, 1127.
Placenta, detachment of, 970; hemorrhage due to malinsertion of and cesarean section, 297; prævia, air embolism in, prevention of, 1113; prævia, metreurynter incision of Dührssen, in treatment of, 578; prævia, treatment of, 204.
Plague, bubonic in squirrels, 684; cats in prevention of, 373; pneumonic, 1020; precautions in dealing with, 18; rat, 1061; rats and, 914; rat in England, 1057.
Pleura, effusions of, 648; mechanical effects of effusion, 29.
Plexus, lesions of brachial, 791.
Pneumococci, analysis of, 27.
Pneumonia, lobar, treatment of, 789; mechanical and surgical conditions of, 687; postoperative, 683; progressive universal, with recovery, 789; question, public and private aspects of, 789; treatment of, 125.
Pneumothorax, 683.
Poisoning, aconite, 921; by hyoscyamus niger, 1113; fish, 976; magnesium, 1161; nitrous acid, 734; release from damages for injuries by, not invalidated by inability to read, 1214; treatment of rhus, 330.
Poison ivy rash, 161, 243.
Polioencephalitis, 1627.
Poliomyelitis, 593, 684, 836, 985; arthrodesis in, 76; clinical aspects, 500; contagiousness of, 910; contribution of experimental to human, 634; diagnosis of in preparalytic stages, 722; distribution of in the United States, 771; electric treatment of, 172; etiology, 1198; experimental, 509; failure of nerve anastomosis in, 504; in Russia, 743; management of, 657; in Toronto, 1014; investigation of, 327; nasopharyngitis in, 1198; neck and diaphragm paralysis in, 500; operation in, 593; pathology of, 509, 1120; relation of experimental to human, 924; relation to the community, 508; second attack in the same patient, 526; treatment, 500, 826, 1010, 1120.
Polyarthritis, in childhood, chronic progressive primary, 155.

Polymyositis, acute primary, 1160.
Polyneuritis, sensory alcoholic, 505.
Polythelia, and axillary milk glands, 977.
Polyuria, experimental, 75.
Pond, A. M., fractures of the skull, 1049.
Pons and medulla, topical diagnosis of, 1165.
Pool, E. H., a useful accessory in the treatment of varicose ulcers, 192.
Potter, N. B., typhoid spine, report of a case with radiograms, completed bibliography, 1092.
Pott's disease, advantages of braces, 507; causes of paraplegia, 507; steel bars in, 507.
Practice, lodge, 776, 872; right to license, necessity of diploma for, in Washington, 1213; without license not legal, 1213.
Pregnancy, and puerperium, sudden death during, 1016; artificial termination, indications, 1202; blood-pressure in toxemia of, 193; cervical mucosa in, 334; chronic ureteropyelitis in, 106; complicated by fibroid, 83; duration of, 770; bilateral tubal, 81; ectopic, 41; ectopic, relation of quinine to, 682; extrauterine, 164; extrauterine at full term, 1159; extrauterine, deferred operations for, 738; extrauterine, delayed versus immediate operation in, 793; extrauterine, of eleven months, 119; extrauterine, occurring twice in same patient, 203; extrauterine, treatment, 19; fibroids complicating, 339; interstitial, 40; mechanical ileus in, 876; ovarian, 40, 1211; pyelonephritis of, and vaccine therapy, 245; renal activity in, 1162; ruptured tubal, 40; ruptured tubal, and tubal abortion, diagnosis, 738; toxemia of, 637; toxemia of, value of blood-pressure determinations in, 594; treatment of fibroids complicating, 339; vomiting, 1063; vomiting persistent, 632.
Prescriptions, ownership of, 732.
Principles, active versus gross drugs, 969.
Procidentia uteri, cure by means of intramural sequestration and fixation of uterus, 82; and cystocele, improved operation for, 81.
Professional cramp, treated by psychoanalysis, 985.
Prostate, pathology of enlargement, 332; hypertrophy, 647; hypertrophy, etiology of, 435; obstruction, electric treatment of, 732; small fibrous, 823.
Prostatectomy, suprapubic, post-operative care of, 882.
Prostitution, regulation of, 1107.
Psoriasis, 835, 887.
Psychiatry, clinical, teaching of, 645.
Psychoanalysis, Freud's method of, 289; Jung's, 1129.
Psychoneuroses, an interpretation of, 87; and psychotherapy, 1160.
Psychopathia, recognized in German army, 115.
Psychopneumatology, 78.
Psychoses, acute, and heart disease, 331; postoperative, 1077, 1106.
Psychotherapy, fallacy of, 916; place and uses, 533; present status of, 789; uses and abuses, 927.
Ptomain poisoning, 501, 631.
Ptoses, visceral, surgery of, 121.
Pubic bone, fracture of, 676.
Pubiotomy, as a justifiable operation, 120; for dystocia, 1212.
Public health, museum, 911.
Puerperium, infection of, 742; infections of, treatment, 30; influence of exertion upon morbidity of, 632; prevention of fever in, 294; sepsis of, surgical treatment of, 120; sepsis of, when to operate for, 120, 1212.
Pulmonary tuberculosis and chest muscles, 1022; as studied in dispensary, 888; chemistry of urine in, 351; diagnosis of incipient, 573; early diagnosis of, 785; heart in, 366; hemorrhage in at high altitudes, 964; intravenous medication in, 1020; leucocytes in, 331; mercury as specific in, 311; physical signs in incipient, 592; protein and fat absorption in, 777; recent surgery of, 374; sanatorium treatment in children, 592.
Pulse, liver, 1041; paradoxical, and compression of the subclavian, 505; permanent slow, 498.
Pupil, measuring diameter of, 1148.
Purgatives, abuse of, 458; with abdominal pain, 1119.
Purpura, from iodides, 163; hemorrhagica, successfully treated with human blood serum, 931; Henoch's with intussusception, 594, 732.
Pustule, malignant, 921.
Pyelitis, in children, 209.
Pylorus, congenital stenosis of, 502, 648, 781; insufficiency of, 855, 1198; obstruction of, 1147; obstruction of, of extrinsic origin, 807.
Pyonephrosis, puerperal, 1023.
Pyoneumothorax, pulmonary sloughing in, 419.
Pyorrhea alveolaris, treatment of, 1022.

Q.

Quarantine, house, 1200.
Quinine and urea hydrochlorate as local anesthetic, 342.
Quinquad's finger crepitation, 977.

R.

Rabies, case, 1077; in Germany, 1248; in New York State, 980.
Race betterment, by means of surgery, 259.
Rachitis, 779; calcium metabolism in, 828; phosphorus metabolism in, 868.
Radiculitis of cervical and brachial plexuses, 383.
Radiography, instantaneous, 245; of appendicitis, 248; of digestive tract, 720.
Radium absorption of emanations through the skin, 29; contributions to surgery, 163; effect on healthy cells, 418; excretion in urine, 288; in treatment of cancer, 244; in treatment of malignant tumors, 981; isolation of, 727; new method of extraction, 873; therapy, 78, 238, 914.
Railway accidents, 281.
Rat-bite fever, 28.
Raynaud's disease, 983.
Reciprocity, rupture of, between New York and New Jersey, 109.
Recruiting and preventive medicine, 1168.
Rectum, cancer of, 338; cancer of, appearing simultaneously in husband and wife, 29; feeding by way of, 34; multiple adenomata of, 322; myomata of, 106; operation for prolapse of, 597.
Reflexes, pelvic, 745.
Registration, sanitary, of houses, in Mexico, 550.
Refrigeration, therapeutics of, 601.
Research, defense of, 914; Defense Society, 24.
Respiration, artificial in newborn, 287; suspended during operation, 972.
Respiratory tract, bacteriology of nontuberculous infections of, 984.
Retina, detachment of, etiology and treatment, 1113; detachment of, treatment, 834.
Retroperitoneal enlargements, 27.
Rheumatism, of children, heart in, 908; pathology of, 733; treatment by bee-stings, 286, 412.
Rheumatoid arthritis, etiology and treatment of, 686.
Rhinitis, bacterial flora in, 633.
Rhinolaryngology, and general medicine, 1198.
Rhinology, relation to preventive medicine, 332.
Rhinorrhea, treatment by calcium chloride, 203.
Rhinoscleroma, in East Prussia, 596.
Rhus poisoning, treatment of, 330.
Rhythm, nodal of Mackenzie, 788.
Richards, W. M., some peculiar results of eye-strain, 861.

Stenosis, mitral, 788.
Sterility, male, and semen findings, 921.
Sterilization of women by Röntgen rays, 549.
Stewart, A. H., the probable duration of life, 1144.
Stoll, H. F., the relative value of symptoms, physical signs, tuberculin, and the *x*-ray in the diagnosis of tuberculosis, 670.
Stomach, cancer of, and metastases in nervous system, 464; cancer of, conditions simulating, 338; cancer of, early diagnosis and treatment of, 338; cancer of, new test in, 634; dilatation of, acute, 792, 809; dilatation of, *Bacillus coli* in, 643; dilatation of, chronic, 793; disease of, from medical standpoint, 917; disturbances of, caused by thyroidism, 461; examination of with bismuth capsules, 733; free acids in, 976; function of, as related to gall-bladder, diseases, 465; motor functions of, 1163; new method of inflation, 418; pneumatosis of, 783; stricture of cardia of, 461; surgery of, 875; ulcer of, 501, 731; ulcers of, excision, 338; ulcer of, treatment, 1157; *x*-ray diagnosis of ulcer of, 782, 1165.
Stovaine, in shock, 732.
Streams, self-purification of, 550.
Strophanthus, clinical use of, 971.
Strychnine poisoning and intratracheal insufflation, 733.
Stuttering, relation to amusia, 202.
Sulph-hemoglobinemia, 987.
Sugar in healthy urine, 203.
Suggestion in treatment of disease, 77.
Suprarenal capsules, in pregnancy and puerperium, 908; tumor of medullary substance of, 595; sarcoma of, 360.
Surgery, abdominal and pelvic, for hyperchlorhydria, 318; ambulance, 632; celluloid in, 333; clinical, in Japan, 686; drainage and dressing of wounds in minor, 101; evolution of, 781; for race betterment, 259; in nervous women, and results of, 1118; in New York in the middle of the last century, 1; intracranial, some principles of, 33; in visceral ptoses, for relief of neurasthenic conditions, 121; mishaps of, 210; of upper pelvic floor, 84; past, present, and future, 792; preparation for practice of, 644; radium's contributions to, 163; relation to nervous patients, 566; rôle of in preventive medicine, 457; teaching of, 825; versus expectant treatment of brain tu-

mors, 1190; when and by whom it should be advised, 208.
Symptoms, treatment in hospitals, 1066.
Syphilis, acute abdominal manifestations of, 648; amenorrhea in tertiary, 420; arsenic in, 1107; aural manifestations in, 832; arsenical treatment of, 634; complement fixation test in, 959; congenital, ocular affections in, 832; early ocular signs of, 832; Ehrlich-Hata preparation in (see Ehrlich-Hata preparation); experimental, 164; hereditary, 930; hereditary, and the Wassermann reaction, 373; in insanity, 202; innocently acquired, 371; modern advances in, 832; modern treatment of, 822; Noguchi test in, 143; of bones, 511; of nose and throat, 832; of ear, 67; recognition of by provocative injections of mercury, 247; simple complement fixation technique in, 187; serum diagnosis, 969; superinfection in, 419; transmitted to guinea-pigs, 548; treatment, 161; treatment with arsenic, 961; undescribed sign of, 544; treatment of hereditary, 596; vascular pathology of congenital, 288.
Syringocystoma, 691.
Syringomyelia in mother nad daughter, 505; with disturbance of sensation, 257.

T.

Tabes, gastric crises of, and resection of dorsal spinal nerve roots, 253; dorsalis, modern treatment of, 169; dorsalis, ocular changes in, 384; visceral anesthesias of, 825.
Tapeworm, dwarf, 778.
Taylor, H. L., practical points in the management of poliomyelitis and its sequelæ, 657.
Teeth, caries of, 368; in pathogenesis, 332.
Temperature, subnormal in infancy, 503.
Tendon, transfer for spastic hand deformity, 175.
Tendinitis, of quadriceps femoris, 1165.
Tentorium, laceration of, in labor, 828.
Test meals, value of, 201.
Testicle, hygroma of, 645; malignant disease of, 1020.
Testimony, of physician's examination, not barred by exclamations of pain, 1213.
Tetanus, cryptogenetic, 459; early symptoms of, 595, 636; following vaccination, 811; chloretone in, 975; in septuagenarian, 419; magnesium sulphate as cure of, 720; treatment of, 262.
Tetany, gastric, fatal case of, 28; leg-phenomenon in, 196.
Theobromine, stronger than caffeine, 284.
Therapeutics, bacterial, 169; measures of, standardization of, 834; progress in empirical, 790; progress of, 125.
Therapia sterilisans magna (see Ehrlich-Hata preparation).
Thiosinamin, use of in scars following burns, 902.
Thomas, W. S., the use of internal aluminum splints in the treatment of fracture, 54.
Throat, anemic ulcers of, 457.
Thromboangitis obliterans, bacterial fixation tests in, 665.
Thrombosis, postoperative, 884.
Thymus, rôle of, in pathology, 248.
Thyroid, and adrenal activity, 972; anomalies of function, 19; enlarged in rheumatism, 138; extract, in rheumatoid arthritis, 1164; preparations for use, 166; hematoma, 1061; medication in obstetrics, 963; relation to the parathyroids, 107; therapeutics based on pathological physiology of, 1210.
Thyroidism, in gastric disturbances, 461.
Thyroiditis, acute, 973; cardiovascular complications of, 363.
Tilton, B. T., special dangers associated with operations in the biliary passages and their avoidance, 398.
Tinnitus, audible, 814.
Tissues, cultivation of, outside of body, 780.
Tobacco, effect on the ear and upper respiratory tract, 76.
Toe phenomenon, pathogenesis of, 1016.
Toes, congenital fusion of, 67.
Tongue, black, 426; black, in nursling's, 689; hairy, 1190.
Tonsils, and the singer, 833; enucleation of, 876; enucleation with guillotine, 635; germs in wounds following operations on, 423; forceps, 1017; indications and dangers of removal, 833; infections of, causing neuralgias and functional disturbances, 457; removal of, with soft silver-wire snare, 833; research, 56; snare, 779; tuberculous, 876.
Tonsillectomy, 876; hemorrhage following, 246.
Trachoma, bodies, and gonococci in mutation, 452; bodies, and the gonococcus, 109; campaign in, 834; in Western Pennsylvania, 833; nature of exciter of, 880; quartz lamp in, 333; treatment of, 1116.
Training, diet in, 194.
Treponema pallidum in congenital gumma, 163.
Trichinosis, 497.
Trichocephaliasis and anemia, 218.
Trichophytin reaction, cutaneous, 541.
Tricuspid, regurgitation with unusual tracings, 603.
Triplets, 247.
Troops, sanitation and health of, and responsibility of army medical officials, 107.
Tropics, Europeans in, 378; sanitation in, 411.
Trypanosoma, relation with spirochete, 914.
Trypanosomiasis, 967; human, 378; and the tsetse fly, 772; with periodical increase of parasites, 115.
Trypsin, in local tuberculosis, 628; in surgical tuberculosis, 1070.
Tube, fallopian, adenomyoma of, 340.
Tubercle bacillus, cause of cancer, 319; Gasis's staining of, 419; human and bovine in cervical adenitis, 1119; in circulating blood, 165; in acnitis, 373; in cured cases, 156; in feces of tuberculosis, 286; in lupus, 333; in the sputum, 70; paradox of, 52; relation of to other bacteria, 845; secondary saprophytic infection with, 248.
Tuberculin (see tuberculosis and pulmonary tuberculosis); in genitourinary tuberculosis, 600; in joint disease, 510.
Tuberculosis, and children, 1197; and lactation, 204; and poverty, 496; and syphilis, 646; apyretic action of tuberculin in, 548; aural in children, 1056; avenues of infection, 190; bovine, 240; coincident with syphilis, 592; county hospital care for, 979; day and night camps in the treatment of, 400; differentiation of, by meiostagmin reaction, 459; doctor's duty in, 720; effect on leucocytes of, by treatment, 789; evolution of, therapy in, 650; gynecological and peritoneal, 35; high temperature in, 163; hospital infection of, 20; human and bovine, 962; incidence in childhood, 203; industrial, 826; in India, 378; in milk, 730; in the Philippines, 241; laryngeal, signs of, 1019; laryngeal, treated by alcohol injections into superior laryngeal nerve, 114; laryngeal, treated by artificial pneumothorax, 30; laryngeal treatment, 200, 1022; laryngology in diagnosis of incipient, 190; local, trypsin therapy of, 628; neurologic aspect of, 640; of bone, diagnosis and treatment of, without abscess formation, 1003; of bones and joints, 644, 917; of cattle, 409; of glands, 163; of gland, causing asphyxia, 425; of glands of neck, hyperemia as after-treatment, 29; of hypoderm, nodular, 693; of joints, 147, 731, 918; of joints, tuberculin in, 510; of the optic nerve, 78; open questions in, 394; physique in, 732; progress of infection in, 1110; propaganda against, 440; pseudoapical murmurs in, 458; pulmonary (see pulmonary tuberculosis); relation to generative functions, 286; relative diagnostic value of symptoms, physical signs, tuberculin, and x-ray in, 35; relative value of signs in, 670; renal and tuberculin treatment, 203; renovesical, bacillus emulsion in, 600; sanatorium for, at Muskoka, 369; Spengler's immune blood in, 645; surgical, treated outside of cities, 76; syphilis and cancer, 1008; the king's evil, 719; thoracic lymph nodes in, 288; traumatic, 288; traveling car in fight against, 635; treated by immobilization of portions of trunk, 546; treatment of, in children, 106; treatment of, outside the sanatorium, 33; treatment with potassium bichromate, 1068; treatment with mercury succinamid, 1188; trypsin in surgical, 1070; tubercle bacilli in feces of, 286; genitourinary, tuberculin in, 600; tuberculides in diagnosis of infantile, 972; tuberculin treatment in advanced stages of, 952; tuberculin treatment of, 30; urinary, tuberculin in, 632; urogenital, tuberculin in, 632; vaccine therapy in, 246; vaccine therapy in genitourinary, 599; war against, 161, 545, 922.
Tumors, adipose, 1061; biochemistry of, 877; desmoid, 973; immediate microscopic diagnosis of, 686; metastasis and immunity of, 1019.
Turbinectomy, 1116.
Typhoid bacilli, potassic iodide and arsenic for destruction of, 596.
Typhoid carriers, 414, 627, 971; Mandelbaum's reaction in the detection of, 239; treatment of, 327.
Typhoid fever, agglutinating power of blood serum in, 210; ambulatory form in children, 78; and drought, 680; decrease in, 586; differential diagonsis of, 1159; effect of floods in prevalence of, 629; etiology, 162; initial throat symptoms of, 602; in New York, 819; in Pennsylvania, 785; inoculation against, 685; Mandelbaum's reaction in, 334; more feeding in, 24; perforations, 974; perforation, double, in, 1120; prevention of, 155; problems, 503; prophylaxis of, 783; prophylactic surgery against intestinal complications of, 793; pustular roseola in, 545; source of infection by sputum, 285; spermatocystitis and prostatitis in, 586; spread by milk, 504; statistical analysis of mortality, 625; therapeutic indications,

126; tracing of, 728; treatment of, 877; treatment of, by bacterial vaccines, 115; treatment by turpentine enemata, 287; vaccination against, in the United States Army, 1101; vaccine in, 622, 1160.

U.

Ulcer, duodenal, diagnosis of, 288; duodenal, in infant, 297; gastric and duodenal, 972; gastric and duodenal, cause of, 731; gastric, excision, 338; gastric, surgical aspects of, 201; gastric, treatment of, 504; perforated gastric, 743; varicose, treatment of, 192.
Unger, M., desirability of excluding contagious diseases from dispensary clinics, 330.
United States Public Health and Marine Hospital Service, 815.
Uremia with facial paralysis and intestinal ulceration, 827.
Ureter, anastomatic repair of, 83; calculi of, 1024, 1065.
Urethra, primary epithelioma of, 1098; prostatic, 113; rupture of male, 1161; stricture of male, 582.
Urethritis, non-specific, and cell inclusions, 116.
Urethrotomy, external, without a guide, 226.
Urine, as temperature indicator, 416; chemistry of, in tuberculosis, 351; permanent preparations of sediments, 734; sugar in healthy, 203.
Urticaria, caused by sun's rays, 193.
Urogenital organs, malformations and malpositions of, 123.
Uterine stem, use of, 83.
Uterus, bicornis unicollis, 1068; cervix of, erosion, 378; fibroids of, 123; fibroids of, complicating labor, 744; fibroid complicated with cancer of, 698; fibroid of and tubal pregnancy, 698; fibroids of, electrical treatment, 836; fibroid of, removed by extensive myomectomy, 698; fibroids of, surgical treatment, 377; fibroids of, treated by *x*-ray, 827; fibroids of, intraperitoneal hemorrhage in, 378; inversion of puerperal, 729; involution of puerperal, 378; multiple puerperal abscesses of, 1212; myomatous, removed by abdominal route, 698; operations on appendages of, 744; polypus of cervix of, 1201; retroversion of, 729; retroversion of, occluding bowel, 340; rupture of, 295; rupture of, due to absence of vagina, 40; sacral suspension of, 978; wandering, and fumigation, 687.

V.

Vaccination, decline of in London; tetanus following, 811.
Vaccines, and immunity, 728; and serums, value of, in treatment, 115; autogenous, in urinary infections, 600; autogenous, in endocarditis, 972; autogenous, routine use of, 168; bacterial, in pyogenic urinary infection, 632; bacterial, in the aged, 661; gonococcus, 419, 1118; in acute infections, 1160; in ear suppurations, 778; in eye, ear, nose, and throat infections, 178; in genitourinary diseases, 600; in gonorrhea, 830; in gynecology and obstetrics, 119; in infants and young children, 229; in puerperal septicemia, 742; in pyelonephritis of pregnancy, 245; in septic and inflammatory conditions, 120; in skin diseases, 694; in tuberculosis, 246; neoformans, in cancer of colon, 465; neoformans, in treatment of carcinoma of colon, 572; of unknown organisms, 973; relation to practice, 879; simple method of enumerating, 639; standardization of, 649; staphylococcus in treatment of cutaneous lesions, 628; streptococcus in adenitis, 492; streptococcus, in scarlet fever, 177; therapy, 169, 423, 634, 972; therapy, experimental basis of, 417; therapy, in aural and nasal infections, 163; therapy, in orthopedic diseases, 510; treatment of gonorrheal complications, 636; typhoid, 1160; use of, in urology, 599.
Vagina, absence of, causing rupture of uterus, 40; absence of, with rudimentary horn of uterus, 40; and uterus, absence of, 697; atresia of, 1015; complete absence of, with pregnancy and rupture of uterus, 699; congenital transverse septum of, 1023; dilatation of, in breech presentation, 908; operations on, in obstetrics, 1022; surgical treatment of, delivery by, 699.
Valk, F., the method of simple extraction of the lens, 488.
Vandegrift, G. W., the practical value of a positive complement fixation test in syphilis, 959.
Van Gieson, I., the paradox of the tubercle bacillus, 52.
Veins, diffuse sclerosis of superficial, 602; varicose, surgical treatment of, 247.
Venereal diseases, as epidemic diseases, 786; control of, 1164; prophylaxis of, 786; among seamen, 553; prophylaxis, in U. S. Navy, 553; sources of, 969.
Venesection, in circulatory disturbances and substitutes, 116.
Ventilation, library, 531; of sleeping cars, 555; in schools, 173; of cars, 1000; pioneer in, 727.
Vertigo, 731; laryngeal, 67.
Vibration, therapy, 834.
Virchow, memorial to, 502.
Vital statistics, 684, 917; of Ireland, 771.
Vocal cord, epithelioma of, 425.

W.

Wassermann reaction, 648, 874; and hereditary syphilis, 373; clinical value of, 246; conservative utilization of, 1108; determining syphilis in insanity, 202; diagnosis by, 542; in differentiating cerebrospinal syphilis from multiple sclerosis, 420; in eye work, 161; in idiots, 286; in tropical affections, 828; in wet-nurse's milk, 688; Noguchi modification of, 205; present status, 165; simple complement fixation, technique in, 187.
War, medical work in, 500.
Water, in prevention of disease, 649; purification by ionization, 369.
Waugh, W. F., a case of pellagra in Illinois, 191.
Wells, W. A., suppuration of the antrum of Highmore, 756.
Whitman, R., the abduction treatment for fracture of the neck of the femur, 1154.
Widal test, at bedside, 768.
Wiener, A., abscess in the frontal lobe of the brain after chronic frontal sinusitis; erysipelas in conjunction with acute mastoiditis, 715.
Wiener, J., an unusual case of congenital absence of anus and lower end of rectum, 237.
Williams, T. A., a simple clinical method for measuring the diameter of the pupil, 1148; genesis of hysterical states in childhood and their relation to fears and obsessions, 234.
Wines, sulphurous acid in white, 1009.
Wolbarst, A. L., gonococcus urethritis in male children, 766; personal observations on the Ehrlich-Hata 606, 672.
Wolf, C., lodge practice, 776.
Work, therapy of, 28.
Wounds, dressing of, with gutta percha tissue, 548; surface, 1160; treatment of, 1200.

X.

X-ray, action in large and small doses, 69; and special senses, 970; cinematography, 374; diagnosis of gastric ulcer, 1165; effects of, 415; in dermatology, 976; in gastric diagnosis, 886; in treatment of lupus, 149; localization of bullets, 875; malpractice in application of, 1034; radioactivity induced by, 826; study of children, 594.

Y.

Yellow fever, in West Africa, 1157; Mexico free from, 555; permanent elimination, 418.

Z.

Zigler, M., report of three cases treated with the antigonococcus serum, 674.
